Absorption of β-rays. At first sight the absorption curve seemed to have a shape similar to the absorption curve of the β-rays from radium E, thus indicating a simple spectrum with a maximum range of about 150 mgm./cm^2. However, a closer analysis revealed a departure from the standard radium E curve near the end of the range of the β-rays. The experimental errors in this region are inevitably large owing to the presence of a strong γ-radiation, nevertheless the results obtained are sufficient to establish the presence of a 'tail', which indicates the existence of a weak group of β-rays of longer range. It seems rather unlikely that this group is due to a contamination, as it decayed with the same period as the main group. Analysis of the logarithmic absorption curve made on the lines of Feather's method[2] shows that the best agreement with the experimental results is attained on the assumption that the β-radiation from ^{82}Br consists of the following two groups:

97 per cent of the disintegrations have an upper energy limit of 460±10 kev.;

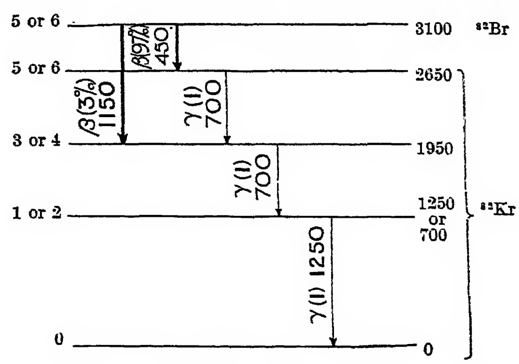
3 per cent of the disintegrations have an upper energy limit of 1,200±50 kev.

Absorption of γ-rays. The absorption of the γ-rays was investigated in lead and aluminium. Here again the absorption curve seemed initially to be a purely exponential one, but on using better geometrical conditions the presence of at least two components was revealed. The best fit with the experimental absorption curve is attained by assuming the existence of two γ-quanta of about 700 and 1,300 kev., the intensity of the former being twice that of the latter.

Absorption of Compton-electrons. The energies of the γ-rays were also investigated by measuring the absorption of the Compton-electrons passing through two counters in a coincidence circuit. The absorption curve showed directly the existence of a γ-ray line of the energy 1,250±50 kev., and the shape of the curve made it clear that yet another component must be present. By comparing that curve with those obtained with sources of thorium (B+C) and radium (B+C) in identical conditions it was found that the energy of the second component is 700±50 kev. After correcting for the efficiency of the counters for γ-rays of different energies, the intensity of the softer γ-quantum was found to be twice that of the harder.

Coincidence measurements. All coincidence measurements were made with counters in a standard position, the efficiencies of which for β- and γ-rays had been previously determined. The ratio of β-γ coincidences to the number of β-rays was found to vary only very slightly with the thickness of absorbers for the β-rays. This result is not in contradiction with the assumed presence of two β-ray groups, since owing to the low intensity of the group of longer range the expected decrease of the coincidence ratio within the whole investigated region (up to 100 mgm./cm^2) is only about 15 per cent, and on the other hand the accuracy of the β-γ coincidence measurements is poor at the end of that region, mainly owing to the large γ-γ coincidence rate. Actually the results indicate a tendency towards a decrease of the relative β-γ coincidence rate, as would be expected from the presence of two β-ray groups; at the same time the results show that even the harder β-ray group is also correlated with a γ-ray emission.

The rate of β-γ coincidences per 1,000 β-rays—with no absorber—is 4·88±0·07. The rate of γ-γ coincidences per 1,000 γ-rays was found to be 3·14±0·07. From these figures we deduce that the γ-rays following the emission of the main group of β-rays form a cascade of 3 quanta per disintegration. The assumption of two 700 kev. quanta and one 1,250 kev. gives also an agreement between the observed rate of β-γ and γ-γ coincidences and the value calculated from the efficiency of the counters for γ-rays of these energies.



All the above results may be expressed in the nuclear level scheme of ^{82}Kr shown in the accompanying illustration, together with the transitions from ^{82}Br. The figures on the right side give the energies

of the states in kev., and on the left side their presumed spins. As seen, the total disintegration energy of ^{82}Br is 3·1 Mev. The assignation of the spin values was based on the absence of direct γ-transitions from the upper levels to the ground-state, and on the small abundance of the more energetic β-ray group. A more definite determination of the spins could not be made without establishing the nature of the γ-transitions.

Refraction Patterns of the Surfaces of Opaque and Translucent Solids

IN a previous note, one of us (Rivlin[1]) has described a method for studying the distribution of facets of various orientations on the rough surfaces (ground, scratched or etched) of transparent solids.

We have since developed a similar method for studying such surfaces of opaque or translucent solids. This consists in making a cast of the rough surface using some transparent substance and in obtaining the refraction pattern in a manner similar to that previously described.

We have found 'Diakon' a suitable substance for the cast. A solution of 'Diakon' in ethyl acetate is painted on to the rough surface and is allowed to harden. The painting process is repeated until a suitable thickness of 'Diakon', say ½ mm., is obtained. The cast is then peeled from the surface. A point source of light is viewed through the cast and a refraction pattern which is characteristic of the surface under consideration is obtained.

The accompanying figure shows the refraction pattern obtained from a cast of the (100) surface of a hypersthene crystal ground with 60-mesh carborundum abrasive. This indicates strongly preferential fracture of the crystal on planes parallel to the zone axis [001]. The *b* axis of the crystal is horizontal.

Observational Clue to the Size of Meteors

CONSIDERABLE difference of opinion prevails concerning the size and mass of meteors. While one school of investigators, attacking the problem from theoretical considerations based on certain relations between amount of light emitted by an incandescent body and its extent of surface and mass, is prepared to give the nucleus of average naked-eye meteors a volume scarcely greater than a few cubic millimetres, another school, consisting mainly of experienced observers, but by no means indifferent to theoretical calculations, argues in favour of much larger dimensions for them—at least several cubic inches. As there is no possibility of observing meteors at close quarters, much less handling them, while on their aerial path, the question has remained undecided.

An observational clue, however, is available. Even in strong moonlight, one can often see distinctly meteors of the 2nd and 3rd magnitude. Owing to the illumination of their background, moonlight meteors not only appear to be much nearer objects, marking their trails, not *on* the dark background of the sky, as they usually do in moonless nights, but *in front of* the illuminated background. Occasionally, they send forth a momentary flash (which greatly adds to their brightness), due undoubtedly to the reflexion of moonlight from their surface. For such a thing to happen, not only should the reflecting surface of the meteor be suitably disposed towards the moon, but also it should have an appreciable area also.

Having observed the phenomenon a number of times quite distinctly, I believe that it furnishes observational evidence in favour of the relative large size of meteors.

Ionization Potentials of Polyatomic Molecules

THE recent development of our knowledge of the electronic structures of molecules makes it possible to specify with reasonable certainty the particular electron with which a definite molecular ionization potential is to be associated. In an organic molecule the variation of an ionization potential with, for example, alkyl or halogen substitution reflects the change in negative charge density in that part of the molecule in which the electron is located. The existence of resonance in a molecule also considerably affects the ionization potentials of the resonating electrons. It is clear, too, that ionization potentials are intimately bound up with chemical activity, dipole moments, refractivities, combination radii, electronegativities, etc.

In a programme concerned with the determination of molecular ionization potentials we have used absorption spectra in the vacuum ultra-violet whenever the absorption bands obtained were sufficiently discrete for the photo-ionization limit to be observed. When this was not the case electron impact methods were employed, the values being substantiated by whatever limited spectroscopic evidence was available. The spectroscopic values are accurate to at least 0·01 v., while the electron impact ones have the lower accuracy of about 0·1 v. Higher ionization potentials than the minimum have in general been obtained only by the electron impact method and are of a somewhat lower accuracy. Some of the values so far derived for the *first* ionization potentials

of certain classes of molecules are collected below:
H_2O, 12·56; CH_3OH, 10·8; C_2H_5OH, 10·7; C_3H_7OH, 10·7; $(CH_3)_2O$, 10·5; $(C_2H_5)O$, 10·2; H_2S, 10·42; C_2H_5SH, 9·7; $(CH_3)_2S$, 9·4; $(C_2H_5)_2S$, 9·3; $n(C_3H_7)_2S$, 9·2;
NH_3, 10·8; CH_3NH_2, 9·8; $(CH_3)_2NH$, 9·6; $(CH_3)_3N$, 9·4;
H_2CO, 10·83; CH_3CHO, 10·181; $(CH_3)_2CO$, 10·1; CH_2CHCHO, 10·06;
$CH_3CHCHCHO$, 10·19;
CH_3CCH, 11·25; $HCCCCH$, 10·74;
H_2CCHCl, 9·95; $ClHCCHCl$, 9·61 (*cis*), 9·91 (*trans*); C_6H_6, 9·19; $C_{12}H_{10}$, 8·3; $C_6H_5CH_3$, 8·77; $C_6H_4(CH_3)_2$ (*o*, *m* and *p*), $\sim$ 8·3 electron volts.

Values given to 0·01 v. are spectroscopic, the others are electron impact values. For H_2O, H_2S, H_2CO and their alkyl derivatives the electron removed is a non-bonding $p\pi$ oxygen (or sulphur) electron. For NH_3 and the amines the minimum ionization potential corresponds to a $2p_z$(n) electron, which is non-bonding with orbital perpendicular, to HHH plane[1]. In methyl acetylene, diacetylene, the halogenated ethylenes and the aromatic molecules, π electrons of the double and triple bonds are involved, these being modified by resonance in molecules where conjugation occurs.

For acetaldehyde, acrolein and crotonaldehyde, very extensive Rydberg series were found in the vacuum ultra-violet, enabling the ionization potentials of these molecules to be obtained with unprecedented accuracy. One of the Rydberg series found for acetaldehyde contained sixteen members and gave a limit corresponding to $10{\cdot}1811 \pm 0{\cdot}0007$ v. This is the most accurate ionization potential so far determined for a polyatomic molecule. A fifteen membered series was obtained for crotonaldehyde giving an ionization potential of $10{\cdot}187 \pm 0{\cdot}001$ v. and a series of ten members in acrolein converging to a limit of $10{\cdot}057 \pm 0{\cdot}006$ v.

Carotenoids of Grass Silage

WHEN using Moon's[1] method for the estimation of 'crude carotene' in routine silage samples, we have applied Moore's[2] chromatographic technique for removing other chromogens from the carotene solution, as obtained by Moon's method, in order to obtain a value for 'pure carotene'. In the case of silages the 'pure carotene' values may be considerably less than the 'crude carotene' values.

Latterly we have sought to replace the customary phase separation of 'crude carotene' and xanthophylls by using the same chromatographic technique for the removal of xanthophylls as well as of non-carotene chromogens from the petrol ether solution.

Values for 'pure carotene' obtained by (*a*) passing the petrol ether solution of 'crude carotene' after phase separation of xanthophylls through a column of dicalcic phosphate (prepared as recommended by Moore[2]) and by (*b*) passing the original petrol ether solution of total carotenoids through a similar column were in close agreement. For routine carotene estimations on silage, procedure (*b*) has the advantage of avoiding the phase separation.

The chromatograms of a series of samples of laboratory grassland silage examined in this way displayed an interesting feature. From the fourth day after ensiling, a well-defined blue-green band about 1 mm. wide appeared some 5 mm. *below* the strongly adsorbed 'xanthophyll' band at the top of the column. While attempting to repeat this observation on later samples, this band was not always obtained at once, but a light yellow band of the same thickness appeared in the same position on the column. On sucking off the petrol ether from the column this yellow band changed in the course of 3–5 hours to the same blue-green as originally observed.

This ready isolation of a blue-green chromogen from the petrol ether solution of the carotenoids of grassland silage may have a bearing on the production of 'grass yolks' in eggs from hens fed on silage[3].

A seasonal incidence of olive-tinted yolks has also been observed in egg-packing stations in Northern Ireland. In one case it was found that the birds were ranging on young pasture rich in suckling clover; the incidence of the olive tint was cured by shutting the birds off from pasture for a time.

It seems possible that the cause of this seasonal incidence of olive-tinted yolks may lie in the special richness of early summer pasture in carotenoids, together with factors increasing the lability of the carotenoids and favouring the production of carotenoid derivatives of blue or blue-green colour. One such factor might be acidity, present alike in grass silage and in the fowl's crop.

Polygenic Variability in Wild *Drosophila melanogaster*

SEVERAL authors have reported the recovery of variant types by inbreeding *Drosophila melanogaster* caught in the wild. The mutations described have generally been of single major genes, recognized either by their obvious morphological or lethal effects; inverted sections of the chromosomes have also been found. The literature of the subject has been reviewed by Dobzhansky[1].

Adaptation and speciation, however, chiefly depend on the action of selection upon what has been called quantitative, or more recently polygenic, variation[2]. Many genes, each having a small effect, control this type of variation, which probably affects all characters showing a range of apparently continuous variation. Such polygenic variation has now been shown to exist in wild populations of *D. melanogaster*.

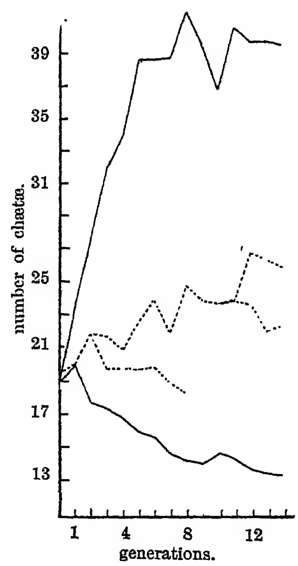
Flies were trapped in various parts of southern England in the summer of 1940. Two strains derived from flies caught at Ockley and Ealing respectively were subjected to selection for increase and decrease of the number of chætæ in the sternopleural regions. Dubinin and collaborators[3] have shown that populations from different parts of the U.S.S.R. have characteristic and different numbers of sternopleural chætæ, and my own experiments (unpublished) have shown the variation to be polygenic.

Before selection the two strains had a mean number of sternopleural chætæ within the range of variation found in laboratory stocks and flies collected from other localities. The Ockley strain had a mean of 19·05, a variance of 5·1552 and a range from 24 to 16 in a rather crowded culture; the Ealing strain a mean of 19·65, a variance of 2·3346 and a range from 25 to 15.

The results of selection are shown in the accompanying graph, in which the mean of the two sex-means is plotted against the filial generations. The Ockley strain (solid line) was selected in the first and following generations of the experiment. The line selected for increased number shows a remarkably rapid advance for five generations, during which the number of chætæ was doubled; from the fifth to the fourteenth generation no further advance occurred. The line selected for decreased number shows a slower but continuous advance after the first generation under the influence of selection, which appears to be still operative in the fourteenth generation.

The Ealing strain (broken line) was mated at random in the first two generations of the experiment, during which the number of chætæ increased slightly; selection in both directions was begun in the third generation. The high selection line shows an irregular advance which has not ended by the fourteenth generation. The low selection line returns to the parental level, where it remains stable for three generations. A decrease then begins which is ended by the death of this selection line. A second low selection line was started in the tenth generation by back selection from the high line; this led to a reduction of chæta number after the first generation of back selection. Thus after eight generations of selection sufficient variability was still present to permit not only of new increases, but also of decreases in chæta number when the direction of selection was reversed.

Both the wild strains selected possess a store of polygenic variability; in one, the Ockley strain, this was readily available to the action of selection, especially in the direction of increased number, giving an advance far greater and more rapid than



——— Ockley strain
· · · · · Ealing strain
mean of ♂ and ♀ means.

has been obtained by selecting the progeny of crosses between laboratory stocks. In the Ealing strain the variability was more gradually released, so that selection was still operative after twelve generations. Such a liberation of stored variability is brought about by the recombination of internally balanced combinations of + and − polygenes[2].

The genes available for selection were not alike in the two strains; those in the Ockley strain increased the number of dorsocentral and scutellar bristles as well as the sternopleural chætæ on the number of which selection was carried out (the low selection line, however, showed the normal number of four dorsocentral and scutellar bristles). In the Ealing strain no change was observed in the number of dorsocentral or scutellar bristles.

Polygenic variability has previously been demonstrated only in laboratory stocks and domesticated plants and animals, although its existence in wild populations has been deduced from the behaviour of interspecific and inter-racial hybrids. It is now shown to exist within wild populations of *D. melanogaster*.

Importance of Adult Education

I READ many articles concerning after-the-War problems, but all are vague and not wholly convincing. At one time we had here in Colorado a Populist Party. It was a party of protests and for a time prospered, but it withered away because it had no adequate programme. Some wit wrote: "A Populist is a man who doesn't know what he wants, but wants it damned bad."

It seems to me that the first step towards a reasonable programme is to define our objectives. Let us begin with these: (1) every man his job; (2) an adequate standard of living.

We then proceed to ways and means. Universal employment implies universal capacity to render service, excluding only the unemployable, who have to be segregated in institutions, and many of these can undertake simple types of work. The ability to do useful work requires suitable and varied education. This education must have moral and cultural aspects, developing social conscience and breadth of view as well as technical skill. The work must be done for use, not primarily for profit, but there must be material rewards.

The standard of living depends especially on two things: (1) ability to produce; (2) ability to use.

The facilities for production have increased so greatly in recent years, that I have not met a man who does not believe that poverty could be abolished. Ability to use depends largely on education and social contacts. Thus the lovely English countryside is capable of affording enjoyment to thousands who at present regard it with indifference, and with no extra cost to any one, except perhaps facilities for getting about (when young, I used to go on foot, with a pack on my back). The libraries offer us untold wealth, if we care to use it. Thus the standard of living depends very largely on the standard of life.

At the same time we must recognize the fact that in recent years not only has the production of wealth greatly increased, but also this wealth has reached the people, and represents a triumph of democratic economy. The New York *Sun* recently offered some statistics, of which I quote a part: In 1900 there were in the United States about 1,000,000 telephones; now there are 20,400,000. In 1900 there were 8,000 automobiles; in 1941 there are 25,000,000. In 1920 there were only 1,000 radio sets; in 1941 there are 43,000,000. In 1910 there were 16,372,000 savings accounts; in 1941 there are 46,000,000.

These gains are enormous, yet not without their disadvantages. In the United States nearly a hundred thousand persons die from accidents each year, a large proportion due to incompetent handling of automobiles. The radio brings us wisdom, but more trash. Thus we have to learn to enjoy and profit by our blessings, avoiding their misuse. Here we have a clearly defined programme, and we can carry it forward without waiting for the end of the War. Among reasonable people it should meet with no hostility, but it does imply willingness to co-operate, and a certain degree of courage and faith. I can believe that very many of those who are now our enemies would be glad to join with us in the endeavour, once they are convinced that we are sincere and unafraid.

A Scientific Press Bureau

THE second editorial article in NATURE of August 30, "Physics and the Future", remarks how remote is science to the majority of citizens. As never before, pure and applied science to-day plays an essential part in affairs, and it has recently been said that scientific development can make good in a very short time the material wastage and set-backs of this War. But it is only occasionally, as when 'Radiolocation' was announced, that the average citizen realizes that science is not entirely a means of producing more and more terrible weapons of destruction. The scientific attitude applied to our post-war problems, we believe, can rid civilization of recurrent wars and economic chaos. If we admit the ideal of democracy, the power of science to accomplish these ends must depend upon the public acceptance of science as a desirable thing.

Now how does the average citizen learn of the work of science? We find in the *Manchester Guardian* and *The Times* excellent accounts of new developments, but the mass-circulation newspapers almost without exception ignore scientific news but for occasional garbled items of a sensational nature, or comic strips of the "Buck Ryan and his Space Ship" type.

In the United States, newspaper readers are better served. Natural science editors contribute special and weekly articles in most of the large papers, and Science Service, directed by Watson Davis, publishes the weekly "Science News-Letter" which is frequently quoted by the Press.

While planning for the future, the representatives of science in Great Britain must admit the question of public relations in the post-war period, otherwise science may not attain the recognition necessary for it to contribute fully towards a better world. Instead, antagonism might grow up among those who know only of the inventions that have been misapplied in war and in commercial exploitation.

What is required now is a 'set of blue-prints' for a future Scientific Press Bureau, supported by the scientific societies and engineering institutions and staffed by experienced journalists. Bold in conception and vigorous in its policy, it must bring to the man in the street, through his newspaper, accurate and balanced knowledge of the work, aims and achievements of science and the technical arts.

Herts. Aug. 31.

Plankton as a Source of Food

IN reply to the latest communication under this heading[1], I would like briefly to recall (*a*) the common agricultural practice of green manuring[2] in which often the only obvious addition to the land is of 'carbon'[3] though the benefit to future crops is undeniable[4], (*b*) the importance of freshwater algæ as soil surface-binders[5] even if the addition of potential humus is small, (*c*) the facts that many algæ are notoriously rich in vitamins[6] and are now known to contain growth-substances[7] in such amounts as might conceivably be absorbed from the soil by seeds[8] and roots[9] and have a formative and growth-promoting action upon various organs of vegetable plants[10], (*d*) that the exact manurial and other treatment can further condition the vitamin content and growth and robustness of a crop for reasons not yet understood[4], (*e*) the ubiquity and usual wastage of the human system as a source of combined nitrogen and phosphorus as well as of auxins[10], and (*f*) that Cyanophyceæ capable of fixing nitrogen can be grown in mineral solutions as well as on or near the surface of soil[11], while the presence of other algæ increases nitrogen-fixation by bacteria[5]; on the other hand it is often wasteful and may be harmful to add nitrates and ammonium salts to soils that have to be watered[12].

In my previous communication[13] I did not, nor do I now, contend that any (or even several together, so far as they are applicable) of these or related matters that may be concerned with plant nutrition via watering will actually benefit the growth and production of vegetable crops to an appreciable degree; my object was merely to suggest a mode of practical application after pointing out such a possibility, which, I maintain, should be fully investigated by means of controlled field experiments in proper bulk.

DRY FUEL FORESTS OF THE MADRAS PROVINCE

A SMALL illustrated monograph written by Mr. A. L. Griffith, I.F.S.* provincial sylviculturist, Madras, merits the close attention of the administrative and forest officers in West and East Africa.

A century ago in the 1830's and 1840's Madras was passing through some regrettable and painful forestry experiences. The administration for four decades had had no belief in the necessity of a forest policy or in forest protection; and the people naturally wanted neither. Whilst, therefore, during the first half of the nineteenth century the finest teak forests or the most accessible at that time were despoiled, the larger areas of forest situated in the central and eastern regions—what are termed here the dry fuel forests (savannah or bush in Africa)—were regarded as of no value and the population allowed to cut, burn and overgraze them, as in the past. Even when the Government realized that some form of protection should be given these areas, they were not regarded as 'forests' or placed under the then existing Forest Department. The idea grew and persisted that the work of the forest officer should be confined to the management of marketable timber forests only—an idea which has resulted in irretrievable harm to much forest and has caused the disappearance of large areas both of 'timber forest' and 'dry fuel' or 'bush' forests. Mr. Griffith writes: "The dry fuel forests of the unreserved, waste lands and panchayat forest" (in which the administration at one period placed such a childish faith) "have either completely disappeared or are very rapidly disappearing due to the ravages of man and his animals, chiefly goats." Some of Mr. Griffith's predecessors were writing nearly identical words almost exactly a century ago; the country, be it remembered, being at that period much less developed and the population and their animals very much less numerous.

At the present day we are told that the dry fuel forests of Madras are one of the most important types occurring in the Province, and in reserved forest alone they consist of roughly 900,000 acres with an annual cut of approximately 30,000 acres which produces an annual revenue of Rs.400,000. This type, says the author, occurs in twenty-two out of twenty-eight districts, and the general climate has an average rainfall of from 10 to 35 in., most of this precipitation coming from the north-east monsoon in October and November. Apart from this rainy period the rest of the year is generally very dry and very hot. These forests are essentially 'local' forests, and supply the needs of the local villages with fuel, agricultural implements, small building timber, grazing, etc.

What is the difference between this 'type' and that of the large areas of so-called savannah or bush in Africa, upon which the people equally depend in one way or another for the chief ingredients of existence? Yet in Africa, by many of the administration at least —and probably not a few forest officers (all brought up in the belief)—savannah or bush was until quite recently not regarded as forest or as meriting or requiring any attention. That the recognition of the value of the type took upwards of a century in Madras is surely no reason for wasting so long a period and making the same mistakes in Africa. The following brief extract from the monograph, which must be read to be fully appreciated, may be considered:—

"These areas which are in the reserved forests are worked in general on a thirty-year rotation, now in many cases being raised to forty years, by the system of simple coppice. At each coppicing the mortality of stools is 5–10 per cent and this is not being replaced by natural regeneration.

"*Hence the improvement and maintenance of these forests by artificial regeneration is an absolute necessity*" (italics are the author's).

During the past ten years it has been shown that this artificial regeneration can be done with a certainty of success and at a reasonable cost even under the poorest conditions by the 'rab' method, and at practically no cost at all by the '*rab-kumri*' method, that is in conjunction with field crops (shifting cultivation).

* "Note on the Artificial Regeneration of the Dry Fuel Forests of the Madras Province" (*Ind. For. Rec.*, Silvic. (New Series), 3, No. 8. New Delhi, Govt. of India Press: 1940).

STEAM HEATING OF BUILDINGS

SO long ago as 1653, Sir Hugh Plat, of London, heated glasshouses with steam from a cast-iron pot placed outside. This is described in his book on horticulture, "The Garden of Eden". James Watt is believed to have used in 1784 the first elementary steam radiator. It was fitted in his study and consisted of an iron box with connecting pipes through which steam was passed from boilers. In 1825, Matthew Murray, of Leeds, the well-known competitor of James Watt, heated his house, which was locally known as "Steam Hall", by means of exhaust steam from the engine of his adjoining works. Meanwhile, in 1804, Oliver Evans in the United States had mentioned in one of his patents the use of exhaust steam from engines for heating.

An interesting article by David Brownlie, which deals specially with steam heating in the United States, begins in *Engineering* of September 5. He points out that from the technical and scientific point of view, one of the most serious defects of modern civilization lies in the fact that the condensing steam engine and turbine still lose some 55 per cent of the total heat in the coal, or other fuel, in the condenser. Even more serious is the use of the non-condensing engine, of which a particularly bad example is the steam locomotive operating at a thermal efficiency of no more than 6–8 per cent. Now experience with thousands of plants, mostly relatively small, has shown that great economy in fuel can be obtained by employing back-pressure or pass-out engines and turbines and utilizing the exhaust steam for heating and process work. The actual thermal

efficiency under average conditions is thus raised to 65—75 per cent by the reduction or elimination of the loss of latent heat.

The exhaust steam can be used directly in individual establishments or by what is popularly termed 'district heating' In general this means the supply of steam or hot water by means of long-distance pipe lines for the heating and general service of all types of buildings extending over a whole district or part of the area of a town.

The re-organization and improvement of the whole fuel system of Great Britain is long overdue, and one of the most important requirements is an extensive development of district heating. To indicate the possibilities in this direction the author first discusses the two chief countries in which district-heating is employed, namely the United States and the U.S.S.R. An important point, the significance of which has not yet been generally realized, is that most of the heating in the United States and all other countries except the U.S.S.R. is carried out on thermally inefficient lines by live steam, and not by the exhaust steam, so that the total power generated in the heating stations is very small. Russia is the only country that has developed district heating upon an extensive scale by using exhaust steam from public supply electric power stations.

In the United States there are at the present time about 175 district heating companies in operation, probably supplying more than 35,000 million pounds of steam per annum. This represents only a small proportion of the total heat used in the domestic field, which requires more than 100 million tons of coal (anthracite and bituminous) per annum in addition to large amounts of oil, natural gas, coke and other fuels. District heating was made a commercial success in 1877, at his house in Chestnut Avenue, Lockport, New York, by Birdsill Holly, who founded the first steam heating company, known as the Holly Steam Combination.

The largest district heating system in the United States at present is that of the New York Steam Corporation. In 1882 the first heating station was put into service at Cortlandt Street in the Broadway area, supplying steam at 80 lb. pressure through three miles of mains. The present total length is equivalent to about ninety miles of 12 in. pipe. It has five heating stations all operated on modern steam-driven power-station lines, the largest being the Kips Bay plant at 35th Street on the East River. The pulverized-fuel equipment for the five boilers at Kips Bay consists of seven mills in an adjoining building with a total duty of 160 tons of bituminous coal an hour. An important feature of the equipment is the softening plant dealing with New York town water.

The ninety miles of mains interconnecting the five stations are of lap-welded steel with welded flanges and corrugated copper expansion joints, and numerous draining stations, capable of operating, if necessary, at 250 lb. per sq. in. pressure. Most of the insulation is 85 per cent magnesia, in blocks 2 in. thick, with canvas and tarred felt outer covering. The mains are generally laid below the pavements in concrete and tile conduits with cast iron covers, the space between the mains and walls and floor of the conduit being filled with loose slag wool.

ANTARCTIC DISCOVERIES

By Prof. R. N. Rudmose Brown

Some preliminary accounts of the important discoveries of the United States Antarctic Expedition, 1939–41, under Rear-Admiral R. E. Byrd, are published in the *Geographical Review* of July, in an article by Lieut.-Commander R. A. J. English, U.S.N. The vessels of the expedition, *North Star* and *Bear*, reached the Bay of Whales on the Ross Ice Barrier on January 11, 1940. A base to accommodate thirty-seven men was set up on the barrier within a few miles of Admiral Byrd's old base of Little America. The *North Star* then left to establish the east base for sixteen men in Marguerite Bay on the west coast of southern Graham Land. There she was joined by the *Bear* and when the unloading was completed the two vessels left for the United States not to return until the early months of 1941, when both bases were evacuated and the whole expedition left for home.

The year in the Antarctic was well used in sledge journeys and in flights. Between Charcot Island on the east and the Ruppert Coast of Marie Byrd Land there was a gap in the known coast-line of Antarctica extending over some seventy degrees of longitude. To the south of the unknown coast-line Ellsworth had established continuity of ice-covered land with many peaks in his trans-antarctic flight of 1935. Light was thrown on this problem by flights from the *Bear* on her journey from the Bay of Whales to Graham Land, which was approximately along the parallel of 70° S. There were several short but important flights. A flight along the Ruppert Coast to about long. 135° W. revealed a coastal range about 4,000 ft. in height, snow-covered but with rock exposures near the coast. Far to the south the peaks of other ranges were seen. From lat. 70° 58′ S., long. 105° 33′ W. a flight southward again revealed such ranges lying parallel to the coast. Lastly, a flight from lat. 70° 4′ S., long. 95° 19′ W. confirmed the impression of the last flight of a mountainous peninsula immediately to the west, and the main coast-line was found to extend eastward in about lat. 73° S. These flights have thus filled in the coast-line south of the Pacific except for a stretch of some three hundred miles between long. 115° and 122° W.

The general arrangement of the mountains in this section of Antarctica would appear to be a series of ranges more or less parallel with the coast. The Rockefeller Mountains seem to be the western end of a long range broken by many glaciers pouring northward from the high plateau of Marie Byrd Land. The highest peak discovered was Mount Hal Flood, over 10,000 ft. in altitude, in lat. 76° 4′ S., long. 135° 50′ W. Farther eastward there were sighted bare coastal mountains towards which the interior plateau fell. These coastal mountains extended at least as far as long. 133° W. They suggest

a continuation of the Andean folds of Graham Land. Incidentally also later flights supplemented Rymill's charting of Alexander I Island by adding the southern coast-line. This was determined in flights from the east base. Another of these flights mapped the western end of King George the Sixth Sound, which was also examined by one of the numerous sledge expeditions from the same base.

Some new facts in regard to the Ross Barrier seem to have been discovered. A flight from the base to lat. 81° 8′ S., long. 176° 15′ W. showed wide fractures in three places, not yet specified, which suggests that the ice was aground. A large snow-covered island, about thirty miles long, was noted south-east of Roosevelt Island in approximately lat. 81° S., long. 158° W. This, of course, would mark a land area overlain by the shelf-ice of the Barrier.

A flight was made along the northern face of the Queen Maud Range from Mount Hope near the Beardmore Glacier to long. 147° W. In long. 175° W. a mighty glacier nearly as large as the Beardmore Glacier was noted.

Perhaps, however, the most important result of all was achieved from the east base in a flight southward and then south-eastward across the Eternity Range of southern Graham Land to the missing western coast of the Weddell Sea. This coast has proved unapproachable by sea. Larsen, Bruce, Filchner and Shackleton each were foiled by heavy packs in attempts to penetrate the western part of the Weddell Sea and between lat. 71° S. and the Weddell or Filchner Barrier in lat. 77° to 78° S. nothing was known. The Eternity Range was photographed and followed southward to lat. 74° 37′ S., long. 61° 15′ W. Beyond this as far as lat. 77° S. a south trending coastal range was visible with summits of apparently decreasing altitude. These discoveries suggest that the Weddell Sea may be wider at its southern end than had been believed. From both the west and east bases further work was done by plane and sledge, and extensive photographic surveys were made especially in Marie Byrd Land. Other aspects of the work of this highly successful expedition are not available. The article in the *Geographical Review* includes a preliminary small-scale map.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned.

DIRECTOR OF EDUCATION—The Town Clerk, Belfast (endorsed 'Director of Education') (October 3).

SPEECH THERAPIST—The Director of Education, Leopold Street, Sheffield (October 6).

ASSISTANT LECTURER IN MECHANICAL ENGINEERING—The Registrar, University College, Nottingham (October 6).

DEMONSTRATOR IN ZOOLOGY—Acting Head of the Department of Zoology, the University, Edgbaston, Birmingham 15 (October 7).

LECTURER IN ELECTRICAL ENGINEERING SUBJECTS—The Director of Education, City Hall, Cardiff (October 8).

INSPECTOR OF SCHOOLS (WOMAN)—The Director of Education, Guildhall, Hull (October 18).

HEAD OF PHYSIOLOGY DEPARTMENT—The Secretary, The Rowett Research Institute, Bucksburn, Aberdeenshire (October 31).

LECTURER WITH QUALIFICATIONS IN MATHEMATICS, PHYSICS OR ENGINEERING—The Principal, Technical College, Kendrick Hall, Stroud, Glos.

DEMONSTRATOR FOR THE BIOLOGY DEPARTMENT—The Secretary, King's College of Household and Social Science (University of London), c/o University College, Leicester.

SENIOR MATHEMATICAL MASTER—The Principal, King William's College, Isle of Man.

ASSISTANT ELECTRICAL ENGINEER for the Federated Malay States Government Electrical Department—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M/9769).

THE CHARTER OF SCIENTIFIC FELLOWSHIP

IN the conflict of ideas, the clash of two diametrically opposed ways of living, which are involved in the present War, the British Association's recent Conference on Science and World Order may well prove to have as profound a significance as President Roosevelt's clear enunciation of the four freedoms which are at stake, and as the declaration which arose out of his Atlantic meeting with Mr. Churchill. In place of the thoughtless blaming of science for the misuse of the knowledge and power with which scientific discoveries and their application have endowed mankind, we have the recognition that from henceforth science and statecraft, in Mr. Eden's words (see p. 403), must march together.

Nor is this all. The very holding of such a meeting in war-time, a meeting as truly international as the meeting of the Inter-Allied Council held also in London in the same week, attests the existence of the goodwill and faith in international co-operation required to lay the foundations of a better world. The merest glance at the programme of the Conference will have revealed how profound is the contribution of science to that task ; and how grave is the responsibility of statecraft to see that the fruits of planning by men of science are not misused, and to secure the free enjoyment by all of the greater health and leisure which science has made possible.

What is equally significant is that this partnership of science and statesmanship in the building of a new world order is only possible in the nations that still remain free. Without full freedom science cannot long persist, for the fountain heads of new knowledge and creative thought dry up and the quest for truth degenerates into the practice of a technique or cult. This we have already seen happening in Germany, though as many countries know to their cost, science is not yet dead in that country. None the less, the persistent interference with freedom of scientific investigation, of the expression of scientific thought, and with the international interchange of thought had already some time before the War led to a marked deterioration in the quality of scientific work in Germany, especially in fields of new and fundamental research. The British Association Conference in itself is a welcome reminder of the immense and incalculable assets, which are ours in the struggle against Nazism, through the international exchange of scientific thought still possible among the free peoples and the exiled men of science in their midst.

These are truisms obvious to any scientific worker, but it is well that they should be so clearly stated for a wider public, as has been done in the Declaration of Scientific Principles adopted at the final session of the Conference (see p. 393). The

Declaration indeed contains nothing new. It is an educational instrument of the first order, and if it is studied aright by scientific workers and by statesmen and administrators, there should be an end to the charge that in Great Britain, ministers of State or the Civil Servants under them are insufficiently equipped in scientific knowledge or grasp of scientific method and technique.

This Declaration of Scientific Principles is no mere statement of the conditions upon which such co-operation is possible. It demonstrates first and foremost the extent to which the future of science is bound up with that of democracy and the overthrow of Nazism. This struggle is part of the age-long struggle of scientific workers to preserve freedom of thought, of investigation and of expression in the face of unreasoning prejudice, stagnation and repression. The Declaration is an open renunciation of neutrality and an acceptance of special responsibility in the struggle against a tyranny which threatens to overwhelm intellectual liberty everywhere.

The acceptance of such responsibilities is not, however, prompted by the mere instinct of self-preservation, the conviction that to-day complete freedom of thought and interchange of knowledge and opinion are supreme necessities. It is equally prompted by a consciousness of the harmony of interests and aspirations between science and democracy itself. As the Declaration insists, full freedom of expression is of the essence of both science and democracy : where thought is enslaved both wither and decay.

More than this, since the direction of and resources available for scientific work are determined by the social and economic conditions in which the scientific worker finds himself, science is equally concerned with the economic freedom, the third freedom enunciated by President Roosevelt, and all that is implied in the adjustments of social and economic life, required for its realization. This is not merely a matter of the application of scientific knowledge or the mobilization of scientific resources for the acquisition of fresh knowledge in fields insufficiently explored. It is a question of outlook, of the adjustment of ways of living to facilitate the full and free adaptation of ideas to new conditions.

If, therefore, the Declaration of Scientific Principles is an affirmation of those principles upon which it has long been recognized that the fellowship of science is based, and of opposition to any policy of power which deprives men or nations of their free practice, it is equally a challenge to intense mental effort and clear vision. The vision of the possibilities inherent in the contribution of science to the solution of post-war problems and to the building of a nobler world order which the deliberations of the Conference have given, needs to be supplemented by exactly such a statement of principles and challenge to thought and endeavour.

It is well, therefore, that all should understand the basic implication that science must be the partner, not the handmaid, of the statesman or administrator. The State must impose no limits on liberty to learn, opportunity to teach or power to understand if society is to reap the full advantages of scientific thought and knowledge. Science can co-operate while retaining its independence. To sacrifice its independence may destroy co-operation by destroying science.

That truth can scarcely be emphasized too strongly to-day, and there was no more hopeful sign at the Conference than its ready acceptance by Government spokesmen as by the spokesmen of science. Equally vital is the stress laid in the sixth and seventh points of the Declaration on the world fellowship of science. Science truly has the world for its province, and the discovery of truth as its highest aim. The pursuit of scientific inquiry demands unrestricted international exchange of knowledge as well as complete intellectual freedom, and can only flourish through the unfettered development of civilized life. The Conference itself bears witness to the extent to which such international fellowship is still possible in Great Britain and to the hope which may justly be entertained of re-establishing it in Europe when the Nazi power has been destroyed. It may well be hoped, however, that the Conference with this pointed Declaration will stir us to use far more effectively than hitherto the immense moral and intellectual resources in international co-operation which we possess, not alone through our allies but also through the presence of *émigré* men of science from Germany and the occupied countries of Europe.

Any partnership must be based on mutual understanding and respect. No scientific worker, therefore, can fail to mark and honour the pledge given in the fifth point of the Declaration. Men of science are among the trustees of each generation's inheritance of natural knowledge. It is, as they attest, their determination to foster and increase that heritage by the fidelity of their guardianship and service to high ideals, shown to-day in their devotion in the defence of that heritage in the present struggle, no less than in the planning and thought which must go to safeguarding it in a new order yet to be. To scientific workers no less than to the administrator or statesman, the Declaration is a summons to thought and action. To both it may well bring the reflection : *noblesse oblige.*

SKILLED MEN IN THE STATE SERVICES

ONE of the most striking features which has emerged from the recent debates in the House of Commons on war production and on the coal industry, when attention was focused on serious deficiencies in the Government's man-power policy, is the extent to which such deficiencies are due to neglect to use scientific methods or knowledge. Shortcomings in policy are, in part at least, due to the absence of the knowledge essential for a right decision. Failures to use man-power or woman-power to the fullest advantage are equally due to the neglect to use scientific knowledge and method in the selection of personnel, whether in industry or in the armed forces. Absenteeism and other causes of lost time or defective output are due as much to neglect by management of experience acquired as long as twenty-five years ago as of the methods of management and administration which in recent years have rapidly acquired sound claims to be considered a science as well as an art as to failings of the workers themselves.

The importance of the contribution of science in this field has been well illustrated in a further broadsheet on man- and woman-power issued by Political and Economic Planning (P E P), in recent reports from the Select Committee on National Expenditure, and in interim reports of the Kennet Committee on the Calling Up of Civil Servants and of the Beveridge Committee on Skilled Men in the Services, which have appeared almost simultaneously. All alike point to certain matters in which the national effort falls short of the maximum through neglect in the past of scientific method or knowledge. Not all these defects can be remedied immediately. The Select Committee indeed suggests that the system of selection by testing could only be giving the fullest value to the Forces at the present time if it had been in use already for ten or twenty years.

The handicap which has been placed on our war effort by such neglect in the past is particularly well illustrated in this twenty-second report of the Select Committee and in the Beveridge and Kennet Committees' reports, all the more emphatically from the restraint which characterizes their recommendations and their warning against expecting to achieve rapid results by a sudden reversal of policy. The Select Committee points out that two types of test are at present necessary in the Forces: a simple intelligence test to ascertain if a man or woman is suitable for further training as a specialist, and a special aptitude test to determine what his or her particular work should be.

The latter tests must be designed by persons in the closest touch with those who have wide experience of the type of work to be carried out, and it is advisable to proceed gradually with their application. The Committee thinks that they should probably not be used at present outside such technical corps as the Anti-Aircraft and the Royal Armoured Corps. By the wider use, however, of the former simple testing of intelligence and by also ascertaining the capabilities of recruits by tests applied by the Ministry of Labour and National Service before they are posted to a corps, it should, in the Committee's view, be possible to remove many of the present anomalies. Other recommendations include a test of mental capacity level of those called to attend a medical board after registration and the rapid discharge of unsuitable personnel, as well as the grading of new intakes into classes for training in accordance with their intelligence levels.

The Committee, in addition, recommends that better use should be made of the capabilities of younger men, and while it recognizes that the qualities essential to an officer cannot be ascertained solely by testing, and recommends that the system of reports by commanding officers as to the suitability of men to be entered as cadets should be continued, these should be reinforced by a system of tests many of which have yet to be devised. The principle that officers should as a rule be selected from those whose intelligence, as measured by tests, reaches a certain level is, however, far-reaching, and its adoption may well make an important contribution to the discovery and selection of leaders in the armed forces and in civil life. There is no more vital problem for democracy to-day than that of throwing up its potential leaders in all ranks of society and training them for the duties and responsibilities they must carry whether at the highest or at intermediate levels.

The Beveridge Committee's interim report on skilled men in the Services indeed shows that the responsibility of making the fullest use of skill and knowledge is fully appreciated. Both in the Army and in the Air Force the necessary work of modification, repair, maintenance and servicing of machines and instruments of war, in the Committee's view, is now being performed with a notable economy of skilled men, secured by a high degree of dilution and extensive and well-designed arrangements for training. In many such matters of organization the armed Forces have long been far ahead of industrial or civilian establishments generally. Moreover, vigorous efforts are being made by the Army and Air Force to discover men now in the Forces not already engaged on such

work whose qualifications make it likely that they could undertake it with success or could be trained to do so.

In spite of this, in view of the military programmes, a large increase of men engaged on such work is inevitable, exceeding the numbers who can be obtained within the Services by training or transfer, and although the information before the Committee in respect of the Navy was less, with the development of the war at sea the time has probably come when substantial addition to the recruiting of skilled men for the Navy has also become inevitable. Moreover, the report comments on the vital importance of guarding against the danger that the machines on which the lives of fighting men and the safety of the country depend may have to be entrusted to hands insufficiently skilled under inadequate supervision.

No scientific worker can fail to appreciate that this is a much more serious risk than the use by the Services of an excessive proportion of skilled men in relation to unskilled men on repair and maintenance. That such a choice may require to be made emphasizes the importance of eliminating another type of waste, not so much of scarce specialized skill in engineering and allied trades, as of physical strength or of education, experience and ability, to which the report also directs attention. Many men of military age are doing clerical, storekeeping and other light work in the Services which could be done by women or by older men. Until, however, the extensive plans already prepared in the Service Departments for substitution of women for men in all suitable kinds of work are realized, and so long as men of military age are used on work within the capacity of others, whether with or against the will of the Service Department, the Government will not escape criticism for waste of man-power.

On this question of remedying defects in the development or execution of policy the Kennet Report on the Calling Up of Civil Servants throws a significant sidelight. After the War of 1914–18 the Civil Service did not revert to normal recruitment on any substantial scale for nearly ten years. Meanwhile, recruitment was almost wholly from ex-Service men. In the clerical, executive and analogous fields there is an abnormally large proportion of persons between the early forties and the late fifties and a low proportion between thirty and forty. On the other hand, the thirty to forty group, or for the higher personnel, the twenty-five to forty group, is understood to contain many of the best of these with experience.

Such facts have to be taken into account in considering withdrawals from the younger group, while they indicate the basic reasons for some of the criticism that has of late been levelled against the Civil Service. Civil servants cannot be blamed for the consequences when the advice that they have given has been ignored by their Ministers or by the Cabinet, but the Civil Service as a body must bear a fair share of the responsibility if the techniques for obtaining information and for shaping and presenting policy lead to an excessive proportion of decisions proving to be ill-advised. The age-structure described by the Kennet Committee is what might be expected if the Civil Service as a whole tended to be using obsolete or inadequate technique and was not quite abreast of technical, scientific or social developments.

It follows from this that if the Kennet Committee is right in its opinion that the process of substituting women and older men for men of military age which is still in progress in the Civil Service can now be extended and accelerated, it is of the utmost importance to see that the loss of efficiency involved does not outweigh the advantage to combatant strength. The Committee recommends that this should be done by raising the age of reservation for Civil Servants in specified grades to much the same degree as it is being raised for reserved occupations in general, and that this should be accompanied by the cancellation of all deferments. Allowance must, of course, be made for exceptions, but the test must be whether deferment is necessary to provide for the efficient discharge of work essential under war conditions. Where the work is necessary and substitution wholly impracticable, deferment might be granted for an indefinite period. Similarly, efficiency demands a reasonable time to provide and train the substitutes, particularly in the higher grades, while the contemplated extension and acceleration of calling-up underlies the Committee's observation on the striking examples of waste which have already occurred through delay in rectifying the return to the Civil Service of men who were invaluable in their former office and where removal has been the cause of inefficiency and loss of man-power.

If the new drive to secure the full use of our man- and woman-power is to have its proper effect this test of efficiency must be kept in mind at every stage. It is from this point of view that the recommendations of the successive reports of the Select Committee on National Expenditure are of surpassing importance. There is no room for departmental failures in supervision, such as that of repair work in shipbuilding or reconditioning, or of individual eccentricities such as those of the trade union delegate upon which the Committee comments trenchantly in twentieth report. Such treacherous activities must be swiftly and ruthlessly suppressed.

The whole of the twenty-first report of the Select Committee is concerned with this question

of eliminating waste of man-power, from the point of view of seeing that available labour is used as effectively as possible. It is of the utmost importance that, with our limited man- and woman-power, the output of every worker should be increased to the maximum. For this purpose it is necessary not merely that the individual worker should work his hardest, but also that the work should be organized as carefully as possible. It is this latter aspect that has received inadequate attention from the Departments concerned, and many of the problems it involves cannot be solved without scientific study.

Once again the Select Committee finds it necessary to direct attention to the neglect by managements or departments of the experience gained in the War of 1914–18, and particularly to utilize the services of the Industrial Health Research Board in inquiries into such problems as the number of working hours per week which gives the best output in any particular kind of industry. Neglect of this kind is far more damaging than absenteeism to the national effort, and the Committee points out that while a high rate of absenteeism is not always associated with bad management, good management certainly reduces it.

The Committee recommends that the Industrial Health Research Board's rightful status as the proper body for research into industrial health should be recognized. The Board should work in the closest co-operation with the Production Departments and have every opportunity to carry out investigations on a scale wide enough to cover the main problems of industrial health and efficiency in war. For this purpose its staff should be strengthened, and one of the first objects of inquiry should be the best length of working week for a wide range of different kinds of work, particularly the working week giving the best continuous output over a long period.

More important than the question of Sunday labour is that of securing that on the other six days of the week factories and plants are employed for as much of the twenty-four hours as possible. Only a minority of factories are working twenty-four hours a day, because a sufficient labour force has not yet been recruited and trained. Consideration should also be given to wages, for in so far as high wages are the result of bad rate-fixing they operate to cause loss of output.

Management, however, remains one of the most important factors affecting output, and the evidence shows that idling is frequently due to bad management or want of supervision. The pace and general spirit of a factory come from the top, and the importance of setting a good example in energy, punctuality and enthusiasm need not be stressed. Moreover, lack of work and enforced idleness, whether due to mismanagement inside the factory, insufficient stocks to tide firms over temporary breakdowns of supply, or to irregular allocation of contracts by Production Departments, cause loss of output by inducing a sense of frustration in workpeople which ultimately lowers their morale.

Many of the observations in the report are the everyday practice of modern management, and it is a sad reflection on the general standard in war-time that the Committee should find it necessary to allude to such commonplaces as the value of taking workers into the confidence of the management in overcoming difficulties, the importance of handling a recruit correctly at the outset of his career, the need for appointing men to positions of authority for their personal qualities of leadership, tact and organizing ability as well as for their technical skill, or to recommend that the Factories (Canteens) Order 1940 should be amended so as to require factories engaged mainly in work on behalf of the Crown, with a sufficient number of workers to make the arrangements feasible and necessary, either to provide their own canteens or to make suitable alternative provision. Similarly, although considerable scientific work has been carried out on the effects of conditions of lighting and ventilation upon output, and desirable standards of heat, light and ventilation are known with some precision for broad categories of work, these standards have frequently not been applied. It might well be argued further that the question of incentives to output, also stressed in the report, is largely a management matter, particularly in demonstrating to workpeople the real need for ever-greater output, which in war-time should be the ultimate stimulus.

If this admirable report appears to stress chiefly the responsibility of management, particularly in raising the quantity and quality of managerial ability and in increased collaboration with the workpeople, it equally indicates the contribution to be made by the other two partners in the industrial team. Departments must accept a greater responsibility for the working conditions which affect the output of industry and for removing the external obstacles to output such as inadequate housing, transport and feeding arrangements. Workpeople must recognize that the conditions of industry during the War cannot in the nature of things be ideal, that special efforts are needed to overcome difficulties, that improvements, however energetically pursued, take time to achieve, and they must also realize the importance of the contribution of the individual to the total output.

When all this has been recognized the influence of the central administration remains a vital factor. There lies the main responsibility for keeping constantly under review the disciplinary provisions of the Essential Work Orders or for the executive action

involved, removing from reservation a persistent offender who refuses to obey a direction under the Essential Work Orders. Moreover, the bringing to maximum efficiency of all members of the labour force is only one of the three stages of man-power policy which must be co-ordinated and developed by the Government itself. Unless this stage finds its place side by side with the systematic withdrawal of man years for the armed Forces and the civil defence services and with the determination of the civilian man-power necessary to maintain the output of goods and services for the armed Forces, for essential civil needs and for export, maldistribution of the existing labour force will persist and our war effort fall short of its maximum.

The P E P broadsheet gives an admirable analysis of the principles and problems involved in each of these three stages. The Schedule of Reserved Occupations is the sheet anchor of man-power policy, and it is clear from the Beveridge report that it is improbable that there are too many skilled men in the Forces relative to the number employed in industry. The criticism that in the distribution of man-power the armed Forces are favoured at the expense of production is less easy to answer and is likely to be further provoked by the present situation in the U.S.S.R. and the revision of the Schedule. The P E P broadsheet points out that the criticism might well be met so far as the Army is concerned by making its members both soldiers and workers. The Home Guard indeed represents one such solution, the use of specialized units such as Pioneers and Royal Engineers for the clearing of debris or maintenance of communications after an air raid another, while the use of soldiers in harvesting or their release for industrial employment is a further method, the possibilities of which should be fully explored during the winter months, particularly in view of the success of the system in Germany during the past winter.

It is upon the transfer of man- and woman-power to essential work that attention is chiefly focused at the present time. It would appear from the reports already cited that the Government is still without much of the essential information upon which to base a sound decision as to the civilian man-power necessary for war production and essential civil needs and exports. This alone would account for the hesitancy of the Minister of Labour and National Service and for his reluctance to use his wide powers of compulsion. None the less, as the broadsheet points out, it is very clear that the Schedule requires drastic revision, especially in the removal of reservation from many mobile girls who could be replaced by older women.

Here, as elsewhere, the evidence does not warrant the belief that our objective will be reached by persuasion alone. In the concentration of industry very few satisfactory arrangements have been made, while concentration has not yet been enforced upon the vast retail trades. There are far too many shops, even food shops, particularly butchers', and a reduction in these numbers will have to be considered, just as a reduction in women personnel is being done.

Again, the broadsheet points out that in the concentration of industry, efficiency indicates the importance of keeping management intact if possible, and turning efficient management over to the running, for example, of a factory dispersed on strategic grounds. Training again still receives inadequate attention, as well as the necessity of altering production methods not only to economize on skilled labour but also to simplify training. The economy of man-power in essential industry demands careful study if the periodical bottle-necks due to the shortage of workers with a particular kind of skill or experience are to be minimized, the transfer of workers from one type of work to another not impeded by difficulties in regard to wages or other conditions and the utmost advantage taken of youth and mobility among women.

The reports to which we have directed attention, and the P E P broadsheet do not afford ground for either pessimism or optimism. They point indeed to definite shortcomings and indicate ways in which those shortcomings and mistakes may be and are being rectified. The dominant impression they leave is, however, the immense importance of the scientific contribution in thought, in technique and in material. No adequate man- and woman-power policy can be evolved without the fullest possible use of scientific methods of inquiry and of scientific analysis of definitely ascertained facts. The execution of such a policy will equally fail of its objectives unless from top to bottom there is the fullest use made of scientific and technical knowledge already available, the persistent application of scientific methods to all appropriate problems and unfailing readiness to utilize the help which scientific workers or scientific organizations can give in all matters affecting production, output or welfare. Impatient as scientific workers may sometimes be that more use is not made of their individual services, whether through the failure of the Central Register to function properly or through other causes, this is a far graver concern of them all—the responsibility of seeing that no opportunity is missed of bringing home to the nation, from the Government downwards, of the immense and vital contribution which science can make in our war effort. In that task they will rarely find such abundant ammunition as lies to their hand in the pages of the P E P broadsheet and these reports.

SCIENCE IN PROGRESS

Science in Progress

By L. J. Stadler, F. W. Went, J. F. Fulton, Douglas Johnson, Alfred C. Lane, H. P. Robertson, Carl D. Anderson, Duncan A. MacInnes, J. W. Beams, J. C. Hunsaker. Edited by George A. Baitsell. Second Series. (The Society of the Sigma Xi devoted to the Promotion of Research in Science: National Lectureships, 1939 and 1940). Pp. xii+317. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1940.) 24s. net.

THE tremendous advances which have been made during the past century all along the scientific front are not, it must be admitted, entirely without their counter-vailing disadvantages. Even if we reject the suggestion put forward by Rabindranath Tagore that science is the modern Mephistopheles to which mankind has sold its soul in return for material benefits destined in the end to bring about its destruction—a thesis which at the present time seems painfully plausible—and admit that the passion for scientific discovery which characterizes our age is one which must and should be satisfied, the extent and variety of the knowledge gained raise intellectual and philosophical problems of a formidable kind. A century ago a not unduly gifted individual might, if he cared to take the trouble (and many did) have a reasonably comprehensive view of what was afoot in all branches of what could then truly be called natural philosophy. To-day there is no natural philosophy; only an ever-increasing number of sciences, each with its specialists directing a closer and closer scrutiny on an ever-narrowing field of vision.

This is a pity; and not merely from a philosophical point of view. Fresh advances and new techniques developed in one science frequently open the way to big discoveries in apparently unrelated fields of action. Moreover, it is more than possible that the biggest advances of all are to be achieved in that no-man's-land which lies between the biological and physical sciences, and will be won by a combined attack from both sides. It is obvious that one of the most urgent needs of to-day is for better liaison work between the sciences. Possibly some enlightened university may be persuaded to re-establish the professorship of Things in General once held by the late Herr Teufelsdröckh at the University of Weissnichtwo. In the meantime, and as a sort of substitute, the Society of Sigma Xi has established in the United States a series of national lectureships to serve something of the same purpose. Reports of ten of these lectures, given in 1939 and 1940, make up the contents of this volume of "Science in Progress".

It is a very attractive and impartial cross-section of the sciences which is offered to the reader in this very attractive and handsomely produced volume. The subjects covered include the experimental alteration of heredity, the regulation of plant growth, experimental studies of the functions of the frontal lobes in monkeys, chimpanzees and man, how the earth shows its age, recent advances in aeronautics, and, of course, the expanding universe and cosmic rays. In addition there are articles of rather more specialized interest on the ultracentrifuge, on the motions of ions and proteins in electric fields, and on mysterious craters of the Carolina coast. Merely to read these subject headings is something of a tonic; it helps to restore one's faith that, however incompetent man may still be in the political sphere, he has some claim to his self-bestowed title of *Homo sapiens*. To appraise each separate article in the volume is beyond the scope of this review, and any selection would, probably, only reflect the personal tastes of the reviewer. I can only place on record that one reader, at any rate, found every article—each of which has been written by a research worker of international reputation in his subject—of interest, and that the collection as a whole was an intellectual stimulus.

The lectures, one gathers from internal evidence, were designed primarily for men of science, though no doubt intelligent non-scientific specialists were welcomed. Such an audience is one to put even the most distinguished lecturer on his mettle; for in spite of the division of interest, on which stress has already been laid, the unity of the scientific spirit remains unimpaired. Most of us know that our colleagues in other sciences are capable of most pertinent and valuable criticism of our theories when once we have succeeded in making clear to them what these theories are. The principal barrier between the sciences is not so much a difference in interest as a difference in vocabularies. Science suffers, along with the rest of mankind, from the curse of Babel! More than one of the authors of "Science in Progress" allude to this difficulty. Prof. Fulton, for example, writes "The title of this chapter should really have been 'Encephalization and functional localization in the primal frontal lobes.' However, I feared that this might frighten the physical scientists, for, although they invent words far more terrifying, they always seem a little intimidated by the simple words we devise in the biological sciences!" It cannot truthfully be said that all the distinguished authors who have contributed to the present volume have been equally successful

in overcoming the language difficulty. Some have taken great pains to do so; others seem scarcely aware that the problem exists. One does, occasionally, become aware of the substance behind the common complaint made by the layman that men of science "write an unintelligible jargon." What, for example, can a reader whose knowledge of chemistry is, perhaps, forty years out of date gather from such a statement as "Proteins can be broken down into various amino acids in addition to prosthetic groups?" And yet, as the author might justly retort, how can the matter be put more clearly? Probably science, like poetry, to which it has many affinities, is actually untranslatable.

No series of disconnected lectures, however distinguished, can produce the reintegration of science, so much to be desired. Yet the present volume stimulates the hope that such a reintegration is possible. Through all the diversity of topics one becomes aware of a unity of purpose, a unity of method, and a unity of thought much closer than one had imagined. Biology and physics do not seem so remote in outlook as one had sometimes thought. It is to be hoped that world conditions will not interrupt the activities of the Sigma Xi, and that the third series of "Science in Progress," promised for the autumn of 1942, will duly make its appearance.

J. A. CROWTHER.

METHOD IN TEACHING CHEMISTRY

Numerical and Constitutional Exercises in Organic Chemistry

By Dr. J. L. B. Smith and Prof. M. Rindl. Pp. ix+214. (London: Methuen and Co., Ltd., 1941.) 7*s*. 6*d*.

Calculations of Qualitative Analysis

By Prof. Louis J. Curtman and Sylvan M. Edmonds. Pp. vii+156. (New York: The Macmillan Company, 1940.) 8*s*. 6*d*. net.

THESE books originate, one from South Africa, the other from the United States, both countries of wide open spaces in which the larger proportion of the inhabitants live by doing practical things. Such environment might be expected to have an influence on the teaching in the universities at least of chemistry, which is essentially a practical subject, and it comes as a surprise to find students expected to give much time to mathematical exercises. Would-be chemists should certainly be taught mathematics up to the limit of the time available in their course, but this should be real mathematics. As Eric Gill has written in his autobiography, we are educated by the doing and not by the learning: this is the whole secret of education whether in schools or in workshops or in life. The actual business of learning—the acquiring of the use of tools without using them—is the very smallest part of a proper system of education. Some would say it is impossible, and it is largely for this reason that some of the hard-headed men in Lancashire and Yorkshire are sceptical of the value of a university education for their sons.

We do not go to school to learn football or cricket but to play them: there are not a few who hold that games are the backbone of our public school system, as is evidenced by the fact that those who are proficient in them are sought after for the better positions in life.

Organic chemistry in particular must be taught at the bench. The great school of von Baeyer at Munich was essentially a practical one, so was that of Emil Fischer in Berlin. Most of the chemists of repute, German or foreign, went to one or other of them; they toiled all day long and often far into the night in the laboratory, seldom went to a lecture but read avidly and omnivorously the original literature; hence they had the widest knowledge of chemistry as a whole. W. H. Perkin brought the bench tradition to England, and there are few among our leaders of yesterday and to-day who escaped his influence.

All the achievements have been at the bench. It is unfair to the student, to my mind, to keep him in the classroom when he should be at the bench. The original sin must, of course, be laid at the door of the examination, which means that the student is taught to satisfy the examiners and not the subject by which he hopes to earn his livelihood. There is much talk of peace aims: surely the greatest would be to abolish the present system of examinations which has put a dead hand on learning in schools and colleges, and to induct the student into a "brave new world" though of a more moral kind than Huxley's. There would then be fewer disappointments when an honours degree man finds himself a failure in practice in the late twenties.

Teaching as exemplified by these books is essentially on the wrong road: we must see that it is marked "no entry, unexploded bomb", in the most unmistakable way.

While we have criticized the system it would be unfair to be unkind to the books themselves. It is

scarcely possible to deal with them in detail, they represent a careful attempt to treat the subject-matter according to the views of the authors.

To us sugar can never be $C_{12} H_{22} O_{11}$; we think of its crystals, its properties, its stereochemical formulæ; of the uncertainties which surround this; of those who have wrought at the solution of the problem; of how it is made by the plant in Nature; of the sheer marvel of its molecular architecture and the changes produced by shifting a hydroxyl group here and there; of the ways in which we can perhaps effect its synthesis.

Such an insight into a single substance is pure poetry: it has a spiritual implication beside, forced on us by the sheer orderliness of things. The student could be taught all this in a few lessons and become a seeker after knowledge with poetic fervour, which he could never achieve from a course of numerical and constitutional exercises.

E. F. ARMSTRONG.

SIGNIFICANCE OF THE HYPOTHALAMUS

The Hypothalamus and Central Levels of Autonomic Function

Proceedings of the Association for Research in Nervous and Mental Disease, December 20 and 21, 1939, New York. (Research Publications, Vol. 20.) Pp. xxx+980. (Baltimore, Md.: The Williams and Wilkins Co., 1940.) 10 dollars.

THIS volume contains thirty-four separate papers on different structural, functional and clinical problems related to that part of the brain which is known as the hypothalamus. A brief historical résumé of the literature and a reprint of Fröhlich's memorable contribution on a case of dystrophia adiposa genitalis form a fitting introduction to the papers which follow. Written by authors who have done outstanding work on the problems discussed by them, the various papers provide not only a review of previous work but also much unpublished new data.

On the structure of the hypothalamus there has been an attempt to codify the nomenclature of the cell masses and fibre tracts in the region, which will be of the utmost value to future workers. The unravelling of the connexions of the nerve cells and the fibre tracts which pass through this part of the brain has not yet been completed, but notable advances have been made. The very incompleteness of our knowledge of its structure makes the story of the functional significance of the region all the more fascinating. Knotted together in this relatively small part of the brain are the most diverse functions—cardiovascular control, water, carbohydrate and fat metabolism, control of body temperature, some aspects of sexual behaviour, gastro-intestinal regulation, an influence on pituitary activity, some measure of sleep control, and an effect on the somatic muscular responses. Contributions on each of these functions are to be found in the section on the physiology of the hypothalamus. The relation of the hypothalamus to the endocrine glands and especially to the pituitary body is discussed in many of the papers. Although the exact anatomical connexions between the pituitary gland and the central nervous system are by no means clear, abundant experimental and clinical evidence is disclosed to show that the nervous control of pituitary functions is of great importance.

Studies of diseases and new growths involving the hypothalamus are included in the third section of the book. Such studies are invaluable as they provide a means of checking in man the value of stimulation and extirpation experiments on animals. Actual stimulation of the region has been carried out in conscious human patients with results identical with those found in experimental animals. Changes in personality and emotional disturbances have been correlated with certain lesions which seem to release the hypothalamus from an inhibiting cortical control. The clinical and experimental evidence for such a control over hypothalamic activity seems now to be well founded. From the evidence now available, it seems probable that the hypothalamus can be regarded as the 'motor cortex' of the vegetative nervous system, receiving stimuli from, and acting under, the dual control of the thalamus and cerebral cortex. More explicitly, the hypothalamus is that part of the brain which maintains by means of the vegetative nervous system and certain endocrine glands the constancy of the *milieu intérieur*, or the internal environment of the organism.

The 'evenness' of the papers and the lack of serious overlapping are worthy of comment. There is every sign of careful editing in the production of the volume. While the papers are the products of those working in North America, there is ample reference to the activities of those in other countries, and especially to those pioneers who opened up, more than eleven years ago, in the proceedings of the Association for Research in Nervous and Mental Disease, the field which has been so abundantly fruitful. An extensive bibliography completes an outstanding volume which will be for many years an invaluable book of reference.

CONFERENCE ON SCIENCE AND WORLD ORDER

WHILE the older sections of the British Association from A to M have been obliged to suspend their activities because of the exigencies of the War, the Division for the Social and International Relations of Science—the youngest and, one might say, the adopted child of that elderly yet virile organization—organized a Conference on Science and World Order at the Royal Institution, London, during September 26–28. On the day preceding its public sessions, at a luncheon arranged by the British Council and attended by many members of the Government and Diplomatic Corps, Mr. Anthony Eden, the Secretary for Foreign Affairs, expressed the growing appreciation by our higher statesmen of the value of scientific training, scientific research and the applications of science in the conduct of public affairs (see p. 403).

The six sessions of the Conference were well attended by a varied and representative gathering. At the opening session on Friday, September 26, a message of commendation was received from the Prime Minister (see p. 403); and a letter outlining the basis of the Conference was sent to H.M. the King, from whom a message was received later (p. 403). Sir Richard Gregory, president of the British Association, and chairman of the Division for the Social and International Relations of Science, then gave the inaugural address. He announced that sub-committees to deal with the main topics raised at the Conference would be appointed by the British Association.

The deliberations during the sessions covered the relations of science to government, human needs, world planning, technological advance, post-war relief and the world mind, respectively. The many valuable papers presented will be more amply noticed in a series of articles in forthcoming issues of NATURE. A perspective of the proceedings alone will be attempted here.

The discussion on "Science and Government", under the chairmanship of Sir Richard Gregory, was opened by Viscount Samuel, distinguished in the fields of both statesmanship and philosophy. He paid tribute to the scientific spirit, outlined the present organization of Government research departments (see Lord Hankey's speech in the House of Lords, NATURE, April 12, p. 432), and advocated the establishment of science attachés to the principal embassies. Prof. A. V. Hill, M.P., Foulerton research professor of the Royal Society, followed with a warning to scientific men to be continually aware of the dangers arising from interest, prejudice and emotion, dangers which are certain to creep in when one attempts to deal with government and politics. He stressed the need to remove barriers between "government science" and "independent science" by the creation of more scientific advisory bodies attached to departments of State and the Cabinet.

Prof. L. Gulick, of the U.S. National Resources Planning Board, followed with a description of the New Deal's successful Tennessee Valley Authority and its achievements. Six main river dams have been completed and three more are under way on the Tennessee River itself, and several more on its tributaries for the multiple purpose of improved navigation, electrical power development and flood control. The present installed generating capacity now exceeds one million kilowatts, and by 1944 this will have been doubled. The revenue derived from the sale of electricity covers the operating expenses of all the Tennessee Valley Authority programme, which includes social work tending to improve housing, education, health and the standard of living generally.

Dr. P. W. Kuo, vice-minister of finance and former president of the South Eastern University of China, outlined the many ways in which a scientific approach to industrial problems has enabled China to strengthen its resistance to aggression, and how a reform of the currency system has contributed to China's ability to utilize to the utmost its resources. Prof. J. D. Bernal sketched five stages in the application of scientific method based on information, research, development, execution and control. Prof. J. B. S. Haldane gave a spirited address comparing the Academy of Sciences of the U.S.S.R. with the Bank of England in their relation to their respective Governments. Dr. A. Labarthe, editor of *France Libre*, formerly lecturer in technology and thermodynamics at the Sorbonne, speaking in French, pleaded for the establishment of a ministry of scientific research which would erect trial industrial plants for the investigation of new processes. Dr. J. Negrin, formerly professor of general physiology in the University of Madrid and lately head of the Spanish Republican Government, supplied the reflections of a professional man of science forced to take a leading part in the management of State affairs.

The second session of the Conference, which dealt with "Science and Human Needs", was under the chairmanship of H.E. the American Ambassador, Mr. J. G. Winant. He said in a speech which

directed attention to the need for eliminating both the threat of force and of poverty: "We must abolish both hunger and the sword as a means of forcing labour."

Prof. E. Abel, formerly of the University of Vienna, expressed the gratitude of his many Austrian colleagues who are working in Great Britain.

Sir John Orr, director of the Rowett Research Institute, Aberdeen, implemented the chairman's appeal with fact and figures. He spoke with his usual vigour and clarity in favour of a food policy that would raise the health and intellectual standard of the masses, and advocated the appointment of an international convention to prepare the plans for a post-war food policy.

Sir Harold Hartley, chairman of the Fuel Research Board, gave a well-documented address on the world's heat and power requirements.

The Right Hon. Herbert Morrison, Home Secretary and Minister of Home Security, without committing the Government, agreed that a maximum and not minimum standard of living should be aimed at, and said that a scientifically defined welfare standard creates a principle for international collaboration. He ended upon a challenging note: "Shall man's mind become the master of material needs or shall it be tossed hither and thither by surging and misdirected economic forces?"

Dr. Wilder Penfield, president of the Royal College of Physicians and Surgeons of Canada, mentioned the action of official methods and stressed the necessity of making full use of suggestions given by men of science outside the official machine. He made a strong appeal for an air-borne ambulance service, in which a beginning might well be made in the Near and Middle East, and he read a manifesto from McGill University asking that research workers should reconsider their work in relation to the urgent requirements of war.

Prof. W. G. Holford, professor of civic design in the University of Liverpool, discussed in a paper the correct use of land in the country and the opportunities and limitations of planning. Mrs. Mary Agnes Hamilton, of the London County Council, spoke as a representative of consumers, and made an appeal to men of science to help the poorer housewife do away with the drudgery associated with house-work.

The last speaker of the Friday session, Prof. A. C. G. Egerton, professor of chemical technology in the Imperial College of Science and Technology, pointed out the problems of food and power, both of which are derived from the sun's radiation, and pictured diagrammatically a scheme of human activities illustrating the interconnexions.

Saturday morning's session on "Science and World Planning" was under the chairmanship of H.E. the Soviet Ambassador, M. Maisky. He pointed out that in the U.S.S.R., a country with unified and strong administration, which has accepted the principles of planning, twenty years has been necessary to reach the present state of planning. One must not expect that the necessary requisites of world planning can be crowded into a day or two. M. Maisky said that Soviet men of science were unable to attend the Conference owing to difficulties of communication, and their speeches that were to have been relayed by radio had been jammed by German interference. He read a message from the U.S.S.R. Academy of Sciences in which Soviet men of science expressed their solidarity with their colleagues in allied countries in their combined effort to achieve final victory over barbarity and tyranny.

A message from General Smuts sent by radio and reproduced by gramophone was also heard by the Conference. "Science", said the voice from the other hemisphere, "is the greatest torch which the spirit of man has kindled in the modern world, and nothing—not even in the dark hour of our civilization—should be allowed to interrupt its kindly light. With our victory, science will not merely be reinstated to her honoured status, but a new era will open for her. Our aim is not only more knowledge and ever-new discovery of truth, but also the promotion of social welfare and the building of a great society of free people."

The session began with a paper by Lord Hailey discussing the colonial problems of the British Empire. He showed how the changed conception of the function of the State, namely, its intention to deal with the welfare of the individual, is bound to have a beneficial repercussion upon colonial policy. From his wide experience in Africa he illustrated the type of problems which have to be solved. A collaborator of Lord Hailey, Prof. G. Findlay Shirras, professor of economics in University College, Exeter, directed attention to some of the problems confronting India, with its large and ever-increasing population.

Prof. Alvin Hansen (political economist, Harvard University, and special economic adviser, Federal Research Board) outlined the current programme of research in the United States relating to post-war reconstruction, such as soil conservation, agriculture, nutrition, urban development and international relations. "It is my conviction", he said, "that internal prosperity in my country could be very much promoted by continued economic collaboration between Great Britain and the United States of America—collaboration to pursue parallel and co-ordinated policies of internal expansion."

Prof. P. Sargant Florence, professor of commerce in the University of Birmingham, analysed the problems of distribution of industry and advocated greater dispersion of "foot-loose" industries to ensure the blending of town and country amenities and outlook.

Prof. J. Métadier brought greetings from the Free French Forces and submitted a fairly detailed plan for the creation of an international society for promoting scientific research.

Mr. D. P. Riley, of the University of Oxford, who is known for his work on X-ray crystallography, spoke as one of the younger generation of British scientific workers. He pleaded for a greater share for the younger men of science in the councils of scientific planning, in the laboratory and in the factory. He advocated setting up sub-committees of the British Association to investigate further the problems raised at the Conference; also the formation of an international committee, including workers of all grades and, if possible, the setting up of a club in London which would serve as a meeting-place for scientific men of all nationalities. The president, Sir Richard Gregory, intervened at this point and expressed his sympathy with the younger scientific investigators. He pointed out that so far as the Division for the Social and International Relations of Science of the British Association is concerned, they have taken an important part in its development. As he had mentioned earlier, in his presidential address, the Council of the Association will be asked to set up special sub-committees to consider the problems brought to the notice of the Conference.

Mr. Hugh P. Vowles, in a forceful address on "Giant Power and World Planning", compared the Soviet electrification programme with that in other countries, and concluded that only under a non-profit system is it possible to develop the power resources in a co-ordinated scientific manner.

Captain H. Barnard, of the Free French Forces, brought greetings from General de Gaulle and was warmly received by the Conference. He discussed the steps necessary to render it impossible for Germany to wage another war, and stressed the point that men of science have means of helping to prevent economic crises, which are the major source of widespread unemployment leading to such movements as Nazism.

A communication from the Right Hon. Lord Onslow dealt with the conservation of wild life and advocated the establishment of national parks. Mr. O. N. Arup discussed the elimination of waste by planning and standardization. Dr. Othmar Ziegler outlined what a rationally extended international system could do to ease social tension.

Mr. Maurice Dobb, lecturer in economics in the University of Cambridge, pointed out that the postulates of early economists no longer hold good owing to monopolist competition, and advocated socialist planning. "Unless there is a boldly conceived action by the State on an extensive scale," he declared, "we may face a post-war slump that will put 1920 and 1929 in the shade."

The fourth session of the Conference covered the field of technological advance and was reminiscent of the usual British Association gatherings. The President of Czechoslovakia, Dr. Beneš, took the chair. He recalled that the first president of his country, the late Prof. Masaryk, had been a distinguished man of science, and declared that science and technology have played a decisive part in the progress and prosperity of his country. After analysing the growth of technology and its danger when used as an instrument for nationalist and expansionist aims, he concluded: "This conference of scientists is the manifestation of the urgent and categorical needs of the free world to liberate subjugated science, to use science and technology in the post-war world for the work of real, social reconstruction. But it is also a manifestation of our definite and firm will not to permit in the future the misuse of great inventions and all kinds of technological progress for criminal and destructive purposes."

The first paper was by Prof. C. H. Desch, scientific adviser to the Iron and Steel Research Council. It covered the field of conservation of natural resources, showing that while agricultural products may be periodically renewed under rational cultivation, mineral ore deposits are not inexhaustible. Indeed, copper, tin, gold and phosphate deposits, at the present rate of production, are believed to have a life of less than a century. Commercial exploitation tends to "skim the cream", and the proposed international authority which will control the fair distribution of mineral resources will likewise have to deal with the question of conservation.

Dr. L. E. Howlett gave an account of the progress made by Canada's optical industry, greatly helped by Research Enterprises Ltd., a Government-owned company working in close co-operation with the National Research Council. Dr. G. Coumoulos (Greece) stated that Greek industry and technology have tended to be much influenced by outside considerations instead of developing organically from the needs of the country.

Mr. A. J. Couzens presented a paper, prepared by himself and Mr. M. Yarsley, upon the uses and advantages of plastics. He stated that the War has given a powerful impetus to the plastics industry and that plastic material can be developed to meet specific needs.

A French man of science—who desired to remain

anonymous—attempted a mathematical analysis of technological progress. The development of aviation and other technical developments may be represented by an exponential law; that is, such factors as the amount of goods and passengers carried, if plotted with their logarithm against time, give a straight line (law of organic growth). The same speaker suggested that there should be organized a special team of research workers whose duty would be to foresee the problems likely to arise from new technological development, or from present trends solve them before they become acute. For example, the problem of new sources of energy must be solved before the reserves of fuel are exhausted.

Dr. C. H. Waddington, of the Strangeways Laboratory, Cambridge, predicted, among the likely technical advances in biology, more extended technique of vernalization, utilization of hybrid vigour, and the production of entirely novel crop plants by means of such drugs as colchicine. Animal productivity will be increased by artificial insemination, and the hormonal control of sex development may well play a part in the poultry and perhaps the dairy industries.

The next paper to be presented was by a group of three Czechoslovak investigators, Drs. G. Lewi, R. Eisler and J. Cisar, and dealt with the technology of insufficiently utilized raw materials or waste products. This was followed by an outline of the technical advance in the building industry by Mr. R. Fitzmaurice, principal scientific officer to the Building Research Station, and by a communication from Dr. J. H. de Boer on the need for closer collaboration between universities and industrial research laboratories.

A rather different note was struck by Dr. J. E. D. Swann of the Association of Scientific Workers in a paper on the "Organization of Science for War Production". In an incisive manner the speaker criticized the inefficient utilization of scientific workers in the war effort and the insufficient exchange of information between different manufacturing concerns.

Prof. Enrico Volterra returned to the purely technological aspect with a paper on some recent applications of the theory of elastic dislocations in civil engineering, and finally Mr. Ritchie Calder wound up the afternoon's proceedings by pointing out that a definite picture of a "second industrial revolution" resulted from the many papers presented to the Conference.

"Science and Post-War Relief" was the theme of the fifth session, under the chairmanship of H.E. the Chinese Ambassador, Dr. Wellington Koo. "The trying experience of relief workers at the end of the last world conflagration", Dr. Koo said, "shows clearly that rationalization and co-ordination through the use of scientific methods are necessary to the accomplishment of efficient results free from delay and waste." Like the chairmen of previous sessions, Dr. Koo emphasized that only a successful issue to the present struggle will enable scientific people to build according to their plans a new edifice of world order.

Mr. Philip Noel Baker, M.P., formerly professor of international affairs in the University of London, suggested that Governments should agree to strive towards an international food standard on the lines set out by Sir John Orr, and outlined the relief work done after the War of 1914–18 by the Nansen organizations and other bodies connected with the League of Nations.

Mr. R. Allen, of the American Red Cross, gave some of his recent experiences of relief work in Unoccupied France, and stated that a reservoir of medical supplies is being accumulated at Geneva and elsewhere to be used in case of epidemics. Prof. J. Löwy, of the University of Prague, mentioned the curative resources of Europe—sea and mountain air, climatic factors and medicinal springs—which should be made more generally available, and suggested that a special body should investigate this subject. Dr. Kuo Zing-Yang expressed the desire of Chinese men of science to collaborate in solving post-war problems, and pleaded that China should be granted full partnership and not be treated from the point of view of diplomatic expediency.

Mr. W. L. Kelly, of the International Institute of Wool, speaking as an Australian farmer, asked that measures should be taken now towards the storage of foods in such countries as Australia. Mme. Priestman-Breal, of the Friends Relief Mission, gave an excellent address on the psychological approach of relief work, based upon her experience in Poland after the War of 1914–18.

Sir John Russell, director of the Rothamsted Experimental Station, whose original theme was to have been the "Impact of Science on Agriculture", substituted instead a talk on "Restoring the Scorched Earth". He appealed to the competent authorities in the United States and Canada to ensure that the numerous varieties of crops specially suited to their different regions, which have been produced by Russian plant breeders, should be given a temporary home under suitable conditions.

Dr. Anni Noll, of the Pioneer Health Centre, Peckham, London, gave some of the findings from that unique experiment in the promotion of healthy surroundings for the family as a unit. Dr. E. Kodicek, lecturer in psychology in the University of Prague, advocated an efficient organization of scientific experts and politicians. Dr.

Eugen Wallach, formerly manager of the Hirsch-Kupfer Gesellschaft, discussed the post-war control of metal resources and the human aspects of industrial reconstruction. Mr. H. G. Norman, chairman of the British Federation of Social Workers, stated that in the new post-war world, human emotional needs must have a place, and trained social observers, experienced in the art of human understanding and social healing, will be needed. The session ended with an address by Mr. Hugh H. Smith, of the Rockefeller Health Foundation, on the role of epidemiology in the post-war world.

The last session of the Conference was devoted to "Science and the World Mind". The chairman, Mr. H. G. Wells, confronted with a much too limited time to do justice to the subject, arranged for his address to be duplicated and distributed; he requested the speakers to comment on several definite points, a federal world language, the problem of spelling and phonetics, the meaning of words and the storage and distribution of ideas. Unfortunately, Mr. Wells's suggestions did not reach the various contributors in time, and while some made a commendable attempt to rewrite their papers or adapt them to the chairman's suggestions, the majority spoke on their prepared subjects.

Prof. L. Hogben, professor of zoology in the University of Birmingham, had originally prepared a paper on education for government. In a brilliant improvisation he sketched the history of the idea of auxiliary international language, towards which some four hundred attempts have been made from the seventeenth century onwards.

Mr. J. G. Crowther, of the British Council, dealt with education of the public, and Prof. Max Born, professor of natural philosophy in the University of Edinburgh, with the teaching of science. "The human race", Prof. Born said, "is slowly awakening from a dream mind into a state of clearer consciousness." Dr. J. Needham, reader in biochemistry in the University of Cambridge, developed the theme that a principle of increasing organization is discernible in living beings and culminating in social organization counter to the principle of degradation of energy to a dead level.

Mr. J. A. Lauwerys, of the University of London Institute of Education, under the title the "Scientific Content of General Education", presented the views of a group the members of which are concerned with the training of science teachers "Mere giving more time to science is not enough," he said; "the scientific method and the scientific attitude must be fostered and the material must be chosen from a wider field and treated in a modern manner."

Mrs. S. Neville-Rolfe, of the British Social Hygiene Council, in a well-delivered address, advocated an institute of social biology and stressed the need for a wider understanding of the emotional nature and the requirements of man. The causes of war, she stated, lie in the lack of ability, character and emotional development of man himself. A true democracy can only be created by the emotional and intellectual development inspired with a positive purpose in life. Youth can appreciate the opportunity and accept the responsibility of mustering the forces of evolution and directing them to the development of man.

Prof. Skalinska, of the University of Cracow, spoke on behalf of the Polish men of science, men and women who had to find refuge in other lands, and Count Zamoyski assured the Conference that no man-made creeds will in future obstruct the relations between Poland and the U.S.S.R.

Prof. Julian Huxley, like some of those who had preceded him, did not speak on his prepared subject, "The Scientific View of Education as a Social Function", but undertook the difficult task of summarizing the main points that had emerged during the proceedings of the Conference.

The meeting was then taken over by the president, Sir Richard Gregory, who repeated the promise that committees would be appointed by the Council of the British Association to prepare considered reports upon several main points that had been raised. He then presented the Charter of Scientific Fellowship (see p. 393), a concrete proof of the new spirit which the Division for the Social and International Relations of Science has been formed to foster.

Thus ended a memorable Conference, leaving a mixed impression of light and shade, of brilliant flashes of intellect and dark patches of unco-ordinated effort. Unfortunately, in practically every session the time allowed to the speakers became progressively shorter towards the end of the meeting, irrespective of the nature and the importance of the subject-matter. There was much lack of unity and proper relationship in the too numerous papers, insufficient drive towards results to be achieved, and lack of clear vision of the potentialities of the situation. Some would claim that the Conference was nothing but a sterile hybrid between the free-platform attitude of previous British Association meetings on one hand, and the purposeful drive which inspires many younger scientific workers on the other. Others hold that in spite of all imperfections, one can discern in these deliberations the amœbic beginning of a world mind, as yet halting and incoherent, but full of promise for the future.

THE COMMONWEALTH OF SCIENCE*

INTELLECTUAL freedom is an essential condition of progressive human development. Throughout the ages, individual scientific workers have been forced to fight and to suffer in order that life and intellect may be preserved from the effects of unreasoning prejudice, stagnation and repression. To-day they feel compelled to proclaim their special responsibility in the struggle against any subjection which would lead to the betrayal of intellectual liberty.

The war now devastating our world involves an age-old conflict of ideas. Liberal minds of the last generation were convinced that the battle for independence of thought and free expression of opinion was finally won; yet once again this conviction is being violently assailed. The fight to maintain it must perforce be resumed, for the danger of losing the heritage of freedom seems graver than ever before.

During the past third of a century, changes in the conditions of life have come about, more profound than any in human history. Distance has been virtually abolished; cognizance of events has become simultaneous throughout the world; all men have become neighbours. Fresh discoveries open up undreamed-of potentialities for good or for evil, but their proper use demands correspondingly high ethical standards.

While only a century ago the village was an almost self-sufficing unit, to-day the world is our unit. To such a disturbing change of outlook and obligations, we are not yet attuned, and we must readjust our way of living, for only by the fullest and freest adaptation of ideas to new conditions can this readjustment be achieved. Intense mental effort and clear vision are now needed.

In the past, freedom for the written and spoken word was desirable; to-day, complete freedom of thought and interchange of knowledge and opinion are supreme necessities. Full freedom of expression is the very essence of science as well as democracy: where thought is enslaved science, like democracy, withers and decays. Men of science must, therefore, declare clearly and emphatically the principles which underlie their beliefs and guide their conduct.

Accordingly, the principles of the fellowship of science are here affirmed; and it is maintained that any policy or power which deprives men or nations of their free practice convicts its agents of an iniquity against the human race.

Declaration of Scientific Principles

1. Liberty to learn, opportunity to teach and power to understand are necessary for the extension of knowledge, and we, as men of science, maintain that they cannot be sacrificed without degradation to human life.

2. Communities depend for their existence, their survival and advancement, on knowledge of themselves and of the properties of things in the world around them.

3. All nations and all classes of society have contributed to the knowledge and utilization of natural resources, and to the understanding of the influence they exercise on human development.

4. The basic principles of science rely on independence combined with co-operation, and are influenced by the progressive needs of humanity.

5. Men of science are among the trustees of each generation's inheritance of natural knowledge. They are bound, therefore, to foster and increase that heritage by faithful guardianship and service to high ideals.

6. All groups of scientific workers are united in the fellowship of the Commonwealth of Science, which has the world for its province and the discovery of truth as its highest aim.

7. The pursuit of scientific inquiry demands complete intellectual freedom and unrestricted international exchange of knowledge; and it can only flourish through the unfettered development of civilized life.

* The New Charter of Scientific Fellowship presented by Sir Richard Gregory, Bart, F.R.S., president of the British Association, at the end of the Conference of Science and World Order.

G. B. CAVE, CHARTERHOUSE ON MENDIP

By F. J. GODDARD AND R. A. J. PEARCE
UNIVERSITY OF BRISTOL SPELÆOLOGICAL SOCIETY

IN these modern times the opportunities for making new geographical discoveries have become very scarce, and for this reason the opening up of a large new cave system, such as G.B. cave, within twelve miles of Bristol, should be of considerable interest to the scientific world.

The range of Mendip Hills in Somersetshire extends from the upper valleys of the Frome and Brue in the east some 23 miles down to the Bristol Channel. It is generally about 6 miles in width, and its south-western face descends to low moors drained by the Axe, and other streams, to Cheddar and Wells. It is with this area that the Spelæological Society of the University of Bristol is concerned.

The Mendips consist principally of carboniferous limestone, but at its highest point, Blackdown, which rises to a height of more than 1,000 ft., the limestone and the limestone shales have been eroded, leaving a cap of Old Red Sandstone. The numerous caves to be found in this district are formed by the action of surface water penetrating the strata at the juncture of the Old Red Sandstone and the limestone.

To the south of Blackdown, the strata dip in the direction of the famous Cheddar Gorge, and on this face there lies a pitted and mine-scarred patch of ground aptly named Gruffy Field. Close by runs the Roman road which once carried Mendip lead to the coast of the Bristol Channel. A small stream runs into this field and disappears at the base of a cliff at the end of a small gorge which it has carved for itself in bygone ages. This stream and neighbouring swallow holes, or swallets, have been investigated by the Society for the past twenty years; most notable of these excavations was that by E. K. Tratman, now professor of dental surgery at King Edward VII College of Medicine, Singapore, who always believed that a large cave system lay beneath the surface at this point.

GENERAL VIEW OF THE MAIN CHAMBER OF G.B. CAVE. THE ROOF OF THIS CAVERN IS 120 FT. ABOVE THE FLOOR-LEVEL AND THE TOTAL LENGTH OF THE GORGE, OF WHICH IT IS THE LARGEST PART, IS 786 FT.

About 100 yards west of the point where the stream now penetrates the rock, there is a dry swallet where it formerly disappeared. At the instigation of F. J. Goddard, who was secretary of the Society at the time, and the co-discoverer of the cave, Dr. C. C. Barker, work was begun in this choked streamway early in 1939. Owing to the small size of the rock fissure, progress in the actual stream bed was found to be very difficult, and another shaft was sunk a few yards away, to a final depth of twenty feet. At the bottom of this hole was revealed a small crack from which

Erratic stalactites on roof of 1st grotto, G.B. cave

there issued a draught strong enough to extinguish the flame of a candle held in it; this gave us an indication that a cave system lay within reach below. However, it was found impossible to enlarge the crack in the solid rock by normal means, and we resorted to the use of a charge of explosive. This proved most effective, and after the debris had been cleared, it was found just possible to force an entry through it into a small passage.

This soon opened up into a gallery leading into a grotto of extraordinary beauty. In this grotto the calcareous formations take on an amazing variety of shapes. Both stalactites and stalagmites branch and twist into fantastic shapes for the formation of which there has as yet been advanced no satisfactory explanation. These erratics have been termed 'helictites', and there are very few caves known where they exist in such profusion as they do in all parts of G.B. Cave. It is interesting to observe that they have not been found elsewhere on Mendip, except for a few examples in a new chamber of East Twin Swallet, in Burrington Coombe, recently opened up by the Society.

The way on from this chamber is up a 10-ft. climb into another grotto rivalling the first in its fairy-like beauty. From this there leads a series of climbs and crawls 300 ft. in length which try the fortitude and tax the agility of even the most hardened caver. They end in an unpleasant water-crawl about 2 ft. high and 18 inches wide, which we have named the Devil's Elbow; emerging from the end of this, one looks down into a large boulder chamber from a height of about 15 ft. The amount of icy water rushing along this passage and over the drop prevented further exploration for some months, but in March 1940 four members were able to fix a rope over the lip and descend into the chamber.

We were delighted to find that a large rift led steeply out of this chamber down over a series of potholes to a narrow slit in the rock. Squeezing through this one by one, we found ourselves in an enormous chamber, so high that the light from our acetylene headlamps would not illuminate the roof. We followed the stream along its floor, over a mass of shattered boulders until we were halted by a drop. The chamber, or, as we have christened it, the 'Gorge', widens out at this point into a cavern about 100 ft. in width and 120 ft. high, and its roof is hung with magnificent formations, which can best be viewed from a gallery which runs high up along one wall. Lining one side of the chamber are hanging tapestries of white stalactite fully 60 ft. high, while large stalagmite bosses, many feet across, are set in the walls; in fact, it is only by using lengths of magnesium ribbon as illumination that the true magnificence of this cave can be appreciated, so huge are its dimensions.

After negotiating the drop, we found that the Gorge gradually narrowed down to end in a small sump chamber, where the stream disappeared underneath the rock in a syphon, or sump. At this point one is 480 ft. below the surface, and the total length of the Gorge is 786 ft., so that as a single continuous chamber it must be one of the largest in Great Britain.

Subsequent exploration revealed a new series of chambers and passages leading from the roof of the main chamber, some of which ascend to within 100 ft. of the surface. These chambers contain

Erratic stalactite or helictite, from 1st grotto, G.B. cave

some of the most beautiful formations of all, including some fine erratics four or five feet long, and some curious, slender, apparently windswept stalagmites.

A number of true cave pearls have also been found here, together with a large amount of so-called coral formation, making the cave unrivalled in Mendip both from the point of view of size and beauty.

Owing to its size, and the narrowness and intricacy of its upper passages, the survey and photography of the cave have not been easy. Our work has, in addition, been held up by the salvaging excavation undertaken by members of the Society on the site of our museum, the valuable contents of which were destroyed by fire during an enemy air raid on Bristol.

However, the survey has been completed, and we are now concentrating upon obtaining a comprehensive photographic record of the cave, which offers unlimited possibilities in this direction, and upon an attempt to follow the stream still farther into the heart of Mendip past where we now lose it.

ASPECTS OF MATHEMATICAL LOGIC

By Dr. Harold Jeffreys, F.R.S.

It is recorded that when a pupil asked Confucius what he would do first if he had absolute power, the Master replied "I should reform language". (The development of the theme in the text of the "Analecta" is scarcely worthy of it, but incorporations are suspected.) The history of mathematical logic since "Principia Mathematica" affords an admirable illustration. Even before that great work, the need for unambiguous definitions and for the explicit statement of even the most harmless hypotheses was a main source of inspiration; but later investigators have found that ambiguities remained. In particular, there was a confusion between a symbol and the thing designated by it, and a propositional function was sometimes a property and sometimes what Prof. Willard Van Orman Quine in his recent book, "Mathematical Logic"*, calls a "statement matrix", that is, an expression that would become a statement if it contained names in place of variables. It was hoped also, especially in Russell's popular works, that the actual existence of numbers could be demonstrated in terms of the theory of classes.

It seems to me that such an approach was bound to be unsatisfactory if the scientific use of mathematics was to be justified. For equality of number between classes has to be defined in terms of an empirical method of comparison, and an empirical hypothesis is used in the statement that two classes defined in terms of some property, found similar in one test, will be found similar in another. This hypothesis is so elementary that it has usually passed unnoticed, but if mathematics is justified only for classes satisfying certain axioms, it follows (1) that we cannot significantly speak of the number of individuals with a certain property if the number is liable to change, (2) if there are in the world no classes at all that satisfy the axioms, the whole system breaks down. The fundamental objection to this approach, from the point of view of an empirical scientist, is that we must be able to query and test any empirical statement whatever, and this cannot be done if some such statements are selected and made part of the method of analysis itself.

Later writers have mostly abandoned Russell's attempt; the best known is probably Carnap. Axioms are now regarded as abstract statements, and a clear distinction is drawn between a thing and its name. Logic reduces to stating the rules of a language and investigating what kind of statements can be made in the language. Actual demonstration of the existence of structures formally similar to those laid down in the abstract rules is left to the empirical sciences. Even where the rules are not satisfied they can still serve as a useful standard of comparison. The chief aim now is to show that the rules themselves do not lead to contradiction; ordinary language, if not supplemented by rules that have been discovered by persons still living, does lead to contradictions—some are sufficiently elementary to be given in "The Week-End Book".

It is easy to show that if two contradictory propositions are demonstrable (in the ordinary sense) in a language, then every proposition in the language is demonstrable. If we have p and $\sim p$, and we consider any other proposition q, then p entails (p or q); but $\sim p$ and (p or q) together entail q; hence p and $\sim p$ entail q. Similarly, of course, they entail $\sim q$. This result in one form or another occurs in all the modern languages of mathematical logic. Now if every proposition capable of being stated in a language could be proved both true and false, the language would be of little scientific use; and this argument shows that a useful language must contain no contra-

* Mathematical Logic. By Prof. Willard Van Orman Quine. Pp. xiii+348. (New York: W. W. Norton and Co. Inc.; London: George Allen and Unwin, Ltd., 1940.) 21s. net.

dictions at all. But it also follows that if we can find a proposition in the language that cannot be proved in the language, then the language is consistent. It is not easy to find such propositions; to prove that a proposition cannot be proved is a very different matter from merely failing to prove it. Carnap, however, produces one. But it might happen that every proposition could be proved true or false in the language without any being provable to be both. It has been proved, however, by Gödel that any consistent language that includes arithmetic contains a statement that can be neither proved nor disproved. In his present book, Quine gives a proof that such a statement exists in his system even before arithmetic has been constructed. This is towards the end of the book, and the argument is difficult. But as a result of this type of work we have now much stronger reason than we had for asserting the consistency of logic and mathematics, and we also know that they can never be complete: we can never lay down formal rules that will enable us to decide whether any statement expressible in the language is true. Twenty years ago we might have had doubts about consistency but thought that somehow every proposition could be either proved or disproved, possibly both.

Quine has introduced a novel feature in the treatment of the theory of types, which is much simpler than in Russell and Whitehead's analysis. In the latter the famous contradiction about whether the class of all classes that are not members of themselves is a member of itself or not is resolved by including in the logic of classes a rule that the statement that a class is a member of itself is neither true nor false, but simply meaningless. This led to much complication, because, for example, a real number was defined as a class of rational numbers, and therefore no rational number could be a real number; the real numbers that we ordinarily regard as rational fractions belong to a different type. Quine finds that he can manage with a less drastic criterion. He still finds that certain classes need special treatment, but that he can give a formal rule for recognizing them by inspection of their definitions, and that it is not necessary to deny the meaning of such a class; but it cannot be a member of another class. He is thus able to introduce a universal class V consisting of all things that can be members. This would be impossible in the "Principia" analysis, since no class could include members belonging to different types. We can apparently say now, if we want to, that $0{\cdot}5000\ldots$ is the same thing as $\frac{1}{2}$ and not something different in kind.

Quine's criterion for the recognition of anomalous classes might be compared with the epistemological considerations given in a recent paper by Bridgman. I think that closer inspection would show that the process of constructing them could never be carried out because no consistent order could be given for carrying out the steps. Carnap and Quine both exclude epistemological considerations from their analysis, but I think that without them they lose a valuable source of suggestions, and one that the empirical sciences cannot possibly dispense with.

I would have liked to see some reference to the difficulty in formal expression of logic propounded by Lewis Carroll in "What the Tortoise said to Achilles". The point is that if we know p and (p implies q) we can infer q and proceed to assert q by itself; this is an essential principle of inference. But if we try to state it symbolically and use it, we simply build up longer and longer expressions and never reach a stage where we actually say 'q'. We can *see* what the rule means and act on it, but we cannot state it formally. This is recognized in "Principia". But some of the modern systems try to avoid the notion of meaning altogether and to speak only of symbols as actual specimens of printers' ink, giving rules for substitution of one type of expression for another. We can see what this means, and carry out the various cancellings permitted by the rules. But it seems to me that if the notion of meaning is eliminated, Lewis Carroll's difficulty is reinstated, and the process will only build up longer expressions and never enable a theorem to be asserted by itself. I think that Quine's system retains enough of the notion of meaning to permit an answer to it, but it should be made explicit.

I have been particularly interested in these recent developments because I have been trying to do for induction what Carnap and Quine seem to have done (in different ways) for deduction: to construct a self-consistent formal theory that will enable statements of certain types to be expressed, but such that the theory by itself says nothing about the truth or probability respectively of any empirical proposition. "Principia" assumed some empirical laws, and so, I think, do the 'printers' ink' theories. But for Carnap and Quine logic and mathematics are languages and their study is the analysis of those languages. This is analogous to the only satisfactory interpretation that I can find of the use of numbers to express probabilities; that it is the choice of a language to give more compact and less ambiguous expression than ordinary language can. If this is true in probability theory, it must be true of pure mathematics, which deals with the extreme cases of probability. There are advantages as well as disadvantages when workers follow totally different routes, and nevertheless arrive so near the same destination.

THE INTERNATIONAL EDUCATION BOARD

By R. WEATHERALL,
ETON COLLEGE

THE International Education Board was set up in 1923. The idea behind it was to help to make good some of the ravages of the War of 1914–18. The money, which amounted in all to nearly twenty-eight million dollars, was provided by John D. Rockefeller, jun., who with characteristic modesty imposed no conditions on the manner in which it should be spent, except that it should be used for "the promotion and advancement of education throughout the world.*" The inspiration with regard to the policy which should be followed came almost entirely from the late Dr. Wickliffe Rose, under whose guidance the Board has achieved something which for its breadth and diversity must be unique in the technical progress of the world.

What is education ? In Rose's mind it became for the most part, not the dissemination of certain accepted ideas and cultural patterns, for that he felt might well be left to the various national Governments, but the desire to forward the understanding of the natural world by the best possible means. The claims of educational training, particularly training for agriculture, were not overlooked, but they played a subsidiary part in the comprehensive scheme which he put forward for the support of the best research institutions and the most promising scientific workers, whose work was being held up for lack of funds. His primary object was to add to the total stock of human knowledge, and his scheme he looked upon as "tactics in the campaign against human ignorance." No considerations of national prestige were allowed to stand in the way, and except for agriculture, no attempt was made to strike a balance between the competing claims of the different branches of science, for in Rose's view, "all knowledge is inter-related, and if we help in any one field we help in all the others." So it came about that the greatest scene of the Board's activities lay in Europe, including the British Isles ; but a small number of individual projects in the United States received some of the largest grants, while smaller ones found their way to such places as South Africa, China, the Philippines and New Zealand.

In all, "fifty-seven universities, research centres, and other institutions were provided with new buildings, equipment, endowment and other material aids ; and 603 individuals, chosen for their promise of future usefulness, were assisted in their higher education, given opportunity to study under world authorities in their chosen fields, introduced to new pastures of research under conditions which at the time seemed favourable to their development. Through grants for these various purposes, thirty-nine countries, representing Europe, Africa, Asia, Australasia, and the Americas, were aided."

A visit of Dr. Rose to Europe in 1923 initiated a scheme under which the whole world, but particularly war-worn Europe, was scoured for young scientific workers showing exceptional promise, whose studies were held up through lack of means. After careful scrutiny these were granted travelling fellowships for a year, which enabled them to profit by the best scientific experience available in the world in their own particular line. Within the five years, 1923–28, an exchange of workers and of scientific ideas took place on an unprecedented scale.

But this scheme of fellowships in science would have been held up by the cramped facilities existing in many of the leading research institutions. Realizing this, the International Education Board made available large sums to be spent upon buildings, equipment and endowment. One of the first institutions to benefit in this way was the Institute of Theoretical Physics at Copenhagen, under Niels Bohr. There facilities for research and for teaching were greatly augmented. Grants from the Board also made it possible to provide new accommodation for the Institute of Physical Chemistry at Copenhagen, where J. N. Brönsted had won international fame, and had attracted many students from foreign lands.

The University of Göttingen received very material help. Its pre-eminence lay in the spheres of physics, mathematics and mathematical physics. In 1926 assistance from the Board led to the enlargement of the Physical Institute, and enabled a large number of visiting students to work under the distinguished leadership of James Franck, Max Born, and Robert Pohl. The same year also saw a considerable sum going to build and equip a new Mathematical Institute, which provided far better facilities for the work and teaching of such distinguished mathematicians as Hilbert, Hermann Weyl, Richard Courant, Landau, Herglotz, Felix Bernstein, Paul Bernays, Otto Neugebaur, and

* Education on an International Scale : a History of the International Education Board, 1923–1938. By George W. Gray. Pp. xiii+114. (New York: Harcourt, Brace and Co., Inc., 1941.) 2 dollars.

Emmy Noether. Thanks to the International Education Board, Göttingen became truly pre-eminent in its own particular field.

Proceeding along the same lines the Board came to the aid of the laboratory for low-temperature research under Kamerlingh Onnes, at Leyden, and supplied much-needed equipment with which The Svedberg of the University of Uppsala might pursue his investigations into protein structure. In Paris the Board founded and endowed a professorship in mathematical physics, and allotted further sums for the erection and upkeep of the Institut Henri Poincaré. One small donation, with pleasant associations, amounting to five hundred dollars a year, for a short period provided Einstein with the services of an assistant in making a fresh approach to the mathematics of the quantum theory.

In Stockholm grants from the Board completed the sums necessary for the erection of a Biological Institute. These grants were forthcoming chiefly because of the distinguished contributions which von Euler had made to the chemistry of fermentation. The Board also made itself mainly responsible for the finance of the new Institute of Cosmical Physics at Tromsö, for the Institute of Physics and Chemistry at Madrid, and for the new research outpost of the Jungfrau High Altitude Institute on the Sphinx, the rocky spur adjoining the Jungfraujoch in Switzerland. Much attracted by the zeal and energy of Prof. José Castillejo, Dr. Rose placed great hopes on the new Institute in Madrid. Smaller subventions went to the Universities of Utrecht, Vienna and Warsaw.

In the field of astronomy a comparatively small sum financed the preparation of a bibliography of books, papers and other publications in all languages referring to the minor planets. A considerably larger grant was made to Harvard University to be spent in moving the southern astronomical station from Peru to Mazelspoort, near Bloemfontein in South Africa, and for improving its equipment. There the 60-inch Rockefeller reflector was erected, and as a consequence, the surveying of the southern stellar hemisphere, and in particular of the outer galactic systems, has been considerably extended, to the tune of about five thousand photographic plates each year now pouring into Harvard from South Africa.

But perhaps the one project which will endure as the most symbolical monument to the policy and achievements of the International Education Board is the 200-inch telescope on Mount Palomar. This project required boldness in its conception, it needed very careful preliminary survey work, it depended upon the solution of many intricate problems in applied physics, and it could be carried through only with the expectation that large sums would be forthcoming to bring it to completion. Six hundred thousand dollars, for example, were spent on experiments with fused quartz for the mirror before the decision was reached to use a special form of Pyrex glass. As a result of careful estimates the International Education Board decided in 1928 to set aside six million dollars for the whole project, including the necessary housing and site, as well as the astrophysical laboratory and shops at Pasadena. Of this sum a balance of four hundred thousand dollars remained unspent at the beginning of 1941 to meet the final expenses of construction and installation: fine testimony to those who drew up the original plans.

The biological sciences were not neglected. At the same meeting at which it was decided to finance the 200-inch telescope, a large-scale building programme was agreed upon to bring all the scattered and greatly overcrowded faculties in botany, zoology and general physiology at Harvard University into one single Department of Biology. Not only were material facilities greatly increased and given new dignity, but the co-ordination of these allied branches of biological science promises to have far-reaching results. Mainly at August Krogh's instigation, something similar had been achieved some years earlier at Copenhagen, where grants from the Board assisted in the foundation of an Institute of Physiology to serve for the study of physiology, biochemistry, and biophysics. Thus Copenhagen received assistance from the Board for three separate institutes, each world famous.

Edinburgh was the recipient of generous donations from the Board for its Department of Research in Animal Breeding under F. A. E. Crew; and for housing and equipping the Zoological Laboratories on a new site. The Jardin des Plantes in Paris was given a grant for the rehousing of its priceless herbarium. Assistance was given to the Marine Biological Station at Naples to get it going again after the disturbances of the War of 1914–18, and smaller donations went to the Marine Biological Station at Plymouth, the Botanical Conservatory of Geneva, the French Society of Biology at Paris, the University of Utrecht and the University of Cracow.

Even the claims of scientific publications were not overlooked. A grant was made to the University Foundation in Belgium to help in making good the losses in books and periodicals suffered in the War of 1914–18. Funds were also made available to nurse a number of technical journals in Italy through the critical post-war years. A grant to the International Bureau of Weights and Measures provided an important new measuring instrument, a set of reference books, and a much-

needed addition to its overcrowded building. Similar grants assisted in the publication of two volumes of the Annual Tables for the International Committee of Annual Tables of Constants and Numerical Data in Paris, and for a set of International Critical Tables for the National Research Council in the United States.

In agriculture alone was any attempt made to finance broad experiments in education. Based upon what had already been achieved in the United States, the first of these projects to be set going was a scheme of rural clubs in Denmark. This included farm clubs for boys, and similar ones in gardening and domestic economy for girls and women. Within a short time requests were received to establish schemes in Sweden and Finland. Help was also forthcoming for the Village Association in Hungary, and for the Fram-Kursus Institute in Oslo, which provides correspondence courses in forestry and agriculture. But in the sphere of agriculture a far wider range was achieved through the system of travelling professorships and agricultural fellowships. These together covered thirty-nine countries, and five States in the United States, ranging as far away as China and New Zealand. Some of these fellowships were arranged on an exchange basis, with most happy results.

The University of Cambridge received most generous treatment from the Board. Preliminary plans to finance a Department of Entomology were expanded to cover the extension, rebuilding, equipment and support of laboratories for agriculture, and the associated sciences of botany, physiology and zoology, in a co-ordinated scheme. To round off its benefactions to Cambridge, which in all totalled nearly three million dollars, the Board gave a handsome donation to the new University Library.

One promising development was the sponsoring of a co-operative undertaking between Cornell University and the University of Nanking. Cornell agreed to assign each year one of its professors in the Department of Plant-Breeding to spend several months at Nanking, and the International Education Board met all expenses not otherwise provided for. This arrangement came to an end in 1931, by which time trained Chinese workers were available, and the idea of scientific crop improvement had spread to other parts of China.

Other donations for agricultural purposes included sums to enable the International Institute of Agriculture in Rome to carry through the world census of crops and livestock in 1930, and to extend its library facilities. A small donation made it possible for J. O. Veatch to make a detailed demonstration soil survey of a certain part of Scotland. Assistance was also forthcoming for agricultural institutes in Poland, Hungary, and Austria; for the Agricultural College at Hohenheim in Germany; for the Willie Commelin Scholten Laboratory at Baarn, Holland; for the Central Institute of Agricultural Research at Stockholm; for the Institute of Agronomical Research at Paris; and for Rothamsted Experimental Station at Harpenden. A grant to the University of Sofia completed the sums necessary for the erection of a College of Agriculture, which at the beginning of the present War was the "most competent and active outpost of scientific agriculture in the Balkan States."

The humanities were not forgotten, but the policy here was to make large grants to three selected institutions. One of these grants went to the American Academy in Rome, and was used for extensions, for increasing the number of fellowships, and for the permanent endowment of its library. Another made it possible for the American School of Classical Studies in Athens greatly to extend its work, and to excavate the ruins of the ancient Athenian Agora, which has now yielded priceless archæological finds. The largest grant of all rounded off the pioneering work of Dr. J. H. Breasted by providing a truly magnificent building for the Oriental Institute at the University of Chicago: an institute which has become the centre for Oriental studies in the United States, and has set before itself a stupendous programme in archæological investigations.

In the sphere of education as commonly understood generous support from the International Education Board led to the foundation of the International Institute for Foreign Students working at Teachers College, Columbia University. This Institute has been much concerned with the psychology and culture of foreign peoples of non-European civilizations. It has been of great value in developing a new educational outlook in different parts of the world, to which places students have been able to carry back first-hand experience of Western civilization. A timely donation from the Board helped to bring about the re-organization of Negro education at Atlanta University, with better provision for graduate and professional training. Other grants were made to the Phelps Stokes Fund for educational survey work in British West Africa, and to enable African educationists to visit the United States. Support was also given to educational activities in Liberia, including the foundation of the Booker Washington Agricultural and Industrial Institute at Kakata, modelled on the Tuskegee plan of practical education.

Twenty-eight million dollars is a large sum of money. It is small compared with the amounts

available for spending week by week, whether for war or for peace, in the leading countries of the world. The bare summary of what the International Education Board was able to achieve is fine testimony to the vision and understanding of those who were responsible for devising its policy and carrying it out. With them men counted for more than things, but they realized that even preeminent men cannot work without things, of which they deserve the best that are obtainable.

Now, some of the work of the Board is already in ruins. Buildings have been demolished, men of science driven from their homes, prohibited from pursuing their investigations, and some even put to death. In ever-widening circles across the world, all that the International Education Board stood for is in a state of dissolution and suspense, borne down by the forces of nationalism and ignorance which it strove to eliminate. As men of science we may reflect that even that is a natural phenomenon. Reaction and war have come upon us because we have not yet learned to understand and control those mass movements of mankind which are called national policies.

In drawing up his plans Dr. Rose paid next to no attention to the social sciences. That in its way was characteristic of the period and country in which he lived and worked. His feeling was that in these sciences no clear principles are to be found. The principles may still be wanting. Their lack is the measure of how much is waiting to be done ; for it is useless to go on piling up technical information if knowledge of man himself lags so far behind. We may question the economics which rendered so much scientific progress dependent on the fortune of one man, while realizing that without his aid technical science would have made less rapid strides. When the clouds of war lift again, let us hope that still larger endowments will be forthcoming for the progress of knowledge, the fount of all education, and that they will be used to make the threat of war remote, not by force but by international understanding directed to the good of all mankind.

OBITUARIES

Eng.-Captain J. Fraser Shaw

Eng.-Captain J. Fraser Shaw, of the Fuel Research Station, Greenwich, died at his home at Chislehurst on July 23.

As an engineer in the Navy he specialized in the burning of fuel and he took part in the organization of the courses for naval cadets who had to qualify in engineering. Later he was responsible for courses of instruction on oil fuel and turbines. He was present at the Battle of the Falkland Islands and his record throughout the campaign was a brilliant one. He was mentioned in dispatches and after the Battle of the Falklands was promoted immediately to the rank of commander. It may be recorded that he was a magnificent athlete and played for his country at Rugby football, being popularly known as "Rugger Shaw".

The knowledge Shaw had gained upon the use of liquid fuels was recognized towards the end of the War of 1914–18, when he was appointed liaison officer between the Admiralty and the Ministry of Munitions (Mineral Oil Production Department). During this period of his service he obtained a wide knowledge of all processes for the production of oil from indigenous materials, and in view of this special knowledge he was seconded from the Navy to take charge of the Fuel Research Station during its erection. He continued his service until 1922 when he resigned his commission to take up the appointment of chief engineer of the Fuel Research Station and liaison officer with the Admiralty.

As chief engineer of the Fuel Research Station he was responsible for the organization of most of the programmes, and in particular all investigations which were carried out on a large scale. He was interested in the scientific and technical aspects of the carbonization programme, and especially processes for the production of oil by low-temperature carbonization and hydrogenation. In association with Dr. King he read a paper before the Institution of Gas Engineers and received the Gold Medal of the Institution. A year later he described in a Fuel Research Technical Paper the details of the low-temperature carbonization plant which had been designed and erected at the Station and for which he had been largely responsible. His long experience in the burning of oil in the Navy gave him a special interest in methods of heat transfer and in particular the burning of coal in a pulverized form. In order to realize the essence of his work it may be noted that some of the experimental plants at the Fuel Research Station are on such a scale that the results may be applied directly in industry, and it was the object of the organization to translate the observations made in the laboratory into plant which could be operated in industry. He possessed in a remarkable degree a capacity for improvising plants on an intermediate scale by which the inherent features of a process could be investigated in the first place on this scale before proceeding to the erection of a large-scale unit.

Shaw was a most enthusiastic and kindly leader and he brought together the industrial men who had to operate the large-scale units and the directing staff into the harmony which is necessary when laboratory observations have to be translated on to a large scale. His name will not be found on the title-page of many of the publications of the Fuel

Research Organisation because he wished his assistants to receive the maximum credit. It remains, however, to say that every investigator had been helped to the full by his wise and able guidance.

F. S. SINNATT.

Mr. L. A. Boodle

THE death of Mr. Leonard Alfred Boodle, formerly assistant keeper of the Jodrell Laboratory, Royal Botanic Gardens, Kew, on August 22, has removed from our midst a very learned botanist and a most conscientious and devoted public servant.

Boodle started his botanical career at the Royal College of Science, and after taking his A.R.C.S. he was for seven years demonstrator at the College under the late Dr. D. H. Scott. Soon after Dr. Scott went to Kew as honorary keeper of the Jodrell Laboratory, Boodle joined him as his private assistant, and it was then that Boodle's valuable work on plant anatomy commenced. Before that he visited South Africa and worked on marine algæ, with the late Mr. George Murray. The genus Boodlea was named after him.

When Dr. Scott resigned his honorary keepership of the Laboratory in 1906, Boodle was put in charge, having been appointed an assistant at Kew in 1904. He was appointed assistant keeper of the Laboratory in 1909 and retired under the age limit in May 1930.

Boodle was blessed with a splendid memory and had a remarkable knowledge of botany and botanical literature; he was a very valuable critic. Diffident of his own powers and most meticulous in all he undertook, he spared no pains in working out fully any problem presented to him, but his published work was not very large and much first-class research work he carried out, unfortunately, was never published. His papers on the vascular structure of the Pteridophyta are a worthy memorial of his careful and exact methods.

Prof. E. J. Salisbury writes: "He was a man of whose profound anatomical knowledge and surefootedness we all had the greatest respect. His extreme modesty and retiring nature led to many not appreciating to the full his great gifts."

ARTHUR W. HILL.

Dr. M. Benjamin

WE have learnt with deep regret of the death in a recent aeroplane accident of Dr. M. Benjamin, while engaged on work for which he was seconded from industry to the Ministry of Supply. He was a physicist of great promise who had begun to make his mark in pure science as well as in applications to industry.

His work in pure physics consists of a number of careful and interesting studies of electron emission from various types of surfaces. The earliest (Benjamin and Rooksby, *Phil. Mag.*, 15, 810; 16, 519; 1933) cleared up in a remarkable way the peculiar features of the emission given by coatings of mixed oxides of strontium and barium. Then followed studies of the migration of barium and thorium ions over various surfaces, the resulting changes in thermionic emission being used to indicate the migration (and evaporation). Quite recently, in collaboration with Jenkins, Benjamin was engaged in the study of electron emission from metal points as a function of direction of emission and surface conditions, studies which are in course of publication by the Royal Society. The observed emission patterns were of great variety and complexity; they promise to provide new and important information for the electron theory of metals, and of the nature and properties of a metal point formed on a single crystal.

There was another side of Benjamin's life and character. He was one of those who took kindly to the practice of maintaining frequent personal contacts with the industry which, in effect, gave men such as him their chance. Although this left only part of his time and energies for his researches, it provided a fund of knowledge on recurrent but unexplained phenomena demanding inquiry. For him, however, the main urge was probably rather in the fact that, in the making of thermionic valves in thousands, the slightest misunderstanding leads to waste and delay; of these he was most impatient, and difficulties increased his activities in factory and laboratory to a fury. Nevertheless, his actual approach was always one of friendly interest, and he was as apt to learn as to teach. This attitude encouraged in all manner of people responsiveness and trust, so that his interventions were not merely accepted but were often claimed with insistence. His most recent work brought out his qualities to the full, with results which will be far-reaching.

That his colleagues in the Laboratory feel his loss to be most grievous goes without saying, but there will be many elsewhere who will miss him and will know the reasons for these feelings.

Prof. C. Bartel

NEWS has reached his friends in Britain that Prof. Casimir Bartel, the distinguished mathematician and former Polish prime minister, was recently executed by the Germans for alleged co-operation with the Russians. His death, at the age of fifty-nine, deprives Poland of a man who would have been most useful to the nation in the future reconstruction after the country's independence is restored.

Born at Lwow, Bartel received a technical education before entering the University of Munich to study mathematics. When he returned to Lwow he taught mathematics (in particular geometry) at the Polytechnic High School, becoming in turn lecturer, assistant professor, full professor, rector and finally principal of this institution of university rank.

In science, Prof. Bartel was the most eminent of contemporary Polish mathematicians. After the War of 1914–18, when Poland regained its liberty, the nation depended upon its men of science and learning to undertake its leadership, and Prof. Bartel was among those who responded to the country's call. In 1919 he accepted the post of minister for railways and communications in Prof. Paderewski's first government, and he was therefore largely

responsible for co-ordinating the three systems previously forming part of the German, Austrian and Russian systems. He resigned in 1922, but four years later became first premier and then deputy prime minister under Marshal Pilsudski. He retired from politics in 1930 and returned to Lwow to resume his scientific and academic interests.

When the Germans occupied Lwow they closed the University and Polytechnic and arrested many eminent men. The fate of Prof. Bartel gives rise to concern for the safety of the other distinguished Polish savants still in Nazi hands. G. D.

We regret to announce the following deaths:

Mr. H. S. Ball, O.B.E., principal of the School of Metalliferous Mining, Cornwall, on September 26, aged fifty-three.

Mr. R. T. Baker, formerly curator of the Technological Museum, Sydney, a well-known authority on Australian eucalypts and pines, on July 14, aged eighty-six.

Mr. D. P. Petrocochino, C.B.E., a well-known benefactor to Greek archæology, one of the founders of the Anglo-Hellenic League, recently in Athens, aged eighty.

Mr. A. H. Smith, C.B., keeper of Greek and Roman antiquities in the British Museum during 1909–25, on September 27, aged eighty.

Prof. Myron Harmon Swenk, chairman of the Department of Entomology in the University of Nebraska, aged fifty-eight.

Prof. Isaac Weinberg, an authority on the Amharic and Abyssinian languages, recently in Warsaw, aged sixty-three.

NEWS AND VIEWS

Conference on Science and World Order

Message from H.M. the King

The following message from H.M. the King was sent to the Conference on Science and World Order, held during September 26–28: "I thank you sincerely for your message on the occasion of the opening of the conference held by the Division of the British Association for Social and International Relations of Science which was so wisely established a few years ago. The social benefits which scientific research, by free practice and under right guidance, can bestow on all mankind grow ever greater. It is right that such benefits should be shared among all peoples alike. I am happy, therefore, to join with you in welcoming the many distinguished scientists from oversea and in thanking them for the free gift of their knowledge. I sincerely hope that this valuable interchange of ideas will further the lofty aims which the British Association has consistently produced since its foundation.—George R.I."

The Prime Minister's Message

The Prime Minister sent the following message to the Conference: "One of our objects in fighting this war is to maintain the right of free discussion and the interchange of ideas. In contrast to the intellectual darkness which is descending on Germany, the freedom that our scientists enjoy is a valuable weapon to us, for superiority in scientific development is a vital factor in the preparation of victory. The presence of representatives of so many different nations is striking proof of that universal desire for liberty of thought which all the power of the Gestapo will never entirely stamp out.

"It will take a long time for the civilised Powers to repair the trail of material and moral havoc which Germans leave behind them. It will require all the resources of science. But I look forward to the day when the scientists of every nation can devote all their energies to the common task, and I wish you every success in the work that you are undertaking now."

The Foreign Secretary's Statement

At a luncheon given to the delegates to the Conference by the British Council on September 25, Mr. Anthony Eden, Secretary of State for Foreign Affairs, said that there was never a more appropriate time for such a conference: the representatives of the free scientific spirit from many lands were in Great Britain—and here of their own free will. They were to discuss what kind of world will be created when Hitlerism is destroyed. In recent generations science has set free new powers for our use, and, if we so determine, for our incalculable good. But lately, in the hands of evil men, these powers have been used to destroy all that is good in order to dominate and enslave all that is humane. No one action can more clearly reveal the present German spirit than the replacement at the University of Heidelberg of the inscription, "To the living spirit", by "To the German spirit". This German spirit has made German scientists slaves of the regime, and opposed to all that science represents. That spirit must be overcome.

We have called on men of science, Mr. Eden said, in the cause for which we are fighting. We shall need them no less in the cause for which we are working in peace. The advent of the machine has brought great material gain, but it has brought its terrors also. It has brought astonishing material advantages to many, but it has led to inequalities, to much selfishness, to unfair division, and to materialism. If after the War we are to remove the fear of want as well as of war, science and statecraft must work together. "In war-time, diplomacy is the servant of strategy. In peace-time I pray that it may be the servant of science."

New Hawker 'Hurricane' Aircraft

INFORMATION recently released upon the Mark II type of this aeroplane is of a certain technical interest. It has become a general fighter in use, and, as such, has now been fitted with a new series Rolls-Royce engine with a two-speed supercharger. This gives improved speed and climb at greater altitudes, while maintaining its good performance at lower heights. The principal change is in its armament, which is now four 20-mm. cannon or twelve machine guns, in the place of the original eight machine guns. The twelve machine gun type with improved performance is intended for dealing with enemy fighters when 'in-fighting', at short range. For this a maximum deluge of bullets for a short period is needed, while the enemy machine is in range. The cannon type is better for attacking the comparatively slow-moving bomber, shipping, or ground targets. The small individual shells are more effective against this type of target when a hit is scored, and the chances of hitting are sufficiently good as the target is comparatively slow in manœuvre, and can be kept in range more easily. Cannon fire is able to destroy enemy aircraft on the ground, armoured vehicles, and even small ships, against which machine-gun fire has been found to be not very effective. In the United States the opinion is held that even larger cannon, 37-mm. type, should be used. The heavier ammunition needed means that a smaller number of shells can be carried, and that the rate of fire is slower, but it is considered that the greater and more widespread damage from the larger shell, when it does score a hit, more than compensates for this.

Wind and Tide

To the layman, the exploitation of natural resources that are now going to waste may appear a good opportunity of getting power cheaply. To the engineer the obstacles in the way of their economic application often appear well-nigh insuperable. Thus the proverbially fickle wind has rarely been regarded seriously for the generation of electricity on any appreciable scale. This is not the opinion of the Central Vermont Public Service Corporation which, according to the *Electrical Review* of August 22, is connecting to its 44-kv. system a 1,000 kw. 2·3 kv. wind-driven alternator, said to be the first of its kind. In describing the equipment *Power* states that the plant, which is installed at a height of 2,000 ft., is expected to run for about 4,000 hours in the year, nearly three-quarters of the time on full load. Possibly the most important feature of the station is its association with a wind-power research laboratory, in which fundamental and engineering knowledge can be gained for the economic design and construction of wind-driven generating units in the future. In contrast to the erratic behaviour of the wind is the exactly predictable ebb and flow of the tide, which in this respect has an advantage over waterfalls that depend upon seasonable and weather vagaries. Its punctuality is not enough, however, to compensate for its intermittent action, and so a purely tidal scheme would have to be debited with the standing charges on steam plant required for filling in the valleys.

It was estimated to be much less expensive in overall costs to provide 550,000 kw. by steam plant than to harness the River Severn for the purpose. Only by virtually changing the scheme to a more ordinary hydro-electric lay-out could power from the tide compete with coal for generating electricity; that is, by using a large proportion of the tidal energy to pump water to a reservoir for driving other turbines in the slack periods. A similar idea was behind the Passamaquoddy project for producing 80,000 kw. from the River Maine. Even then production cost has been estimated at nearly twice that obtainable with a modern steam plant. As an addendum to his report to the United States Federal Power Commission, the chief engineer, Mr. R. B. McWhorter, envisages an elaborate seventeen-project programme, of which Passamaquoddy would form a part, in which case the cost per kwh. would be substantially less than that obtainable with steam. A great handicap to the development of tidal power is the length of time involved in construction—in the case of the Severn Barrage the capital expended would be unremunerative for about fifteen years. Moreover, contingencies are less easily covered by a reasonable percentage than they are with thermal stations. The favourable margin shown by the British scheme in comparison with steam will have increased materially since the report was published eight years ago. Much would depend on the value of improved road connexions between England and South Wales with which the proposals were associated, but unless some improvement is to be anticipated in the coal position after the War, the report might well be re-examined in the light of more recent developments.

Technical Bibliographies

DURING the past ten years the staff of the Sheffield City Libraries have compiled a number of bibliographies on technical subjects of special interest to research workers and technical staffs of local firms. In the compilation of these bibliographies expert help has been enlisted where necessary, and the collaboration between trained bibliographers and technical specialists has resulted in the production of a very useful series of reference lists, each relating to one specific subject and including papers and articles from technical periodicals as well as books fully or in part concerned with the subject. The fact that all the references can be consulted in the Sheffield City Libraries is a great convenience to local students and workers, although it naturally robs the bibliographies to some extent of completeness. Perusal of typical lists shows, however, that this lack of completeness does not detract substantially from the value of the compilations, a testimony to the thoroughness with which the City Librarian has catered for the needs of local industries in his acquisition of books and periodicals.

Since the outbreak of the War this bibliographic work has found and met an increased demand; an extensive annotated bibliography on steel sheet and strip issued in three parts has been in particularly heavy request from other parts of Great Britain and from overseas. Encouraged by this demand from a wider area, the City Librarian has prepared a list of recently compiled bibliographies; the subjects at present available include: acid tanks; austenitic steels; auto-frettage process; bending, straightening and reeling of steel; bonus systems; cold drawing of steel; cold heading of steel; cold pressing: colloidal metals; colouring of metals; decarburization of metals by hydrogen; electrolytic pickling and polishing; extrusion of steel; fatigue of metals; fluorspar-froth flotation; ingots: segregation and crystallization; patents on rock drill bits; manufacture of steel tubes; polarography; riveting of steel; rolling mills; spinning of steel; steel manufacture and properties; sulphur and phosphorus determination in iron and steel; tool steels; vertical boring mills; workshop practice and machine tools (books only). Applications for copies of any of the lists should be sent, with 3*d*. to cover postage, to the Central Library, Sheffield, 1.

The Lister Institute of Preventive Medicine

THOUGH damaged on two occasions and partly evacuated, the Lister Institute of Preventive Medicine has spent an active year, as shown by its annual report. As usual, the work has covered a wide field, including studies on antigens, phosphorylation in osteoid tissue, fat metabolism, and mucolytic enzymes. The Division of Nutrition, working at Cambridge and East Malling, has continued its vitamin studies. The Cambridge group has in particular investigated the nutritive value of different portions of the wheat grain and has been instrumental in recommending the use of 85 per cent extraction flour with added calcium for bread-making; the national wheatmeal flour is of this extraction, but the decision to add calcium to it has not yet been taken. The nutritive value of yeast has also been investigated, and this work is of particular importance since it is easy to grow yeast on certain waste materials, thereby providing a human food rich in first-class protein and vitamins of the B group. Dr. Zilva, at East Malling, has continued his work on vitamin C.

The Henry Lester Institute of Medical Research

The Henry Lester Institute of Medical Research, Shanghai, has also recently issued its annual report, and this shows that all activities have had to be restricted owing to the war in China. Studies on nutrition occupy a large part of the report, and Prof. Earle, who has recently been visiting Great Britain, states that "it is remarkable how many clinical signs and symptoms among Chinese patients can now be explained in terms of vitamin and mineral deficiency". Apart from many cases of two classical deficiency diseases—beriberi and pellagra—it has recently been found that ariboflavinosis is very common among the Chinese: more than a hundred cases were investigated during the latter part of the year. Deficiency of riboflavin is the latest recruit to human deficiency diseases, and has been shown by Sebrell to be surprisingly common in the United States. The condition, which includes eye and mouth lesions, undoubtedly occurs also in Great Britain.

Winter Wheat Seed

THE Council of the National Institute of Agricultural Botany, Cambridge, has decided to offer for sale about a hundred quarters of Steadfast, a winter wheat bred by Prof. F. L. Engledow, of the Cambridge University Plant Breeding Institute. Hitherto the wheat has been grown in the Institute's trials under the number 198 (20c). Orders are invited from members of the Agricultural Seed Trade Association, National Association of Corn and Agricultural Merchants, National Association of British and Irish Millers, and other established dealers in seed corn. Steadfast is the outcome of a cross between Little Joss and Victor, and as regards general habit, growth and type of ear is intermediate between the parent varieties. It possesses the excellent tillering properties of Little Joss, and ripens at the same time, and requires the same seed rate. The straw is shorter and its resistance to lodging is superior to that of Little Joss, but it has the same resilience and excellent thatching and feeding properties of that variety. As regards milling quality, Steadfast approximates the bread-making value of the 'softer' English wheats; it does not attain the exceptional quality of Yeoman or Holdfast. It is particularly suited to light and medium soils, but also thrives on the Black Fen, where its resistance to yellow rust will be specially valuable.

A Film Studio Electrical Installation

MR. F. V. HAUSER, chief engineer of two studio groups at Denham (Uxbridge, Middlesex) and Pinewood (Iver, Bucks), comprising twelve stages with a plant capacity of 7,000 kw., recently gave an illustrated lecture about studios to the Association of Supervising Electrical Engineers in London. Confining his detailed description to the Pinewood installation, Mr. Hauser said that the maximum electric demand for studio photographic purposes approximated to 2,000 kw. As D.C. at low voltage is necessary for arc lighting, five electric diesel generators totalling 2,360 kw. have been installed with three-wire distribution at 230/115 v. for studio lighting and at 230 v. only for all other purposes. To reduce noise and vibration, the engine foundations were formed of single island rafts of concrete 2 ft. thick, set 9 ft. below floor level and covered with a 2·5 inch sandwich of 'Coresil' cork on which rested a common concrete block 7 ft. deep, the whole weighing 1,000 tons. The insulating air space around the foundation is 9 in. wide.

To minimize voltage ripple (hum) interfering with sound recording, the generators have graded air gaps, specially shaped pole faces and skewed armature

slots, so avoiding the expense of heavy smoothing choke coils in main feeders and individual arc lamp circuits. The studio switchboards (four 3,000 amp. and three 5,000 amp. panels) and distribution features include bare aluminium ring mains (19,500 ft., weighing nearly 34 tons) supported by 'Sindanyo' racks attached to the roof steelwork, descending in sheet steel conduit to distribution boards at floor level, which are equipped with audible and visible signals for the overhead distribution 'grid' attendants. The object is to keep the floor free from trailing cables and feeding points, lighting equipment being stored overhead in the grid for quick lowering. Master control is exercised within the studio from a mobile desk on castors, plug-connected by a fifty-line multiple cable.

Recent Earthquakes

THE Jesuit Seismological Association at Saint Louis, U.S.A., has determined tentatively the epicentres of three recent earthquakes. From the readings of seismograms from eight stations the earthquake of June 27 at 17h. 11m. 30s. G.M.T. was found to have an epicentre near 16° N., 93° W., which is south-west of La Concordia in southern Mexico. By the Brunner chart the depth of focus was estimated to be 200 km., which is somewhat unusually deep for the fairly frequent normal and intermediate earthquakes in this area. From the readings of seismograms from sixteen stations the earthquake of July 1, at 7h. 50m. 57s. G.M.T., was found to have an epicentre near 34·4° N., 119·5° W. Damage by this earthquake was done in and about Santa Barbara, California, and the agreement is good. From the interpretations of records from ten seismographic stations the epicentre of the earthquake of July 3, at 7h. 11m. 51s. G.M.T., was found to be near 31° S., 68·7° W. This earthquake was felt at Mendoza in the Argentine Republic.

On August 15, a strong earthquake giving a full suite of pulses was recorded at Kew Observatory. The preliminary pulses registered at 6h. 16m. 45s. G.M.T., S at 6h. 22m. 42s., M at 6h. 29m. 34s. and the earthquake finished recording at 10h. 10m. having lasted nearly four hours. The maximum ground amplitude at Kew was 82μ and from the above tentative interpretation of the record the epicentre has been estimated to have been 4,330 km. distant from Kew.

Disease in New South Wales

ACCORDING to Dr. E. Sydney Morris, director-general of public health of the State of New South Wales, the chief event in the State since 1875 has been the rapid growth of Sydney, so that though the State is about 95 per cent rural the population has become increasingly urban. In 1939 the population was 2,749,134, of whom 1,380,940 lived in the metropolitan area of Sydney. Since 1875 the mortality from tuberculosis in New South Wales has dropped steadily, whereas the cancer mortality has increased at nearly the same rate. In 1875 the tuberculosis mortality was 154 and the cancer mortality 31 per 100,000 population. In 1895 the rates were respectively 109 and 44, in 1935 they were 105 and 39, and in 1939 tuberculosis fell to 37 and cancer rose to 113. The mortality from heart disease has shown an enormous rise in recent years. In 1875 it was 79; it fell to 57 in 1893, and has since risen, at first slowly and then rapidly, to 259 in 1939. As regards infectious diseases, influenza showed a mortality of about 5 until the great epidemic of 1891, when it rose to 87: it dropped to 8 in 1893 and 5 in 1917. In 1919, it rose to 319·3, and in 1920 it fell again to 18. Since then it has shown abrupt rises and falls. In 1899, when the incidence of scarlet fever was the highest on record (48·5 per 10,000 population), the mortality from this disease (2 per 100,000) was the lowest recorded until then. The mortality from measles has shown a great reduction in the height of the peaks since 1915 and a smaller incidence in the intervening troughs.

Population of Sweden

ACCORDING to preliminary estimates of the Central Office of Statistics, the population of Sweden in 1940 was 6,370,964. Comparison with the figure at the end of 1939 shows that the population has increased by about 30,000, corresponding to 4·68 per thousand. The growth of the population was split up as follows: 1,648 in the country, where there are at present 3,990,114 inhabitants, and 27,977 in the towns, where the population is now 2,380,850. Preliminary statistics for births and deaths during the past year show the following figures: 95,457 births and 72,584 deaths, that is, a surplus of births of 22,873, of which 12,927 were in the country. Lastly, there were 6,870 immigrants and 3,186 emigrants, giving a net surplus of 3,684.

Announcements

IT has now been announced that Prof. L. G. M. Baas-Becking, who was placed in custody in a prison in Scheveningen, Holland (NATURE, May 17, p. 606), has now been released by the German authorities and has assumed again the directorship of the Botanical Institute of the University of Leyden.

THE Joint Committee for Scientific, Technical and Engineering Supervisory Staffs, of 30 Bedford Row, London, W.C.1, has arranged a meeting and exhibition of technical films chosen to show the applications of scientific and technical advances in industrial processes, to be held at the Portland Hall, Little Titchfield Street, London, on October 11 at 3 p.m.

THE library of the University of Louvain, which was damaged in the War of 1914–18 and rebuilt largely through American generosity, was again destroyed in May 1940. Of the 900,000 books only 15,000 survive, of 800 manuscripts only 15; 3,000 collections of periodicals were completely destroyed by fire, likewise 811 incunabula and 200 valuable engravings, including some by Dürer and Holbein and 22,606 photographs of all known Coptic manuscripts.

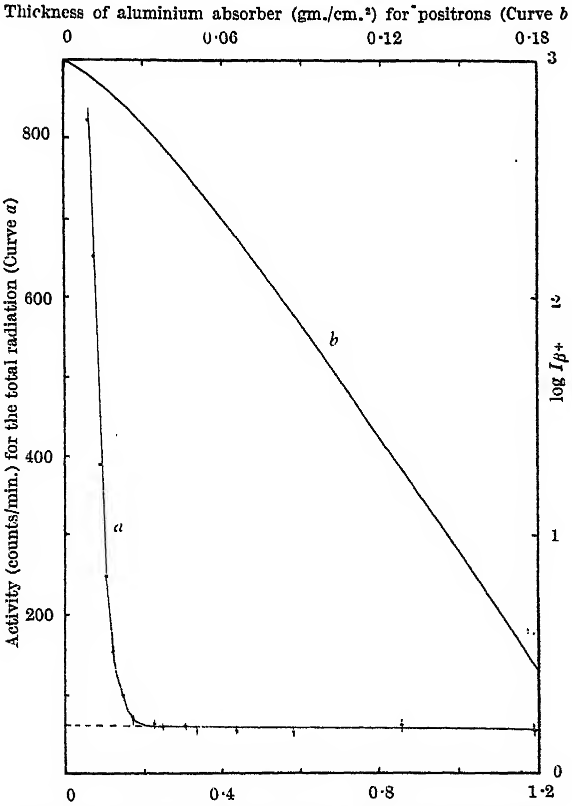
LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

Deuteron-Tritium Reaction in Fluorine

IT was shown in a recent paper[1] that the 'deuteron-tritium' (d, ^{3}H) reaction was responsible for the formation of ^{62}Cu, ^{106}Ag and ^{120}Sb by deuteron bombardment of copper, silver and antimony respectively. The same reaction is known to occur in beryllium[2] and nitrogen[3]. It therefore seemed desirable to look for other examples of this reaction. It has now been established that the (d, ^{3}H) reaction takes place in fluorine also.

Sodium fluoride was bombarded with deuterons of 9 Mev. energy and a lanthanum fluoride separation was made from the irradiated sample. The fluoride fraction showed, in addition to a short-period activity, an intense positron activity decaying with a period of 112 ± 2 minutes. The absorption curve in aluminium for the total radiation is shown in Fig. 1 (Curve a). The logarithmic absorption curve for the positrons obtained after extrapolation and subtraction of the annihilation radiation background is represented in the graph by Curve b. By comparing this curve with that for the β-rays of radium E, one obtains an absorption limit for the positron spectrum



Thickness of aluminium absorber (gm./cm.²) for the total radiation from ^{18}F (Curve a).

Fig. 1.

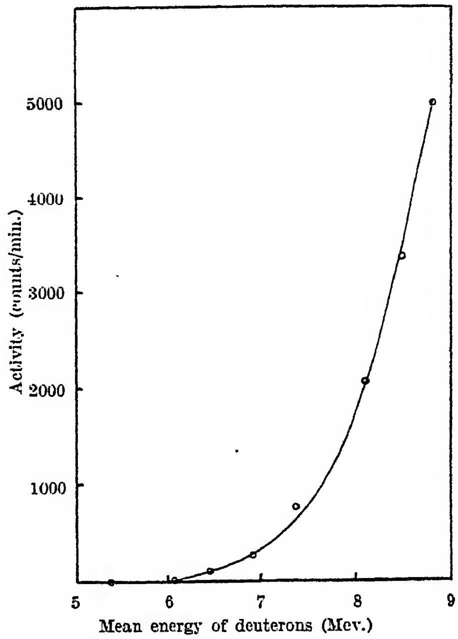


Fig. 2.

EXCITATION FUNCTION FOR THE FORMATION OF ^{18}F.

equal to $0{\cdot}23 \pm 0{\cdot}01$ gm./cm.^{2} of aluminium, corresponding to a maximum energy of $0{\cdot}72 \pm 0{\cdot}02$ Mev. Thus the properties of this radio-element are identical with those of the well-known ^{18}F [4] and should therefore be attributed to the same. ^{18}F is known to be formed from fluorine by the (n, $2n$) reaction. Control experiments which were carried out in order to establish that in the present experiments the 112-min. fluorine activity was formed directly by the action of deuterons, showed that the background neutron effect was negligible. ^{18}F is formed from fluorine under deuteron bombardment by the reaction

$$^{19}\text{F}\ (d,\ ^3\text{H})\ ^{18}\text{F}.$$

Excitation function measurements were made using the powder technique. Targets were prepared by spreading equal quantities (7 mgm.) of pure sodium fluoride as uniformly as possible over an area of 1 sq. cm. on thin copper foils. The layer of powder was fixed in position by the addition of a few drops of a solution of cine-film in amyl acetate. In each case a copper foil of 0·35 mgm./cm.^{2} thickness covered the deposit. Targets so prepared were bombarded separately with deuterons of different specified energies for five minutes each, keeping the beam steady during each run but not necessarily at the same value for all the runs. Aluminium foils were used when deuterons of less than the maximum energy were required. After bombardment, the sodium fluoride was dissolved in water and a lead

fluoride separation was made. The precipitate was washed well and dried. Correction was made for any loss of material that had taken place during chemical separation by weighing the dried precipitate. The activity of the lead fluoride precipitate was measured two hours after the end of bombardment and its subsequent decay was followed. From the family of decay curves the energy-yield curve for the 112 min. positron activity was determined and is reproduced in Fig. 2. In most cases the points plotted represent the means of three separate bombardments at a single energy. The threshold seems to lie at about 6 Mev. Assuming the known masses of ^{18}F and ^{19}F, calculations were made, and a Q value of $-3 \cdot 25$ Mev. was obtained for the (d, ^{3}H) reaction in fluorine. Because of the low probability of escape of the ^{3}H particle from the compound nucleus, no appreciable yield of ^{18}F is obtained for deuterons of energy less than 6 Mev.

The cross-section for the formation of ^{18}F from fluorine under deuteron bombardment was measured. For deuterons of energy 8·8 Mev., the value of the cross-section is $3 \cdot 9 \pm 0 \cdot 4 \times 10^{-27}$ cm.^{2}.

Dr. T. E. Banks and Mr. J. Dainty rendered me assistance in running the cyclotron.

Reproduction in Capuchin Monkeys

So little is known of the reproductive processes of any South American monkey that additional data on the typical genus Cebus are worthy of record. Capuchins seldom breed in captivity, only three records during a hundred years being given for the London Zoo by Zuckerman[1] and no further cases being mentioned in his revised report of 1937[2]. Since that date Hamlett[3] has given a detailed account of the œstrous cycle, ovulation and menstruation in Cebus, but he left many questions unanswered.

The present notes are based upon observations made on two male *C. xanthosternos* mated with three female Capuchins—two *C. vellerosus* and one *C. apella*. All three females have recently given birth to hybrid offspring.

Copulation, which Hamlett never saw, was inferred by him to occur at day-break, or some time before the arrival of laboratory staff, as it "seems unlikely that the monkeys copulate at night". With my animals copulation only occurred at night, usually at dusk. It differs in several ways from the process in Old World monkeys (a) in being very prolonged—up to twenty minutes in duration; (b) in the extraordinary vocal sounds accompanying the performance. These sounds are emitted by both participants and were echoed by an older (half-grown) baby living in the same cage. Copulation takes place *a posteriori*, but the male has long intervals of quietude during which he sits back without withdrawal, though continuing the vocalization. Restriction of copulation to certain periods of the menstrual cycle has not been noted, though this may be possible. No externally visible sign of menstruation has been observed in any of the females.

Gestation is probably of similar duration (that is, six months) to that of Old World monkeys, since one female *C. vellerosus* produced her offspring exactly seven months after first introduction to a male *C. xanthosternos*. Sexual behaviour was observed after the first three weeks.

The new-born differs from that of Old World monkeys in clinging to the mother's back, nuzzling its way round to her breast only at feeding time, thereafter returning to her back, clinging with its arms around her neck and its legs around her flanks. It does not use its tail for aiding its hold. The dorsal position is maintained from the first day.

The placenta is evidently eaten, since no sign of it was to be found within a couple of hours of birth, which occurred in one case in the day-time.

The three babies, despite their differing parentage, are all remarkably alike, and differ equally from either parent. They are all brown-bodied and black-limbed. The head pattern consists of a dark, almost black, oval central patch with a light, almost white, area on either side. The hair is long and soft on the head, not short and stiff like the father's or long and upstanding like the mother's. The body hair is lank and of the same texture as the mother's, so that the baby passes unnoticed except at close quarters.

Another curious feature is the extraordinarily rapid growth of the young compared with the tardy growth of Old World monkeys. The oldest baby was as large as its mother (*C. apella*) at the age of six months, and continued to grow after that, though it has not attained at the age of a year so great a size as its father, which belongs to a larger species.

A more complete account will be published elsewhere when circumstances permit.

Electron Energy-Levels in Biochemistry

The lecture of Szent-Györgyi, recently reported in NATURE[1], prompts us to publish some of the results we have accumulated on the electric conductivity of wool and other materials.

Dry wool shows strong polarization under an applied potential, but as its regain* is increased its conductivity increases exponentially and the polarization is gradually swamped. When its regain exceeds 6–8 per cent it appears to behave as an electronic semi-conductor: the polarization has disappeared and Ohm's law is obeyed[2], and the conductivity has a large positive temperature coefficient when the regain is kept constant. The temperature coefficient is, in fact, three times that of liquid water[3], and appears to be independent of regain above values of 6–8 per cent. When the logarithm of the conductivity is plotted against the reciprocal of the absolute temperature a straight line is obtained, and the slope

* Regain is the percentage moisture content calculated on the dry weight.

of the line corresponds to an activation energy of 1·3 electron volts. This energy is little influenced by ionic impurities, or by the electrodes used to measure the conductivity. If the water is replaced by methyl alcohol, the conductivity phenomena remain unchanged except that the activation energy is lowered to 1 electron volt.

These facts make it difficult to identify the electric conductivity of wool with ionic conductivity, whilst they do appear to fit readily with the hypothesis that the wool-water and wool-methyl alcohol systems are electronic semi-conductors; or that there are electronic energy bands in the system which are separated from the ground-levels by forbidden zones.

The conducting system seems to be the water or methyl alcohol appropriately adsorbed on a surface. This was tested by a study of the conductivity of glass surfaces. These show the same variation of conductivity with relative humidity of the surrounding atmosphere, and with temperature, that other fibres show. The activation energy is 1 electron volt, but otherwise the electric conductivity of glass surfaces appears to be the same as that of wool. The energy band system is therefore a property of suitably adsorbed water molecules. Water molecules adsorbed at interfaces must be common in biochemistry where cell wall surfaces are abundant, and it may be that electronic transfer of energy takes place along layers adsorbed at these interfaces.

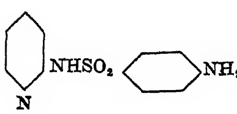
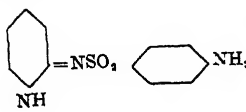
Constitution of a Sulphonamide

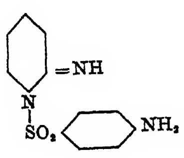
Crossley, Northey and Hultquist[1] consider that 2-(*p*-aminobenzenesulphonamido) pyridine has the constitution I below and not II or III mainly on the grounds that it is unchanged after prolonged boiling with concentrated caustic alkali solution.



I



II



III

This stability to caustic alkali[2] appears to me to be evidence against formula III and this view is supported by the synthesis of this sulphonamide from 2-halogeno pyridines and *p*-acetamido or *p*-amino benzene sulphonamides by the Ullman method[3]. The possibility, however, that this compound is a tautomeric mixture of the forms II and III must not be overlooked. Further evidence for the above view is afforded by the behaviour of 2 (*p*-aminobenzenesulphonamido)-pyridine on treatment with chloroacetamide in alkaline solution when *p*-aminobenzene sulphonyl α-pyridylglycineamide is obtained. This, on hydrolysis with caustic alkali gives *p*-aminobenzene sulphonyl α-pyridylglycine which on further treatment with hot dilute mineral acids gives the hitherto-undescribed α-pyridylglycine. This is a well-defined substance very soluble in water and sparingly soluble in alcohol; these characteristic glycine-like properties are quite different from those of the well-known isomeric compound, α-pyridoneimide-N-acetic acid obtained from α-amino-pyridine and chloracetic acid[4].

This latter compound on decarboxylation is known to give N-methyl-α-pyridoneimide; the interrupted study of the properties of α-pyridylglycine, including its de-carboxylation, will shortly be resumed.

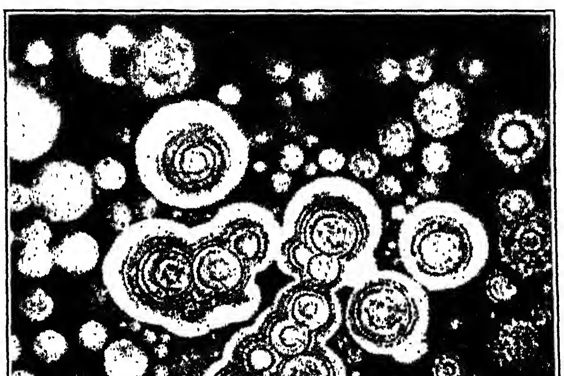
'Onion Skin' Structure of Carbonyl Iron

THE 'onion skin' structure of carbonyl iron is well known to those who are familiar with powder metallurgy technique. W. D. Jones in his book "Principles of Powder Metallurgy" states that this structure is probably due to interruptions in the decomposition of iron carbonyl vapour.

Recently while examining a pressed compact of carbonyl iron we came across a remarkably fine



× 1250

specimen of 'onion skin' structure which was revealed after the usual metallographic polishing followed by etching in 1 per cent Nital. The accompanying photograph shows the structure observed.

Measurement of Physical Fitness

IT is desirable to direct attention, once again, to the need for devising and standardizing an objective measure of physical fitness.

The advantages which would result from the employment of a method of assessing the fitness of physique independently of subjective impressions have long been recognized. Little, if any, consideration has, however, been given to the following aspects of the problems involved.

The grading of recruits to the Services in the pre-enlistment medical examination is, as is well known, to a very large extent over-determined by subjective, qualitative impressions. Cases occur in which initial grading is too high and de-grading has to take place after the soldier has spent some time in a unit for which he is unfit. Many cases occur, no doubt, in which grading is too low. Statistical considerations alone lead one to suspect that there must be great regional differences in the proportions allocated to given medical categories and in the proportion of total rejects in any area. One may suppose that some physicians, not unnaturally, lower their standards of grading in order to provide more front-line men, and the effect is to give too generous a picture of health and virility in the men whom they examine.

There are in existence techniques of assessing physical fitness which, although admittedly subject to improvement, would nevertheless almost certainly add to the validity of the current qualitative procedures and act as a check on their accuracy. Moreover, it should be possible to raise the value of the qualitative estimates by appropriately weighting the constituent elements, for example, sensory acuity, or cardiac condition, according to their regression on physical fitness as measured independently. The statistical problems are very similar to those that arise in the marking of scripts in examinations.

The time is surely ripe for a survey of fitness in the army at different age-levels. It is not unreasonable to attach a biological validity to the concept of physical fitness and to regard it as connoting the 'integrative action' of the organism as a whole, resulting from the efficient functioning of the component physiological processes, the neuro-muscular system, the endocrines, the sense organs and so forth. Apart from social and economic disturbances in selection, physical fitness so defined and measured should, in theory, approximate to a normal distribution. Indeed, the concept is analogous to the notion of general ability as measured by psychological tests. The former should be both easier to measure and possess greater validity.

Such an investigation as is here proposed would provide information on the effects of different periods and types of training upon physique. Furthermore, since the medical history of each soldier is known, much would be added to our knowledge of constitutional predisposition to disease. From the eugenic point of view alone the task is worth undertaking.

JOHN COHEN.

A Peculiarity in Rainfall Variability

A SOMEWHAT perplexing and highly interesting peculiarity in the regimen of rainfall variation is this: all over the world, there is a much greater degree of uniformity in the relative variability of annual rainfall expressed as a percentage of the normal than in the absolute variability expressed as the actual deviation from the normal in inches or millimetres. As regards Great Britain, the late Mr. Carle Salter pointed out in his "Rainfall of the British Isles" that though the percentage variability is rather greater in the dry eastern than in the wet western districts, it is of the same order of magnitude everywhere, which of course implies that the actual differences in the quantity of rain from year to year are much larger in the wet parts. In fact, the deviations in the actual amount of rain above and below normal increase so systematically with the rainfall itself that they swamp the percentage values and become quite useless in comparative statistics.

Take, for example, a plus or minus variation of only 10 per cent, which is almost equally common all over Great Britain: this signifies so large a difference as 20 inches of rain between the wetter and drier year at a place, say, in Cumberland, with an average rainfall of 100 inches, as contrasted with the trivial range of 4 inches at a place on the coast of Essex with an average of only 20 inches; whereas if Nature worked more nearly by the absolute rule than by the percentage rule, a 10 per cent variation at the drier place should be balanced by a 2 per cent variation at the wetter. Evidently, in the natural scheme a few inches more or less of rain a year which appear conspicuous at a dry place count for little at a wet place, and in dry and wet years the total rainfall is not lowered or raised by similar actual amounts everywhere but by similar proportional amounts.

The physical interpretation of the peculiarity is no doubt this: in places of heavy rainfall, any intensification or abatement of the normally acting factors is likely to produce a proportionately large effect in actual quantity of rain, which will not be the case in dry places, though in some parts of the world there are erratic dry climates where very exceptional years of abnormally heavy rainfall point to the operation of unusual factors.

In general, it is remarkable what little interest writers on rainfall statistics show in the dependence of actual variability on the rainfall itself, merely remarking on the convenience or necessity of working with percentage values, as though this dependence were axiomatic and there was nothing more to be said. The proposition, however, is not self-evident to the preclusion of physical discussion. Even V. Conrad, who in a paper published in the *Monthly Weather Review* of January, 1941, demonstrates mathematically the close relationship between absolute variability and the magnitude of the rainfall itself, does not pause to reflect why this should

be the case, but immediately goes on to show that the percentage method of studying rainfall variability which is a necessary consequence is not a perfect measure of true variability because at very low annual rainfalls below 10 inches, the percentage values change unduly rapidly with trivial differences in the rainfall itself.

The Relations between Science and Ethics

IT was an excellent idea to base a general discussion on the relations between science and ethics on Dr. Waddington's stimulating and lucid account of the subject[1]. What has been most striking about the comments which have been made on it is the failure which some of the commentators exhibit to understand his view of the nature of the evolutionary process. The persistent existence of the lowest forms of life (to which Prof. Ritchie directed attention), or the fact that parasites may achieve a high degree of adaptation to environment at the cost of profound degeneration, or the continuation of evolution (in Prof. R. A. Fisher's phrase) "in the teeth of a storm of adverse mutations", have nothing to do with the inescapable fact that, during biological evolution, the degree of complexity and organization has increased. With the appearance of man, the maker and user of tools, the speaker, the moulder of his surroundings, this process, the outward and visible sign of which has been a progressively greater independence of the organism *vis-à-vis* its environment, reached its culmination. Thinkers such as Herbert Spencer (whom some of the contributors go out of their way to attack), were perfectly correct in viewing social evolution as continuous with biological evolution. In social evolution we cannot but see a more or less continuous rise in level of organization parallel with the increasing size and complexity of human communities, culminating in the conception of the world co-operative commonwealth now dawning upon the minds of men. Though there have been backslidings innumerable, there have also been points higher than the main curve of human social evolution sweeping its way across the graph of history.

Some of the contributors seem to be still under the influence of the Darwinian preconception which saw nothing in animal life but the struggle for existence, a concept which, as Engels carefully pointed out, had been introduced from Malthus's analysis of the predatory characteristics of capitalist society. But there were others beside Spencer who showed the one-sidedness of the idea of Nature red in tooth and claw. Kropotkin pointed to the very value of animal associations in this struggle, and Henry Drummond (a much misunderstood thinker) successfully traced the beginnings of social altruism downwards to the numerous phenomena of parental care and even to the donation of part of the self for the succeeding generation in every reproductive act. Drummond even went so far as to say that the goal of evolution was love and the good life, an assertion which his biographer described as "grotesque", but which we can scarcely think so if we recognize, as we must, the highest levels of human co-operative social life as themselves the products of evolution.

This, I take it, is what Dr. Waddington means by saying that the evolutionary process itself supplies us with a criterion of the good. The good is that which contributes most to the social solidarity of organisms having the high degree of organization, which human beings do in fact have. The original sin which prevents us from living (in Prof. Joad's phrase) "as Christ enjoined" is recognizable as the remnants in us of features suitable to lower levels of social organization, anti-social now. There is, of course, the incidental difficulty of continually modifying the letter of the teaching of the great ethical 'mutants' to fit changing techniques and increasing knowledge without losing their spirit.

From this point of view, the bonds of love and comradeship in human society are analogous to the various forces which hold particles together at the low colloidal, molecular, and even sub-atomic levels of organization. Henry Drummond actually dared to say this. If such an idea is accepted, Prof. Joad's insistence that we must have some extra-natural criterion of ethical values ceases to have any point. The kind of behaviour which has furthered man's social evolution in the past can be seen very well by viewing human history; and the great ethical teachers, from Confucius onwards, have shown us, in general terms, how men may live together in harmony, employing their several talents to the general good. Perfect social order, the reign of justice and love, the *Regnum Dei* of the theologians, the Magnetic Mountain of the poets, is a long way in the future yet, but we know by now the main ethical principles which will help us to get there, and we can dimly see how these have originated during social and biological evolution. Prof. Stebbing is perplexed as to whether we ought to call evolution morally admirable or morally offensive; it is surely neither. The good is a category which does not emerge until the human level is reached.

For the benefit of Prof. Ritchie, I may add that whatever label or docket in Prof. Broad's book is attached to the views here expressed is a matter of relative indifference to me. They certainly cannot be called original. Many others have appreciated the emergence of ethical relationships and their interpretation in the light of scientific thought.

JOSEPH NEEDHAM.

Caius College,
Cambridge.

[1] NATURE, 148, 270 (1941).

A SCIENTIFIC statement is essentially an expression of relations derived from and applicable to experience: it is therefore easy to determine whether a statement is scientific or not by considering its relation to experience. Dr. Waddington's statement "The real good cannot be other than that which has been effective, namely, that which is exemplified in the course of evolution", is clearly not derived from experience, for it does not express anything found by observation. Nor is it applicable to experience; when we try to apply it to any actual ethical problem (for example, "Is it morally good to bomb German cities?") it is found to be useless.

I do not believe that Dr. Waddington intends to be among the apriorists, but actually his so-called scientific ethical principle belongs to the company of Eddington's inviolable laws and Milne's cosmological

principle. It provides one more example of the widespread abandonment of science in the name of science. HERBERT DINGLE.

Leadership of Science

THE leadership of science is vital to the preservation and rebuilding of civilization. No less vital, as the recent admirable editorials in NATURE have urged, is a unity of aspiration and effort on the part of the United States and the British Commonwealth of peoples. To create now a moral and intellectual unity of the English-speaking peoples is to lay the foundation of that mighty union of democracy, the prayer of Longfellow and the message of Roosevelt, upon which hangs age-long weal or woe for mankind. The leadership of science must exert itself most fruitfully when integrated with that immense work of political creation. Indispensable to such a synthesis is the saturation of the 'man in the street' with the spirit and aspirations of science, together with a lively comprehension in broad outline, of what it is doing from day to day. Not until science replaces football pools in popular interest will the common person be fit to sustain civilization or the men of science in a position to lead it. Notable work in popular education has been done by many gifted thinkers. But the situation calls for something more organized and comprehensive, corresponding to the world which science has brought into being, where continents and peoples are linked in ever greater interdependence.

Nothing less is needed than a pooling of the common stock of contemporary thought and achievement in science presented in a form assimilable by the common person.

But if science really does transcend frontiers, if Anglo-American unity is not a fantasy, why do we need dispersed and divided plans of educating the public in scientific matters just where the common approach bids to be most potent ? Why cannot British and American men of science give a lead to the spirit of union, to thinking in terms of 'us' rather than of 'we' and 'they', which, as rightly suggested[1], is more important than cut and dried schemes of amalgamation? Should not men of science be the first to give an example of "pooling experience for the growth of mutual understanding", to use NATURE's words ? Speaking for the common person, I say we want to know what American men of science are doing, as the common person in America doubtless wants to know the same of British men of science.

The collaboration of British and American men of science as a body in issuing a periodical publication, say, monthly, of scientific news and progress in popular form, is capable of becoming the greatest move ever made towards the enlightenment of humanity in the mass. The leadership of science in the direction of a world planned for freedom and abundance for all cannot afford to conceive its duty of education in relation to obsolescent conceptions of nationalist sovereignties. The man in the street, if he is to think at once internationally and scientifically, needs the assistance of a new sort of creative journalism which shares those qualities.

"The West Highlands and the Hebrides"

IN the review in NATURE of August 16 of the above book by Dr. Harker, which was recently published posthumously, attention is directed to certain omissions in a Table of Formations which was added to Dr. Harker's original manuscript. Perhaps I may be allowed to explain that the Table was drawn up as an adjunct to the stratigraphy as set out in the text, in order to serve as a handy means of reference for the non-professional reader, for whom the book was primarily written, and also for geologists not conversant with the local details. As a matter of fact, Dr. Harker found occasion in the text to refer to almost all the geological systems and their subdivisions, and in this way has drawn a picture of the stratigraphy which is essentially complete. Since he did not mention certain subdivisions of the Jurassic system which are represented somewhat meagrely, namely, the Kimmeridgian (which is specially referred to in the review), and the Corallian, Callovian and Cornbrash, these were purposely omitted from the Table of Formations. Similarly, the Durness Limestone was placed in the Cambrian, because this long-established British custom was followed by Dr. Harker in the text. It appeared to raise too many complications, and indeed to be unnecessary in this book, to direct attention to the fact that the custom requires modification.

May I take this opportunity to correct one omission ? The New Red Sandstone of Arran was not subdivided by Dr. Harker into Permian and Trias. It became necessary to do so, since a previously published map showing this differentiation was being used as an illustration of the geology of the island. A footnote on p. 7 was therefore added, in which a recent identification of Permian lavas was mentioned. It should have been made clear, since it has so happened that the publication of the book has antedated that of the research paper concerned, that the identification was made by Dr. D. Leitch, of the University of Glasgow.

Huygens' Pendulum Clock

THE interesting article by Mr. A. E. Bell on the "Horologium Oscillatorium" in NATURE of August 30 rather suggests that this was Huygens' first book on the pendulum clock. He published a description, with plates, of the clock in "Horologium" (The Hague, 1658) though without reference to the scientific principles. The book is very rare and is not generally known. Part 1 of the "Horologium Oscillatorium" repeats its contents.

Huygens' specially constructed marine clock was actually tried at sea, and received a favourable report. The report, by Major Holmes, "A Narrative concerning the success of Pendulum Watches at Sea for the Longitude", is in *Phil. Trans.*, 1, 13–15 (1665).

TIN THROUGH THE AGES

AN EXPERIMENT IN MUSEUM SYNTHESIS

By Dr. F. J. North
National Museum of Wales

A GALLERY in the National Museum of Wales at Cardiff is used exclusively for temporary exhibitions, of which there may be three or four in any one year. The present exhibition, "Tin through the Ages in Arts, Crafts, and Industry", was designed to dispel the notion that because we describe an inferior musical instrument as tinny, and dismiss something paltry and ill-conceived as a 'tin pot' affair, tin is therefore a metal of no importance. The subject-matter has been so treated as to demonstrate the connexion between a great variety of apparently unrelated things, with the view of discovering continuing threads in the story of human progress ; this reverses the usual museum practice, which tends to emphasize the difference between groups of cognate objects and to confine synthesis to the material within a group.

A handbook* has been prepared to provide a running commentary to the gallery, but since it summarizes the story which each of the exhibits has to tell, without actually describing them, it will serve as an outline of man's indebtedness to one of the most useful of all metals, independently of the exhibition itself.

A gratifying feature of the exhibition has been the readiness with which (often in difficult circumstances) manufacturers have provided examples of their products and photographs of their plant. Half a dozen museums, too, have contributed material, and my own indebtedness to the Tin Research Institute is considerable.

The story begins with the minerals in which tin is present, and with comparisons between ancient and modern methods whereby they are isolated from their ores, but the major part of the exhibition is concerned with the utilization of the metal, its alloys and its compounds.

When man began to experiment with copper as a substitute for stone in the manufacture of weapons and tools, and realized that the presence of a certain other metal—we call it tin—produced something—we call it bronze—that although harder than copper alone was more easily cast and manipulated, he made a discovery which, by giving him better and more abundant implements, greatly accelerated the progress of civilization ; and tin has played an important part in nearly every subsequent development that has tended to widen man's physical and intellectual horizons.

Strangely enough, the range of articles made from tin alone has always been limited. A few ancient objects of cast tin have been found in Egypt, while collapsible tubes for tooth-paste and wrappers for cheese are made of pure tin, but its importance has always depended mainly upon its capacity for extending the applications of other metals. It is an essential, and often the principal, constituent of many alloys in addition to those included under the general name bronze : pewter, solder, printing metals, bearing metals, organ pipe metal, dental metals, and fusible alloys all owe their special characters in part or entirely to tin.

The Romans knew that a tin lining to vessels of copper or bronze made them more suitable as receptacles for food and water. This use of tin, which has continued throughout the ages and has been applied to iron and steel as well, depends upon its readiness to combine with other metals and its capacity for resisting corrosion, and it shows that the importance of the metal is not to be judged by the quantity that is used, for the coating of tin is exceedingly thin. In the common 'tin can', for example, the protective layer is no more than one ten thousandth of an inch in thickness, and all the advantages we derive from tinned foods (to mention only one kind of commodity that is put into tins) we owe to this extremely attenuated film of tin. That this thin film can be effective is even more surprising, when we realize the strains and stresses to which the tinplate is subjected in the machines that convert it into cans and in the plant that fills and seals them.

One exhibit shows that tin is the principal constituent of pewter, and specimens from Roman to recent times illustrate the way in which its different varieties have been cast, spun, or beaten into vessels for ornament and for use ; another, entitled "Tin in Printing", illustrates the role of tin in printing metals, since the invention of movable types began to make knowledge the heritage of the multitude instead of the monopoly of the few.

It is tin which determines the properties of the varieties of solder ; innumerable articles, affecting every phase of human life, are commercial possibilities because of the ease with which soldered joints can be made, and we owe the effective distribution of water, gas and electricity to the solder which ensures the continuity of the conducting elements. As with the other alloys, the past and present uses of solder are illustrated by specimens and photographs, and the metallurgical explanation of its behaviour is simply described with the aid of diagrams and photomicrographs.

Tin is an essential, although not usually an abundant, constituent in the so-called fusible metals. At one time they were curiosities, as when used for making spoons that melted in hot tea ; later they found practical applications in the sprinklers which caused water to be sprayed in a room where a fire had developed, and nowadays they are employed in many engineering processes, as for example, in bending thin-walled tubes, like those for conveying oil and water in aeroplanes : the tube is filled with molten alloy, bent after the metal has solidified, and then immersed in hot water or in a steam bath so that the alloy can be melted and drained away.

Of outstanding interest is the part which tin has played in 'bearing metals', since the days when it was realized that the development of frictional heat in an engine was diminished by the introduction of a lining

* "Tin through the Ages, in Arts, Crafts and Industry", Handbook to a Temporary Exhibition, July–December 1941, by F. J. North, (National Museum of Wales, Cardiff). Pp. 38. 3*d*.

or bearing of bronze where one metal part moved in close contact with another. Later on, other alloys of tin provided still better bearing metals, and nowadays some of them contain more than 80 per cent of tin.

Many uses have been found for compounds of tin, as, for example, in producing rose tints for ceramic decoration, the white background for majolica and delft, the glaze of modern sanitary fittings, and the enamel of refrigerators, thus adapting to modern requirements a practice dating back at least to Babylonian times.

The foregoing notes show that a heterogeneous collection need not of necessity be haphazard, for with specimens ranging from part of a Roman pump to an electric kettle, and photographs ranging from Egyptian tomb-pictures to a pea-cannery, it is possible to complement the more usual kind of museum exhibit, based upon a desire to separate things which belong to different ages, or were put to different uses. This aspect of the exhibition can be illustrated by reference to one section only, that relating to bronze: approach from an archæological point of view leads to exhibits showing the kinds of implements that Bronze Age man could make, how they were related in time, and how they became more and more efficient, particularly in the direction of better fixture to their hafts: here the museum story usually ends, for iron superseded bronze, and Iron Age cultures demand consideration, and that there is any connexion between the palstave and a machine-component cast in bronze does not appear.

When, however, we add to the archæological information what modern methods of examination have taught us about the properties of alloys, we realize that the improvements in early implements ran concurrently with man's increasing knowledge of the materials he used; we connect up the oldest of metallurgical practice with the newest of metallurgical theory and research, and in our stride we can take in all the things for which the varieties of bronze have been employed—bells and guns, statuary and friezes, measures and machine-parts, and even the wire cloth on which paper is made.

We find that although the modern foundryman can deal with tons whereas his predecessor could only handle pounds, the principles on which he works are just the same. Bronze Age man discovered the principles of all the methods of casting that are used to-day, and learned to make metal reproductions of his moulds that could be used again and again, thus speeding up production and ensuring uniformity of results. Nowadays permanent moulds are made of steel, not bronze, and powerful machines force the molten metal into cavities more complicated than the old-time workers either needed or could have made; nowadays we call it die-casting, but the principle is the same, and so are the advantages claimed—speed of production and uniformity of result.

The experiment seems to have justified itself because the archæologically minded visitor, caring little for modern machinery, has discovered that in his ancient bronzes he has the beginnings of a story that is still in the process of writing; and the engineer, not a whit interested in axes and palstaves, has found that when he tries out a new method for 'babbitting' a connecting rod, he is contributing to a story of which the opening chapters belong to a period so remote that they have to be reconstructed, not read.

An exhibition like this shows how arbitrary are the conventional dividing lines between cultural and academic studies on one hand, and science and industry on the other, and how unsubstantial are the lesser dividing lines within these groups. Material that one would expect to see in a 'trade show' is displayed in the same gallery, and often in the same case as the 'cultural' objects normally associated with a museum, but there is no apparent incongruity either in the arrangement of the specimens, or in the ideas they are intended to suggest.

Taking a dictionary definition of culture as "a state of intellectual and artistic development", it would seem that museums can do much to show culture what it owes to industry, and, by illustrating the methods and results of industrial research (not merely the products of industry), to show that industry is itself specialized culture, for as Pope once put it, all are, indeed, but parts of one stupendous whole.

EXHIBITION OF PHOTOGRAPHY

THE eighty-sixth annual exhibition of the Royal Photographic Society of Great Britain was opened at the Society's Galleries, 16 Princes Gate, S.W.7, on September 5, by the Right Hon. J. T. C. Moore-Brabazon, the Minister of Aircraft Production. This is the second exhibition that has been organized under war-time conditions, and it would be foolish to pretend that it has not suffered in any way.

The Pictorial Section is up to strength, and appears to have maintained its high peace-time standard of quality, and it is gratifying that even this year most of the Dominions and the United States are represented.

The Scientific Section unfortunately suffers from a marked absence of exhibits from abroad. Photography is much used in Great Britain for scientific and industrial purposes, but few examples seem to find their way to the exhibition. It is also regrettable that few university laboratories in the country carry out research directly related to photography, though they certainly make use of it as a tool. In past years exhibits from abroad, such as the illustrations of ultra-high-speed photography of Edgerton and Germeshausen, and illustrations of the use of photography in research on cosmic rays and atomic particles, have been a feature of the Scientific Section. However, apart from these absentees, all branches of the section are represented by exhibits of high standard. There are examples of both low- and high-power photomicrography, the latter being illustrated by two striking examples of diatoms.

The number of exhibits illustrating the use of photography in medical work clearly shows the value of this application of photography. Many of the photographs taken for demonstration purposes are made during the course of surgical operations, and the operator is beset with many difficulties, such as obtaining sufficient light and suitable modelling to show up the desired features without interfering with the course of the operation. Other examples show

the value of the combination of a schematic diagram of an organ and actual photographs of the object. The use of infra-red photography for rendering fine detail of structure in relatively thick sections of fossil stems of plants is illustrated by a number of examples.

Radiographs are well represented, the subjects being mainly of medical interest. The Rodman Medal, which is awarded for the best exhibit of a non-pictorial nature with special reference to radiography or photomicrography, has been given to R. M. Leman for his "Radiograph of Arum Lily" and "Radiograph of Larch". These were presumably taken with soft X-rays, and a relief effect has been obtained possibly by combining a positive and a negative of different contrasts and slightly out of register. The effect is certainly very pleasing from a pictorial point of view.

The remainder of the Scientific and Technical Section consists of a number of exhibits grouped under the name of "Survey and Record Photography". These are largely records of carvings, interiors of churches, etc., of which there are some excellent examples to be seen, and in these times such records assume a greater importance. The outstanding example of record work is the series of ten photographs, by H. Bedford Lemere, of famous London buildings, most of which have been seriously damaged by enemy action within the last twelve months. This exhibit has gained the Hood Medal. The Natural History Section is well filled and contains examples of all kinds, botanical, birds in their natural habitats (always a popular subject), and mammals, mainly feline, photographed in captivity. Natural history photography attracts a number of amateurs who master the technique of photography in order to apply it to their hobby. The pictorialist enjoys his search for good composition; the photographer of Nature gets his excitement in another way, an excitement akin to that of the hunter. There is a photograph of the grey hare appearing out of a burrow set in trackless wastes of snow, and one can imagine the preparation and care necessary to obtain such a photograph.

The Colour Photography Section has suffered seriously this year, which is scarcely surprising, considering the difficulty of obtaining colour film. The transparencies are chiefly taken with miniature cameras on Kodachrome, Dufaycolor and Agfacolor films, while the colour prints on paper are reduced to six examples, three each on Wash-off Relief and Tritone. The lantern slide exhibit is mainly confined to natural history subjects, and both these and the purely 'pictorial' slides are well worth seeing. The slides are mounted in viewing boxes in a darkened room, and clearly illustrate the advantage of the transparency over the paper print due to the greater range of tones that can be reproduced by the former.

In the opinion of many, the most effective photographic reproductions are to be seen in the stereoscopic section, which contains some hundred transparencies, of which about half are in colour. The combination of the extended tone reproduction of the transparency with the stereoscopic effect, and in some cases colour, can produce a realism that may not satisfy the modern pictorialist, but can be very attractive to those who like to see things as they are.

The Exhibition as a whole, which is open to the public daily (except Sunday) from 10 a.m. until 5 p.m. until October 25, is well worth a visit. Though there are some notable absentees among the regular exhibitors, the Ministry of Information has supplied a series of more than a hundred British official photographs illustrating some applications of photography in depicting various phases of the Navy, the Army, the Air Force, in the manufacture of munitions, in home defence, and for propaganda and Press purposes.

LIGHTNING OVER-VOLTAGES IN UNDERGROUND CABLES

The occurrence of lightning over-voltages on underground cables is ordinarily supposed to be impossible except when a cable is connected to an overhead line. In this case surges initiated in the latter may be propagated into the cable. In a recent paper by Dr. H. Einhorn and Prof. Goodlet of the University of Cape Town*, new facts are adduced which prove that the ordinary opinion is untenable. They describe some curious faults on underground telephone cables experienced during the lightning season in the vicinity of Johannesburg which cannot be explained in the general way. Briefly described, breakdowns occurred between the outer cores and the lead sheath and armouring of telephone cables buried to depths up to three feet in dry sandy soil. All the faults occurred during the lightning season, and faults were most frequent in the worst storm areas traversed by the cables.

In one case voltages up to 1,000 volts were measured (by electrostatic voltmeter) between cable-end and earth during a storm. The faults could therefore with certainty be ascribed to lightning; the potential of the cable sheath must in some manner become raised relative to the cable cores. The problem the authors set themselves is to find out how this occurred and investigate possible remedies.

Direct strokes to earth are first considered. If a lightning flash of current I strikes an overhead conductor of surge impedance Z somewhere in a span, a travelling wave of amplitude $\frac{1}{2}ZI$ is propagated along the line in both directions away from the fault. Our knowledge of the propagation of electric disturbances along bare buried conductors is not extensive but is sufficient to allow us to picture events as happening in a similar manner, modified by the considerable leakage into the ground. Tests indicate that if an impulse voltage is suddenly impressed upon a long buried conductor the "effective surge impedance" (defined as the ratio of instantaneous voltage to instantaneous current) will fall from an initial maximum value of the order of 100 ohms down to the ohmic earth resistance of the conductor.

The attenuation of waves along uninsulated buried conductors is very rapid, being usually complete in a distance of less than 100 m., so that reflexion pheno-

* *J. Inst. Elec. Eng.*, 88, Part 2, No. 4 (Power Engineering) (August 1941).

mena are seldom important. An impulse current fed in at one point of a buried conductor will therefore raise its potential to a maximum of about 50 kv. per kiloampere of current entering the conductor.

The formation of fulgurites proves that a lightning flash can penetrate a considerable distance into the ground, and therefore a direct stroke to a conductor buried only 2 ft. below the surface is not an impossibility.

Appreciable potentials may also arise due to earth-current voltage gradients if a flash strikes the ground anywhere in the vicinity of the cable. A similar effect has recently been investigated in connexion with power-system earth faults.

The increase of potential of the ground around substations, under fault conditions, is liable to cause breakdown of the dielectric of light-current cables entering the area when the cores of these cables are maintained at substantially earth potential. The cables can be protected against this hazard by insulating the sheath from earth for a certain distance from the substation.

The authors give a simple theory of the potentials induced on the ground-surface beneath a thundercloud. The separation of charges within the cloud surface occurs relatively slowly and is not accompanied by any sudden field changes at the ground surface. An approximate expression is found for the instantaneous value of the potential of the ground surface. If C is the capacity and R the resistance to earth of the ground surface, the product CR is constant irrespective of the distribution of the conduction and displacement currents in the ground.

An experimental arrangement of apparatus is then described showing the possibility of inducing potentials on buried conductors. A 12-stage 220 kv. portable impulse-generator is fed from a 200/30,000-volt single phase transformer with variable primary voltage over a half-wave thermionic rectifier. The impulses are applied over a water resister to a 2-ft. diameter metal plate, suspended above a bakelite cylinder filled with sand or garden earth. The crest value of the applied surge voltage is measured by means of 15-cm. remote control spheres. Embedded in the sand is a 9-in. brass disk connected to a 2·5 cm. sphere gap which is screened against the top plate and ionized by means of a mercury-arc quartz lamp.

Three different embedding materials were investigated: air-dried sand, moisture-content 0·05 per cent (by weight), specific resistance greater than 10^9 ohm-cm.; garden soil specific resistivity about 10^5 ohm-cm., and steam-wetted sand which had a resistivity of about 4×10^5 ohm-cm.

The conclusion is drawn that for dry sand the induced voltage is purely a matter of capacitances, and is practically independent of the wave front. With garden earth no effect due to the charging stroke could be observed within the possible working range. With steam-wetted sand the potential induced by the charging stroke was measurable and was clearly proportioned to the impulse crest voltage.

The theory given and the results of the experiments suggest that potentials can be impressed on conductors buried in the ground under a thundercloud and indicate an upper limit to their magnitude.

It is suggested that a cable laid in low resistivity soil will not experience induction trouble. Considerable attention should therefore be paid to soil aridity when choosing a cable route. Whether plant growth affects the moisture content of the soil to any appreciable depth is uncertain.

FORTHCOMING EVENTS

[Meeting marked with an asterisk is open to the public.]

TUESDAY, OCTOBER 7

CHADWICK PUBLIC LECTURE (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 2.30 p.m.—Dr. V. Zachary Cope: "The Influence of War on Surgery".*

FRIDAY, OCTOBER 10

PHYSICAL SOCIETY (in the Physics Department of the Imperial College, Imperial Institute Road, London, S.W.7), at 4 p.m.—Prof. J. T. MacGregor-Morris: "Recent Work on the Use of Photo-electric Rectifier-Type Cells in Photometry".

APPOINTMENTS VACANT

(not included in the monthly Books Supplement)

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LIBRARIAN—The Principal and Clerk to the Governing Body, Wigan and District Mining and Technical College, Wigan (October 8).

LECTURER IN ELECTRICAL ENGINEERING SUBJECTS at the Cardiff Technical College—The Director of Education, City Hall, Cardiff (October 8).

ASSISTANT LECTURER IN GEOGRAPHY (MAN OR WOMAN)—The Registrar, University College, Nottingham (October 13).

HEADMASTER of Stockport Grammar School—The Clerk to the Governors, Stockport Grammar School, Mile End, Stockport (October 15).

CIVIL ENGINEERING ASSISTANT—The Clerk to the River Ouse (Yorks) Catchment Board, 7 Langcliffe Avenue, Harrogate (endorsed 'Engineering Assistant') (October 15).

INSPECTOR OF SCHOOLS (WOMAN)—The Director of Education, Guildhall, Hull (October 18).

LECTURER-IN-CHARGE OF MECHANICAL ENGINEERING—The Principal, Aston Technical College, Whitehead Road, Birmingham 6.

GRADUATE LECTURER WITH QUALIFICATIONS IN MATHEMATICS, PHYSICS, OR ENGINEERING—The Principal, Technical College, Kendrick Hall, Stroud, Glos.

MOBILIZATION OF MENTAL POWER

THE relatively late rise of psychology among the sciences is partly due to the fact that its subject-matter is so wrapped in prejudice and entangled in tradition that it is most difficult to examine in a detached and scientific spirit. The obstacles preventing the application of precise psychological information to personnel selection in the army, where tradition is so deeply entrenched, would seem to be particularly forbidding, and the Select Committee on National Expenditure is to be congratulated for devoting one of its reports to this topic*.

One immediate effect of the introduction of intelligence tests in the United States Army in 1917 was the discharge of about eight thousand men on account of mental defect, the transference of about ten thousand to labour battalions and the recommendation that a further ten thousand required special training which would allow for their low ability. Since the War of 1914–18, the measurement of intelligent behaviour has made notable advances both in theory and practice (although, judging by conditions in contemporary society, a parallel progress is far from evident in the trait to be measured), and it can confidently be anticipated that the outcome of a major testing programme carried out now would involve results of great consequence.

* Twenty-Second Report of the Select Committee on National Expenditure. (London: H.M. Stationery Office, 1941.)

In spite of the increase in mechanization, it still remains true that the human element in warfare is, in the long run, more important than technical devices. A necessary condition of the efficiency of any mechanism, organism or organization is that every component should be optimally situated in relation to the whole. To each constituent part should be assigned its most appropriate function. For society to attain that stage of efficiency so essential in total war, full use should be made, so far as is humanly possible, of all the native ability and skill, all the training and qualities of personality that are available. In so far as we fall short of this objective, to that extent are we inefficient. It is, of course, assumed that the supply of talent, innate and acquired, should be related to the military and civilian needs of the nation at war.

The review by Dr. C. S. Myers in NATURE of May 10, 1941, of the applications of psychology already achieved in the present War, indicated the many possibilities of utilizing psychological methods in the Fighting Services and industry. Several examples were quoted in which individuals had utilized such methods, but there is little sign that those in authority regard them as more than interesting experiments.

The report of the Select Committee recognizes that many mental tests in use until now have not fulfilled the selective functions for which they were presumably designed. No doubt this can be

attributed partly to the extended use of verbal rather than perceptual and performance tests. Apart from the existing evidence, which points to a verbal factor orthogonal to intelligence, the use of verbal tests puts schooling at a premium and does not effectively discriminate between the native ability of persons differing widely in educational background, as must be the case in a conscript army.

It is unfortunate that the outworn idealistic belief that abilities are mere entities seated in the mind still makes its influence felt in test construction. A more realistic approach is desirable. So far as the Services are concerned, the guiding principle should be the need for selecting persons capable of performing the tasks required by the more specialized units of the armed Forces. The ability should be defined by the test, not the test by the ability; and the design of the test should, in general, be determined by the activities called into play in the actual performance of the work for which selection is needed.

The elimination of feeble-minded and backward soldiers before money and training have been wasted upon them ought to present no difficulty; tests are available, specially built to deal with these problems. But the careful segregation or placing of neurotic types needs the employment of a new kind of criterion. The Committee's recommendation that the Ministry of Labour and National Service should, in future, not be responsible for posting men to any particular corps but only to the army as a whole, will it is hoped, be put into effect with as little delay as possible.

The suggestion that the testing should rest entirely in the hands of Service personnel is open to criticism. It needs to be stressed that so far as possible the testing in all its stages should be under the control and supervision of qualified psychologists, with a status similar to that of the existing medical boards. Otherwise, the scheme is likely to defeat its own ends. Serious defects in the conditions of administration of the tests can invalidate the results, as may happen if the work is entrusted to officers who have only been given some slight instruction in the preliminaries of testing. The following instances taken from a mechanized unit are instructive. An officer charged with the administration of the tests was accustomed to inform the candidates, after imparting other misleading information, that "they all had an equal chance of doing equally well on the tests", which is the very opposite of the truth. The period immediately prior to the testing was frequently spent 'on the square' and the men were consequently in various stages of fatigue. No account seems to have been taken of poor health at the time of the test. Furthermore, a well-intentioned sergeant apparently always did his best to assist the men in the test; he thought it was the correct thing to do. Copying also went on.

The advantages that would have followed the introduction of scientific methods of selection before or at the outbreak of war will, it seems, be largely obviated because the bulk of the men in the Forces have already received their training and, in the present circumstances of war, transfers on a large scale are considered undesirable. This is recognized by the Select Committee. However, if it is too late in one sphere, the moment is opportune to begin in another. Now is the time to sort out the thousands of youths that have joined the Air Training Corps. Here it is possible, with the aid of psychological tests, to achieve a great economy in time and expense by providing a differential training according to capacity and temperament.

The sphere in which purely psychological criteria of selection, in addition, of course, to physiological tests, could reap their greatest reward is probably that of pilot selection. Now, while there is no reason to question that the medical authorities have availed themselves of the best diagnostic techniques, there are grounds for believing that the possible contributions which psychology has to offer in this urgent field have by no means been fully explored. No effort should be too great to select, with the utmost care, the relatively small number of future pilots out of a much larger number of candidates. It is here that, added to the minimum requirements of intelligence, the qualities of temperament and character exert their most crucial effects. The problems are exceedingly complex. Nevertheless, the traits subserving mental stability, persistence, prolonged attentive power or the capacity to respond rapidly to a succession of surprise stimuli, to mention a few, should not wholly elude measurement. Those characteristics by which a day fighter pilot may be discriminated with a maximum of accuracy from the night fighter pilot and both from the bomber pilot merit all the resourcefulness and imagination in psychological measurement which are available.

The use of diagnostic criteria of ability in the selection and promotion of officers is also advocated by the Select Committee. It would be interesting to know how this would affect the existing distribution of ability among the commissioned ranks. However, given a certain level of intelligence, stress is laid in the report upon qualities of personality, and new experimental methods of assessing the relevant qualities are urgently needed. The system of promotion by seniority, wherever it is employed, is not necessarily calculated to elevate to posts of greater responsibility those men who are distinguished by superior

talents. If anything, increase in age beyond a certain point is probably inversely correlated with many of the qualities which make for success as a soldier. An officer, as a result, let us say, of bravery in the field, may be given a post in which matters relating to strategy are decided by him. But it cannot be assumed that the biological and social factors which operate to select for the quality of courage are the same as those which select for the traits which make a good strategist. Other considerations, which arise wherever appointments are to be determined by experience or by more direct estimates of capacity, also deserve weight. It may happen that a soldier with considerable military experience is entrusted with a high post mainly on this ground; but what is really relevant is the capacity to profit from experience rather than the mere fact of having had experience, and the appointment should be determined at least as much by the former as by the latter.

The scope of psychological methods in the organization of war is not confined to the application of mental tests in the Services. The allocation of new labour in industry, the human element in production, propaganda, morale and evacuation are some of the problems the solution of which would be facilitated were the aid of psychology more fully enlisted. The greatly increased number of trained psychologists which would be required could probably be provided by the Central Register, with the added advantage that the special qualifications of many able research workers in psychology would be utilized to the best advantage. It is to be hoped that the Select Committee will be able to turn its attention to these wider applications of psychology.

HIGH POLYMERS

Collected Papers of Wallace Hume Carothers on High Polymeric Substances
Edited by Prof. H. Mark and G. Stafford Whitby. (High Polymers, Vol. 1.) Pp. xix+459. (New York: Interscience Publishers, Inc.; London: H. K. Lewis and Co., Ltd., 1940). 8.50 dollars; 51s. net.

Physical Chemistry of High Polymeric Systems
By Prof. H. Mark. Translated from the manuscript by K. Sinclair, revised by J. Edmund Woods. (High Polymers, Vol. 2.) Pp. x+345. (New York: Interscience Publishers, Inc.; London: H. K. Lewis and Co., Ltd., 1940.) 6.50 dollars; 39s. net.

It is impossible for one author to attempt to bring within the compass of one or even a series of volumes a comprehensive and authoritative account of high polymer systems. Nothing less than a carefully chosen team of experts will suffice for the task. While the subject has come more and more into prominence in recent years this is only partly due to new knowledge of synthetic polymers, for there has accumulated over a considerable period an extensive and often unco-ordinated body of knowledge of the natural high polymers, rubber, cellulose, proteins and the like. Gradually, however, the whole subject has been cleared of indefinite opinions and conceptions, and some degree of order introduced into this branch of chemistry. This does not mean that all the fundamental problems are solved, and it is now only a question of settling matters of insignificant detail. Much has yet to be done, and a first step in the process is a clear survey of the existing state of affairs. This is the object of the editors—R. E. Burk, H. Mark and G. S. Whitby—in the volumes under review.

Appropriately enough the first volume of the series comprises the collected papers of the late W. H. Carothers. It is difficult to realize that in the short space of nine years Carothers not only contributed handsomely to the subject of polymers but also brought into being two well-known plastics of unique properties—'Nylon' and 'Duprene' (polychloroprene). In these collected papers we see the train of thought which led to the discovery of these substances. Their discovery was no idle shot in the dark or the outcome of a lucky experiment. It was the result of a most painstaking and systematic search at a time when intuition played a large part. In his first paper, Carothers clears the ground by considering in general the theory underlying the formation of condensation polymers; that is to say, it is an attempt to predict whether bifunctional molecules will react inter- or intramolecularly. On this basis an examination is made of those molecules which form polymers, but it is soon shown that the molecular weights of the products are rather low to be of interest from the plastic point of view. The matter is not left there, for it is realized that higher polymers may be formed only if the reaction is finally carried to completion in a molecular still. At this stage molecular weights of the order of 10,000 become a practical proposition, and thereby the prospect of obtaining synthetic fibres of sufficient strength immediately presents itself. Carothers carries the

argument to a logical conclusion by taking two further steps. The first is the realization that lateral interaction between macromolecules is a prerequisite for mechanical strength. The second is that such macromolecules must be orientated side by side and parallel to the fibre axis. Both are achieved, one by resorting to the polyamide system and the other by successful cold drawing of spun fibres.

The search for a variety of rubber exempt from the disadvantages of the natural material proceeded in a similar logical fashion. Here, however, the basic substances, namely vinyl acetylene and divinyl acetylene, were available and the problem was to make from them a satisfactory rubber. Innumerable compounds of hydrochloric acid with these two reactive hydrocarbons were investigated, with the result that in so far as dienes are concerned we now have a much clearer picture of the general type of diene system likely to give rise to molecules of high enough molecular weight. The relationship between rubber-like properties and chemical constitution was not revealed by these researches. Another interesting line of work, upon which there is only one paper, is the synthesis of saturated hydrocarbons of high molecular weight up to $C_{90}H_{182}$. There are many other papers full of new ideas and suggestive side-lines of which mention cannot be made. They all go to show that, had Carothers been spared, he would have made even greater strides than in this decade of intense and fruitful activity.

The second volume in the series, by Prof. Mark, really is Vol. 1 of the systematic treatment of high polymeric substances. This is shown most clearly by the fact that there is very little about polymers except towards the end of the book. It is, however, necessary in a comprehensive treatise to describe in some detail the physico-chemical methods required to deal with the reactions and structure of high polymers. Certainly such a description may be found in a variety of monographs on physical chemistry. In this volume all that is necessary for an understanding of polymers is brought together conveniently and compactly. Enough is given of modern valence theory to form a good basis for the discussion of methods used for the determination of interatomic distances. There is especially a detailed description of X-ray methods as applied to crystalline and amorphous matter. Since the peculiar properties exhibited by high polymer systems are due to a very large extent to the character of intermolecular forces, there is a section dealing with this aspect of the problem.

Molecular weights of polymers are almost invariably determined by measuring the osmotic pressure or viscosity of solutions. Unlike solutions of small molecules, polymeric solutions behave in an anomalous manner, and thus the interpretation of measurements is still a source of intense and as yet inconclusive controversy. It is here that the subject needs exact treatment. Ultracentrifugal technique is not described in detail, but enough is given to indicate the potentialities of the tool.

The mechanism of polymerization, as revealed by kinetic studies, is briefly mentioned, but again lack of space prevents any thorough treatment of the topic. Much has had to be compressed into this volume, and it is a tribute to the author that the subject is presented so clearly and pleasantly. For those not specially interested in high polymers this volume gives an unusual approach to certain parts of physical chemistry not found in the normal text-books.

It is to be hoped that, in spite of difficult times, the editors will find it possible to complete the task of which the present volumes represent a very welcome beginning.

H. W. MELVILLE.

MUSEUM EDUCATION FOR THE YOUNG

Youth in Museums

By Eleanor M. Moore. Pp. ix+115+12 plates. (Philadelphia: University of Pennsylvania Press; London: Oxford University Press, 1941.) 12*s*. net.

THIS volume gives a clear picture of the very important part taken by American museums in the education of children. The author received a generous grant from the Rockefeller Foundation which enabled her to visit 103 museums in the United States for the purpose of studying the work that is being done for children. She also visited museums at Vancouver and Toronto.

The history of the development of museum education for the young is not outlined, but the author remarks that the importance of youth in museum progress is a "comparatively recent realization". It may be recalled, however, that in the United States and also in England there were, even in the 'eighties, far-seeing museum educationists who fully realized the desirability of catering for youth. In 1887 the Horsfall Museum at Manchester was encouraging children's visits and lending pictures and objects to schools, and about that time Sir Jonathan Hutchinson was holding classes for the young in his Educational Museum at Haslemere, where, a few years later he held examinations for children which included the identification of objects and portraits.

By 1900 several of the larger American museums had established sections or galleries specially adapted to the comprehension of children, and prizes were offered for essays.

Gradually it dawned upon the American public that youth is "the life-blood of museums", and, when this was fully comprehended the formation of children's museums was developed with tremendous and characteristic energy. At the present time there are at least two thousand adult museums, and children's museums "are springing up everywhere almost overnight like mushrooms", but those founded without requisite knowledge and without public backing will either quickly pass out of existence, or, like many museums in small towns in the British Isles, struggle on though "doomed to stagnation and eventual extinction".

The successful ones, established with inspiration and foresight, are controlled either by boards of education or by individual schools. A few children's museums are controlled by their own boards, and yet others are a separate but distinct part of well-known adult museums.

A children's museum may be defined as one containing objects selected, exhibited and interpreted for children in a place set aside for children. The title has been subjected to criticism—variants are "Junior Museum", "Recreation Museum" and "Little Museum". There is only one American museum styled "educational"; its principal function is "the lending of large numbers of objects to the public schools of the city [St. Louis] at the request of teachers". Some people, doubtless with dismal recollections of the gloomy and dry-as-dust museums of fifty years ago, even hold that the word "museum" is a forbidding one "for any active modern concern, especially where the stress is laid on making children feel a home-like atmosphere". The reviewer's experience, however, is that if the activities are sufficiently attractive, boys and girls of all ages do not give up their allegiance to the local museum.

The author points out that to-day most adult museums welcome the interest of children and do everything to encourage it. The following quotation conveys a vivid impression of the result of such encouragement in certain museums.

"The Tolèdo Museum of Art has been a veritable Pied Piper until on Saturdays traffic is almost held up by the vast hordes of children arriving for classes. The Art Gallery of Toronto has days when it is almost impossible to walk around the galleries for the children sketching and the various activities in the Cleveland Art Museum crowd the galleries in the same way. The University Museum in Philadelphia looks forward to the yearly visit of hundreds of small boys from a certain school who for years have stretched out on their stomachs on the floors whenever the spirit moves them to enjoy and record better the impressions of their visit in picture form. The Seattle Art Museum and the Newark Museum point out with pride the stone camels continually kept polished by children riding them, and Venus' knee, so shiny and dirty from small hands caressing it every time children pass. These do not point to the fact that children are not wanted or that they cannot be made to feel at home. Many an adult instead of being annoyed is seen to smile at their unconcern over adult intrusion."

Allusion is made to the falling off in museum attendance of high-school boys and girls. It probably results from lack of time as much as from the absorption of new interests. In some places children's clubs have been established in direct connexion with the museum, and the members make expeditions to collect not only flowers and insects but also minerals and fossils—a sound plan which, if adopted in Great Britain, might revivify some of the languishing rural museums.

The author very rightly insists that "No matter how small its beginnings the first thought in the minds of those organizing children's museums must be the setting up of standards. No matter how slowly or how fast the enterprise takes hold those same standards must be upheld to the end to insure the right to assume the name of museum."

We are assured that "from all directions come requests for more publications and of a different type from the usual technical bulletins which most museums offer the public". The demand is met in various ways: for example the Buffalo Museum of Science prints for free distribution coloured game cards, approximately 5 in. × 7 in., with the game—it concerns exhibits in the museum—on one side and an invitation to visit on the other. The Cincinnati Museum of Natural History issues a miscellaneous publication of 330 facts and questions chosen at random to direct attention to the Museum. Here are two of the questions: "Do you know that a single oyster eats 72,000,000 organisms in one day?" "Do you know that snakes walk on the end of their ribs?"

The great value of practical demonstrations is stressed, for such are always popular. "An individual who can actually show how to spin or weave, throw clay on a potter's wheel, paint a picture, stuff a bird, or make a plaster cast always draws a crowd—the act of doing is indeed dramatic."

This very interesting outline of museum doings for youth concludes with the anticipation that the young people's museum of the future will be "A museum whose interests will be entirely interwoven with every facility and every concern of the community, but one whose identity and influence will remain distinct".

BIOCHEMISTRY TO-DAY

An Introduction to Biochemistry
By Dr. William Robert Fearon. Second edition. Pp. xii+475. (London: William Heinemann (Medical Books) Ltd., 1940.) 17*s*. 6*d*. net.

THE new edition of Dr. Fearon's book is very welcome, for, since the first edition in 1934, much that is of profound significance in biochemistry has taken place, and the new edition shows every evidence of careful and up-to-date revision. Some of the chapters might almost be described as miniature monographs, so admirably does the author summarize the essential facts of his subjects. It is perhaps a little invidious to single out individual chapters for special mention, when all are of uniformly high quality, but those on enzymes, hormones and proteins are particularly informative. The book contains little that is non-essential, and the usual discussion of the elementary principles of physical and organic chemistry is fortunately omitted. On the other hand, there is a great deal in the book that one might not have expected to find in a so-called "Introduction", material that up to the present has only been available in the original literature or in occasional reviews.

The book is unorthodox in many ways. For example, the second chapter discusses the "Biological Elements", and the third "Inorganic Compounds", subjects that are usually and quite improperly ignored. The justification for beginning with the inorganic constituents of living matter—the "shovelful of clay"—is doubtless contained in the apt quotation from George Russell which heads Chapter 2. In later chapters, the substances with which the dry bones are clothed—the carbohydrates, proteins, lipides, and other essential constituents of the body—are discussed, together with their functions.

The quotations with which the book is seasoned form another unorthodox feature. These range from Swinburne to Chesterton, from Shaw to Tobit, the last being a particularly apposite reference. The biochemists of Dublin seem to share in the literary atmosphere of that city!

The chapter on hormones is also unconventional, first, by reason of the fact that the old name 'autocoids' has been resurrected and, secondly, because a wider range of factors than usual comes in for consideration by reason of the extended definition. Though Dr. Fearon has perhaps not quite played the game in adopting this artifice, one is glad he has done so, for the result is one of the best chapters in the book.

Unfortunately, the book is not entirely free from errors, mostly small and unimportant, though a few are of more moment. Thus the formula given for α-carotene on p. 202 is erroneous; as to a less extent is that of *iso*alloxazine on p. 206; the statement on p. 246 that vitamin D is found in the leafy part of most plants is clearly wrong, and is in fact corrected on the next page but one; and surely the identity of the vitamin D of fish liver oils with that produced by irradiation of 7-dehydrocholesterol, as established by the brilliant work of Brockmann and his colleagues, is of sufficient importance to deserve mention. A major error, or series of errors, occurs in the list of references on p. 265, where "J. Nutrition" should read "Nutrition Abstracts and Reviews" in all three instances. Another unfortunate but understandable mistake is the inclusion on p. 136 of Kögl and Erxleben's claim to have found *d*-glutamic acid in tumour tissue protein. It is to be hoped that this statement, recently proved wrong by several groups of workers, will be deleted in the next edition. Slips such as these can readily be excused when one considers the wide field that the author has covered, and the heroic struggle he must have had to bring each subject up to date.

All chemists, biologists and clinical workers will profit by a study of this book, and those whose work lies in the biochemical field will find much that is stimulating. Here we are enabled to obtain a comprehensive picture of the rapid expansion that has occurred within recent years, and those with imagination will see hints of the problems that remain to be investigated. What, for example, happens to the energy produced in the brain, "silent and motionless", by the consumption of 0·14 ml. of oxygen per gram of tissue per minute? Does the theory of energy-levels recently advanced by Szent-Györgyi supply the answer? Why does the *in vivo* oxidation of fatty acids occur at the α-carbon atom, when every organic chemist knows that the β-carbon atom is the more reactive? Is the recent observation of Kharasch that the β-carbon atom is more reactive than the α-atom in presence of peroxide or light relevant to these facts? What, if any, is the significance of the occurrence of β-alanine in pantothenic acid on one hand, and in carnosine and anserine on the other? These and like questions that spring to mind will doubtless be answered in due course. In the meantime, we are probably on the eve of further striking developments, and we must hope that the new knowledge thus gained will find its place in the next edition of Dr. Fearon's admirable volume.

F. A. ROBINSON.

The Boy Electrician

Practical Plans for Electrical Apparatus for Work and Play, with an Explanation of the Principles of Everyday Electricity. By Alfred P. Morgan. Fifth edition, revised by J. W. Sims. Pp. 328+11 plates. (London, Bombay and Sydney: George G. Harrap and Co., Ltd., 1941.) 6*s*. net.

IN some quarters the die-hard tradition still lives fully up to its name and in that austere domain this volume would, no doubt, be classed and discussed as just "another of those popular books for the scientifically immature and curious". Such a label, however, would betray nothing but a complete lack of understanding of the times and of sympathy with the aspirations of adolescence. The present book is, in its way, as important to those to whom it is addressed as is many an advanced work to the established scientific or technological worker—maybe even more so in its possible influence in the formative years of youth; because of this we are glad to see the new edition.

The scope of the work is wide and, in parts, a little beyond the capabilities of the average boy experimenter who, for example, will have to advance quite a considerable way with serious studies before he understands the chapters on transmission and on A.C. circuits. No harm is done, however, by introducing these subjects, for they are subordinated to the main issue.

More particularly, the book covers magnets and magnetism, static electricity and machines, cells and batteries, electromagnetism, measuring instruments, telegraphs and telephones, induction coils, electric transmission, transformers, A.C. generators and motors, radio, electric railways, lighting, A.C. circuits, and gas-discharge tubes. The experiments and apparatus devised are such as any boy can carry out and make for himself.

The book is one of a series planned for boys with a craving for investigation, and it serves its purpose well.

S. A. S.

An Outline of Metallurgical Practice

By Prof. Carle R. Hayward. Second edition. Pp. xi+690. (London: Chapman and Hall, Ltd., 1941.) 38*s*. net.

THIS work is intended to serve as a reference book for engineers and also to assist students who are approaching the study of metals without previous practical experience. The first object is excellently fulfilled, it being understood that the term metallurgy is used in a restricted sense, to cover only processes of extraction and refining, and that it is almost entirely confined to American practice, although statistical tables of world production are included. Some previous knowledge is required of the reader, as many of the terms are not defined, and the 400 illustrations are not all self-explanatory. Thus there are several references to the Cottrell treater for dusts, but the fact that this is an electrostatic device is not mentioned. The most valuable feature is the description, under each metal in succession, of typical plants and processes, with drawings and photographs. Unlike many text-books covering similar ground, some of which have passed through many editions, the book is not burdened with accounts of obsolete processes.

Here and there, as in the section on magnesium, the lack of reference to European practice involves the omission of processes which are being used successfully, but on the whole the information is full and recent. In dealing with alloys and some smelting processes equilibrium diagrams and photomicrographs are given, without reference to them in the text, but their inclusion is stated to be deliberate, and to be intended for students who have already followed a course in metallography. As no part of the discussion is based on them, the technical reader without such knowledge is not confused.

Each chapter concludes with a table of the principal properties of the pure metal, and where these have been checked they have been found accurate, although it is not enough at the present day to record hardness only on the Mohs scale. The book is well produced, but the large type employed makes it rather bulky.

C. H. D.

The Fauna of British India

Including the Remainder of the Oriental Region. (Published under the patronage of the Secretary of State for India in Council.) Edited by Lt.-Col. R. B. S. Sewell. Diptera. Vol. 6: Family Calliphoridæ. By R. Senior White, Daphne Aubertin and Dr. John Smart. Pp. xiii+288. (London: Taylor and Francis, Ltd., 1940.) 18*s*.

THIS latest addition to "The Fauna of British India" series deals with a group of considerable economic importance, since it comprises those creatures known as 'blow-flies'. At the same time it is concerned with a group greatly needing thorough study. The authors regard the Calliphoridæ as forming a family separate from the Tachinidæ, to which they are closely related. They deal very fully with the external morphology of its members and include in the account a useful illustrated description of the male genitalia, which are of pre-eminent importance for the separation of the different species. While the primary object of their work is taxonomic, the authors give indications regarding the biology of the various species wherever anything at all is known on the subject. Notwithstanding the unpleasant habits of most of their members, the Calliphoridæ are a group of very definite biological interest owing to the diversity of larval and adult habits and the great range of coloration displayed by the flies.

We can recommend this volume as an admirable introduction to the study of the Calliphorids not only of India but of other tropical lands also. The fact that it only deals with what must be a very small proportion of the fauna of these insects will, it is hoped, induce resident Indian entomologists to collect and observe them with more interest than has been shown in the past.

A. D. I.

SCIENCE AND GOVERNMENT

THE future of the relations between science and government formed the basis of several contributions at the Conference on Science and World Order organized by the Division for the Social and International Relations of Science of the British Association and held in London during September 26–28.

Sir Richard Gregory, president of the British Association, in opening the session, pointed out that men of science can no longer remain indifferent to the uses to which the powers created by their researches are put. They have the right and the responsibility to ensure that the fruits of their discoveries are not left entirely at the disposal of agencies which do not understand their nature or which misuse their promise.

Dr. J. Negrin, formerly professor of physiology in the University of Madrid, and lately head of the Spanish Republican Government, maintained that recovery, reconstruction and the laying of foundations for a lasting peace will depend fundamentally on a successful union between statesmanship and science. No less on this union depends the attainment of the immediate objective of victory in the present conflict, a victory without which our plans will be in vain. Between the statesman and science a dual relation is possible: a passive one, wherein the statesman incorporates learning, assimilates the scientific method, and becomes imbued with the scientific spirit; and an active one wherein he makes use of the teaching and progress of science.

The relation between science and government in Great Britain was discussed by Viscount Samuel. A year ago our resources of scientific knowledge and ability were still being very insufficiently used. Of late there has been a marked advance as seen in Lord Hankey's answer to a question in the House of Lords, in which he gave a full account of the numerous research bodies and advisory committees which serve as a link between scientific men and Government departments (see NATURE, April 12, p. 432).

According to Prof. A. V. Hill, Foulerton professor of the Royal Society, there are Government establishments in which the spirit is a hundred per cent right; there are others in which it is miserably wrong. In the research establishments of the Ministry of Supply, the Scientific Advisory Council and its numerous committees, chiefly composed of independent men of science (including engineers), exert a considerable and beneficial influence. The Admiralty, on the other hand, with its traditional devotion to secrecy, has always resisted any suggestion that an advisory council containing independent men of science should be set up to take an interest in its research. In the Air Ministry and now in the Ministry of Aircraft Production the conditions are intermediate.

It is not necessary—indeed it would be absurd—to ask that an organization of the magnitude of the Scientific Advisory Council of the Ministry of Supply should be set up in every department; but a panel of two or three independent advisers at least is necessary if opportunities are not to be missed. It is essential, if the scientific minds of workers in Government employment are to be saved from sterility, and their souls perhaps from damnation, that there should be as little distinction as possible between them and those in the universities, in industry, and in other independent institutions. In Great Britain we do not believe in bureaucracy. Our national genius has evolved a system by which the activities of officials are continually subject to the advice and help and criticism of public-spirited citizens.

Prof. J. B. S. Haldane, professor of biometry in University College, London, compared conditions in Great Britain with those of the U.S.S.R. He pointed out that in Great Britain the distinction between the pure or academic scientist and his industrial colleague is fairly sharp. In the Soviet Union the gap is bridged in several ways. The same man or woman may work in an industrial laboratory and in one devoted to 'pure' research or teaching. Laboratories engaged in 'pure' research are occasionally assigned certain technical problems.

To prevent the formation of a bureaucracy, the Soviet system is resorted to. The workers in laboratories, including technicians, frequently meet to discuss its problems. In this way centralization from above is balanced by initiative from below.

As Prof. Hill pointed out, there are several ways of ensuring that the initiative and keenness of Government-employed men of science do not become blunted. One may encourage junior and senior workers alike to interchange freely with other departments, with industrial laboratories, or with universities; one may provide facilities for visiting workers, for coloquia and discussion meetings, and for attendance at meetings of learned societies; one may adopt a system analogous to that of the reserve of officers and other ranks by which the Fighting Services prepare for times of emergency. Many of the ablest workers elsewhere would rightly value a period of service in Government laboratories. The plan for a reserve of officers and for frequent and regular interchange between different kinds of institutions need not be limited

to science; it should be open to the Government service as a whole.

Mr. D. P. Riley, of the University of Oxford, speaking on the world planning of scientific research, put forward an eloquent plea for a greater share for the younger men of science in the counsels of scientific planning—a plea which it is hoped will receive sympathetic consideration. He suggested that as an essential supplement to present official plans, we put into direct contact with each other rank-and-file men of science in similar fields of science but working in different countries.

The past shortcomings of British colonial policy were discussed by Lord Hailey, who made several important suggestions for future consideration. It is advisable that the facilities afforded by all great imperial institutions of research should be utilized to the fullest extent and that the energies of colonial research workers should be strictly limited to problems requiring local inquiry. As Dr. Wilder Penfield, president of the Royal College of Physicians and Surgeons of Canada pointed out, if the universities of the United States and the Dominions were kept fully informed on all problems, they might well take up the torch of practical research.

The application of scientific organization to a department of State can be divided into five interlinked stages, according to Prof. J. D. Bernal, professor of physics in Birkbeck College. These are: (*a*) Information, where modern investigation, sampling and statistical methods are used to find the nature and extent of the needs to be satisfied: from this, by analysis, problems can be formulated. (*b*) Research, where the best answers to these problems can be arrived at. This involves a definite programme of work of every grade ranging from fundamental to *ad hoc* research, and good co-ordination between the different branches. (*c*) Development, where the solutions found are worked up into a state in which they can be used in practice. (*d*) Execution, or the putting of the plan into operation. (*e*) Control or the checking of the results by new statistical methods. This is a function of a control organization working in close conjunction with the information service.

The need for closer collaboration between Government design departments and people with production experience was emphasized by Dr. J. E. D. Swann, of the Association of Scientific Workers. Technical men on production or engaged on the development of Government designs frequently comment on the unsuitability of such designs for mass production. The necessity for changes is most appreciated by the younger men of science. Older men may dream dreams; but the younger men see visions of the immense possibilities inherent in science, and they must use this vision to remove the encumbrance of outworn traditions, to sweep aside the hindrances of selfish individualism, and to develop new methods of collaboration and planning. But as Prof. Hill said, if science becomes tied to emotion, to propaganda, to advertisement, to particular social or economic theories, it may cease altogether to have its general appeal, and its political immunity will be lost.

That emotion and intelligence, united in a common objective, obtain astounding results in thought, in action and in conduct was rightly claimed by Mrs. S. Neville-Rolfe, of the British Social Hygiene Council, who also pleaded for a fuller appreciation and utilization of youth in helping to muster the forces of evolution and directing them to the development of man.

There is an overwhelming need for collating, interpreting and applying the various discoveries and concepts in biology, psychology, physiology, anthropology and sociology—branches of knowledge so pitifully ignored by communities and governments. The science of social biology is scarcely recognized at present; but it is one which will need to be incorporated in whatever form the policy of world reconstruction and re-planning takes after the War. In fact, the main problems of social biology are immediate, though they may take a rather modified form during the War.

As Prof. Hill stated, the deliberate application of science in government is a new method; it has never been properly or whole-heartedly tried. If it is to have a chance of success now, it must be saved from the start from sloppy thinking, careless handling or unscrupulous use. Nevertheless, Dr. Negrin stated that in periods of transition and readjustment, such as the present, science provides the statesman with a means by which he can discriminate the noxious from the sound. It provides the touchstone to reveal the senescence of traditions and to point out those which should be removed. Science can help the statesman to remove antagonism in social life and contradictions in individual conduct and collective behaviour; also to correct professional deformations in the statesman himself, by maintaining a balance in his qualities.

It is the duty of science to share actively in the search for remedies. Viscount Samuel pointed this out and added that religion and philosophy are engaged in the same quest. Only when all three recognize that they are interdependent and move together in search of the common goal will the problems of our troubled age approach their solution.

From the above contributions alone, it is seen that the commonwealth of science is a true democracy, and must, therefore, take its right place in the counsels of the world for re-planning democracy when the time comes.

SCIENCE AND THE WORLD MIND

ALTHOUGH no thorough analysis of the concept of world mind was attempted at the Conference on Science and World Order, certain aspects of human consciousness were emphasized and many interesting avenues for further investigation were opened

Mr. H. G. Wells issued the challenging statement that there is no orderly world mind as yet but only a world dementia, a gabble of unheeded and inconsecutive utterances, and that it is the business of scientific men to prepare a working conception of organized will and knowledge upon which mankind can go.

For man as a social being, the essential thing is that he stands at the growing point of a vast evolutionary process the characteristics of which we can see pretty well, according to Dr. J. Needham of the University of Cambridge. The march of living organization, the progress of the world mind, will not stand still where it is to-day. For us, at the middle point of time, the first duty is to appraise the social forces at work around us, to see in what direction they are leading: Which of them make for higher social organization, greater human unity, community and solidarity? This is the point from which we should approach traditional systems of morality.

Science is man's consciousness, his collective property of knowledge about the world in which he lives, according to Prof. Max Born, of the University of Edinburgh. For practical purposes we all agree about the direction which we wish it to take: peaceful co-operation, a maximum of freedom for the individual combined with the optimum of organized efficiency in production, economic and political security as formulated in the Atlantic Charter.

Mr. Wells stressed the fact that conditions of human life have changed so fundamentally during the last forty years that *Homo sapiens* cannot go on living as he has been doing during the past few score thousands of years. If he fails to adapt himself to the new conditions he will degenerate or perish altogether.

Aviation, radio and other means of communication have abolished distance. A stupendous increase in the power of realizing and utilizing material energy has reduced the need for unskilled labour and has led to technological unemployment.

States and communities to-day are biologically different organisms from what they were a few hundred years ago. The average age and literacy are greater; new factors—advertising and propaganda, mass production and selling—have crept in. If there is to be peace on earth henceforth, there must be a federal control of the air and of the material of international transport; of the conservation of world resources, and a declaration of human rights that will ensure for everyone a fair participation in the world's resources and a responsible ownership in our planet.

Immediate steps should be taken towards the development of a world mind: a world language with suitable spelling and phonetics and words that do not change their meaning according to circumstances and are not easily misunderstood. Finally a world-wide memory—a world encyclopædia—or better a world institute of thought and knowledge.

On the question of a world language, Mr. Wells, while highly critical of English as it now stands, considers that some slightly modified form of Basic English, with simplified spelling, might well form the basis for an international language. Prof. L. Hogben, who stated that four hundred international universal languages have been put forward since the seventeenth century, considers that Basic English possesses many of the necessary qualifications for an international language; but he is doubtful about using any of the current languages as a basis because of the prejudices associated with them.

In the matter of spelling Mr. Wells quoted Mr. G. B. Shaw as saying that about forty-one characters are needed to cover world needs.

The institute of thought and knowledge, the world-wide memory organization for the world mind, must have ready access to all the world's learning and thinking. It would include all the museums, galleries, libraries, atlases, surveys and muniment rooms in the world. Much has been done in the matter of documentation to bring together materials from a great number of countries, and the method of microphotography developed by Dr. Kenneth Mees and Mr. Watson Davis of Science Service, Washington, enables the contents of a whole library to be condensed in a small box. In addition we need for the work-room of the world mind general and particular digests, prepared by hundreds of thousands of workers continually bringing up to date and re-planning the general and particular summaries.

Mr. Wells sees in the British Association, and particularly in the Division for the Social and International Relations of Science, and in kindred associations throughout the world, the making of a great international organism for pooling the scatterbrain world into a sane effective mentality.

Through the British Association the specialist can teach and learn and yet remain human.

A proper development of the world mind can only be achieved by a correct education of the young and the re-education of the adult mind to appreciate the full significance of the developments of science. In addition, as Prof. Born pointed out, if science is to be taught in a way appropriate to its place in the world order there must exist a clear idea of the order. This is a question of economics and politics guided by principles of philosophy and religion. The two extreme and opposing theories of dialectical materialism and individualistic idealism need not be irreconcilable any more than the two theories of light, the corpuscular and wave theories, to which Bohr's principle has supplied a solution, namely that waves and particles are limiting cases suitable for the description of particular aspects of the phenomena, two different languages telling the same tale, not contradictory but complementary. We cannot eliminate from human affairs either the collective or the individualistic aspects any more than we can deal with radiation without using notions both of particles and waves. We have to reconcile the individualist with planning, which is unavoidable, and the socialist with freedom of research, which is imperative.

Dealing with the curriculum of schools, Mr. J. A. Lauwerys, of the University of London Institute of Education, stated that much of it has been inherited from a pre-scientific age and that great changes are urgently needed. We must make sure that the material presented during the lessons is relevant to the needs and the conditions of twentieth-century industrial society. A curriculum planned around natural science and social studies is required. To this end a study of the history of science and technology, such as the eight million dollar research into curriculum needs, carried out over the last ten years in the United States, is enormously valuable. Science will cease then to be a specialized study and will help to explain social organization and get people used to thinking in terms of human welfare.

Mr. J. G. Crowther, of the British Council, dealt with the education of the adult mind. In his view contemporary automatism—repetition of the same errors by nations with different forms of governments—is due to a lack of adaptation of social forms to the possibilities of technique and can only be remedied by the scientific education of the general public.

Dr. Julian Huxley, in a paper circulated under the title of "Scientific View of Education as a Social Function", likewise advocates a proper education of the parents as a prime essential. He considers this necessary in order that they should not encourage and intensify the normal infantile repressions in the child. The persistence of such repressions into adult life has several disadvantages, notably the immobilizing of a considerable amount of so-called mental energy, deadlocked between the repressing and the repressed impulses.

Thus, in one sense, the most important single task of education is not an intellectual, but a moral and emotional one, the substitution of conscious, in place of unconscious, repression in the light of tolerance and reason.

The education of the emotional aspect of personality was even more strongly emphasized by Mrs. S. Neville-Rolfe. Every educational system, she stated, has concentrated on the training of intelligence, none has yet taken cognizance of the paramount influence of the emotional condition of man or his behaviour, or attempted to apply even our present knowledge of psychology, etc. (see p. 425). A true democracy can only be created by those who are emotionally and intellectually developed, inspired with a positive purpose in life. The emotionally immature belonging to a previous generation, are not qualified to govern or to lead youth in the present world crisis. The young to-day have a deep sense of spiritual values. They can appreciate the opportunity and accept the responsibility of mastering the forces of evolution and direct them to the development of man.

The Conference scarcely touched upon the problem of how to obtain agreement and unity of action among scientific workers, a point raised by Mr. Wells in his opening remarks. All those who have followed the deliberations of groups of highly intelligent men and women, from the League of Nations Committee for International Intellectual Co-operation onwards, cannot have failed to appreciate the difficulty of obtaining a result commensurate with the great abilities of those represented on such committees.

It seems well worth while investigating how to bring about the necessary unity of feeling, and to arouse sufficient enthusiasm among people agreed intellectually upon the work to be done in order to enable them to pull together as a team. Co-opting more of the younger men in the counsels of science will undoubtedly help much towards this badly needed unity. At present some of the more progressive men of science feel keenly the neglect of their services, especially when older authorities are complaining of having too much to do, too many committees to attend, etc. Once this feeling almost of frustration is eliminated, and younger men are given their rightful place in the advancement of science, a closer unity of feeling will be established.

PHYSIOLOGY AND ECOLOGY OF CUTICLE COLOUR IN INSECTS

By Dr. Hans Kalmus

Department of Biometry, University College, London

SEVERAL papers have recently been published describing differences in the physiological properties of dark- and light-coloured cuticles of insects. Pryor[1], Fraenkel and Rudall[2], and others have shown that the darkening and hardening of the cuticle are one and the same process—a dehydration resulting from the formation of coloured compounds of protein and polyphenols. The darker the cuticle, the harder and drier it will be.

Mackenzie and Muller[3] have demonstrated that resistance to ultra-violet radiation, as measured by the survival-rate of individuals and the mutation-rate of their offspring, is greater in the wild type of *Drosophila melanogaster* than in its yellow mutants. Experiments by Buxton[4] on heat absorption indicate that dark insects become warmer than light ones when exposed to sunlight. These results suggest that the usual explanations of colour differences as protective mimicry and warning signs, which are reviewed in Cott's book, "Adaptive Coloration in Animals"[5], do not completely account for all the phenomena of insect coloration.

There appear to be five main differences in the physiological properties of dark and light insect cuticles.

(1) A dark cuticle gives better protection against high-frequency radiations. (2) A dark cuticle absorbs radiant heat more readily; it also loses slightly more heat. (3) A dark cuticle is tougher and mechanically more resistant. (4) A dark cuticle is less easy to wet. (5) A dark cuticle gives better protection from desiccation.

An individual developing a dark cuticle must necessarily have a different metabolism from a light-coloured member of the same species.

It is not suggested that these differences apply in all cases. In some insects, though certainly not in many, the hardening and darkening processes may be independent. The physico-chemical processes resulting in hardening without darkening, or in darkening without hardening, can be presumed to differ from the processes investigated by Pryor and by Fraenkel and Rudall, and they are probably worth a separate investigation. Perhaps the findings of Hurst[6] on the behaviour of the cuticle towards apolar substances may have a bearing on this problem. Again, metallic colours are usually the combined effect of dark chitin and a special surface structure. Such iridescent structures, while having most of the physiological properties of dark cuticles, will behave like light-coloured objects so far as absorption of heat is concerned. Dark coloration that is not localized in the cuticle, as in the scales of Lepidoptera and the subcuticles of hemimetabola such as stick insects and dragonfly larvæ, will also not necessarily confer the physiological properties listed above. But after full allowance is made for these exceptions, the new findings allow of the formulation of a number of new general rules, indicating new phenomena and giving the first satisfactory explanation of several facts already established. These rules may be listed and classified as follows.

A. Protection from Light

Rule 1. *Of two related forms, the one more exposed to ultra-violet radiation will be the darker.*

For example, melanic forms of insects are found at high altitudes, while those the habitat of which is shaded from light are pale in colour. The pale insects living in caves and under bark and stones die easily when exposed to sunlight. This is reported for Campodea by Handlirsch[7]. Aquatic larvæ such as those of Corethra, which live at a considerable depth and are screened by the water, are colourless, while other mosquito larvæ which live near the surface are dark.

B. Absorption from Heat

Rule 2. *If the mode of life of an insect is such that heat absorption is advantageous, it will be dark; if it is irrelevant or disadvantageous, it may be pale.*

Lord Walsingham[8] first suggested in 1885 that dark insects absorb more heat than pale ones. This has been proved by Buxton[4]. It is not correct to assume, as Schröder[9] did in his "Wärme-Schutztracht-Theorie", that a high heat absorption is always advantageous. Buxton points out that it is obviously a disadvantage to black desert forms, the dark colour of which is explained by rule 12. The small snow insects, which are often dark, must absorb as much solar heat as they can, for their size prevents them from producing or retaining much internal heat. Insects in temperate climates, like butterflies and diurnal moths, which are active during the day, have a dark cuticle, and nocturnal moths a light one.

C. Mechanical Strength

Rule 3. *Those parts of the insect body wall which are subject to great mechanical strain are usually dark.*

Examples include the dark mouth armature of

many otherwise light larvæ ; the dark colour of bee stings and many ovipositors ; and the dark head and thorax of termites and other insects which are otherwise pale. The Ipidæ which mine under the bark of living trees are dark, whereas insects and larvæ living in decaying wood are usually white. In general, boring insects show only a dark armature and head, while burrowers like the mole cricket are entirely dark. The place of insertion of the muscles in beetles is frequently dark (Tower[10]).

Rule 4. *Giant forms are usually black ; bright colours are more frequent among small insects.*

Rules 3–7 depend on the assumption that a dark cuticle is mechanically the stronger. This has not yet been directly proved. It is, however, a fact of common observation that the pale cuticle of the newly emerged imago is more easily deformed than the hard, darkened cuticle of the older insect.

Rule 5. *Hemimetabolic (heterometabolic) insects, before their last hatching, are rarely black.*

The cockroach is an example. A hard cuticle is difficult to moult, hence the exuviæ of hemimetabola are usually whitish or transparent, sometimes with dark mouth armatures and joints. It is also most likely that autotomy only occurs in hemimetabola as a hard cuticle would be difficult to break. It is interesting that very few Crustacea have a black cuticle ; Crustacea continue to moult throughout life. There may be some exceptions among terrestrial forms like land crabs and land isopods.

Rule 6. *Heterometabolic adults are found in the same habitats as their larvæ, holometabolic insects rarely so.*

The persistence of a similar cuticle confines the hemimetabolic insects to a similar environment throughout life. A good illustration is the contrast between the white termites and the dark social Hymenoptera.

Rule 7. *Holometabolic larvæ are paler than their imagines.*

This also follows from the need to moult. Exceptions are to be expected where the larvæ need more protection against desiccation than the adult forms. The larvæ of many Carabidæ and Staphylinidæ, especially if they lead a predatory life, darken deeply after hatching and after every moult.

D. Water Repulsion

Rule 8. *The parts of the insect body where wetting must be avoided are frequently dark.*

For example, the tracheal ends of many metapneustic insect larvæ, living in a liquid or semi-liquid substratum (Drosophila, Eristalis, *Gastrus equi*). Many water beetles are black. Of course, wetting can also be avoided by other means, for example, hairs or oil smears.

E. Resistance to Desiccation

Following on the demonstration by Fraenkel and Rudall[2] that dark and light cuticles differ in water content, Kalmus[11] found differences in the resistance to desiccation of body colour mutants, of Drosophila. In *D. melanogaster* the dark mutants, ebony and black, lost less water and lived longer in a dry atmosphere than the wild type, whereas the light mutant, yellow, lost more moisture and died sooner. Yellow mutants of *D. simulans*, *D. pseudo-obscura* and *D. subobscura* were less resistant than their wild-type allelomorphs. A dark cuticle therefore appears to be a better protection against desiccation than a pale one. The fact that the proportion of water lost from the tracheæ and the body surface is still a matter of controversy does not greatly affect this deduction. Some water is certainly lost through the body wall, and the cuticular layers of the tracheæ are the same colour as the body. The implications of this deduction are of a highly complex but very interesting character.

In my opinion too much stress has been laid on macro-climatic data and on isolated determinations of temperature and humidity in considering the water needs of animals. Measurements of the micro-climate of an insect's environment, and even more direct investigation of its water supply and losses, will certainly lead to a better understanding of the adaptations and protective mechanisms of different species. Almost every insect gradually dries throughout its life, and in natural conditions very many insects die from desiccation before other causes intervene. Hence perhaps the statement of antique authors "Nihil inest". We may deduce from this that the longer the life period of an insect, the greater its need for protection from desiccation, leading to the following suggested rule.

Rule 9. *Long-lived insects are darker than their short-lived relatives.*

Extremely short-lived insects, such as some mayflies, are pale.

Rule 10. *Hibernating and æstivating insects are dark.*

This is not limited to imagines. The eggs of many Phasmodea which are dropped haphazard in the open and take a considerable time to hatch are dark and hard. The eggs of Tipulidæ laid in a similar manner are also dark, whereas the eggs of other Diptera which are deposited on a moist substratum are pale and soft. The triungulid larva of Meloe which hatches in spring is pale, while the triungulid larva of *Sitaris moralis* which hatches in autumn, and hibernates, is black.

Rule 11. *Most non-black insects are found in the tropics. Their related forms become darker as one approaches the poles.*

According to Van't Hoff, a fall in temperature

of 10° C. doubles or trebles the life period; but evaporation is decreased by only about 40 per cent. Hence tropical forms need less protection from evaporation than forms living in cooler regions. Examples can be found in many insect groups. Sturtevant[12] has described this colour gradient in the Drosophilidæ of the New World. The Drosophilidæ of Japan, judging from the description and figures of Kikkawa and Peng[13] show the same correlation between colour and latitude. Alpatov[14] has found that the honey-bees of European Russia are larger and darker in the north than in the south. There is a gradient between the two forms, except in the Caucasus, where dark bees are found.

Rule 12. *Insects exposed to drought are dark.*

Some species of desert insects are conspicuously black, though most are the colour of the sand (Buxton[15]). It therefore seems that increased protection from drought can to some extent counterbalance the disadvantages of absorbing more heat (rule 2), and of being more conspicuous. The dark cuticle of many scorpions living in dry habitats may be explained on similar lines, although they are not insects. Where drought occurs without extreme heat, as on salt soil, larger proportions of the insects are black. Many insects flying in the hot sunshine, for example, metallic insects like dragonflies and beetles, combine a dark undercuticle, which will protect them from drying, with a reflecting superstructure that will probably protect them from over-heating.

Rule 13. *Insects which ingest abundant liquid food are frequently pale.*

This is particularly true of parasites, such as most aphids, bugs and lice. Fleas are an exception. They not only migrate, but are exposed to greater mechanical danger by their mode of activity.

Rule 14. *Insects with a wide range of activities are darker than their relatives living in permanently moist conditions.*

Wide-ranging insects and predators are frequently darker than sedentary and phytophagous forms. Island insects and forms living in small communities in widely scattered biotopes, such as small puddles, where conditions may frequently become unfavourable, may be expected to be dark; for their survival depends on their ability to resist desiccation until they again find a favourable environment.

There must, of course, be metabolic differences between pale and melanic individuals of the same species, but our knowledge of them is very meagre. Graubard[16] was unable to demonstrate any differences in the tyrosinase content of the imagines of various body-colour mutants of Drosophila, though he was partially successful in showing differences in the larvæ. The mouth armature of Drosophila larvæ in mutants of lighter body colour are usually lighter than those of wild type larvæ (Brehme[17]). The industrial melanism of insects affords an interesting field of study. One explanation often put forward, mentioned in Wigglesworth's "Insect Physiology"[18], is that the melanism is a mechanism for fixing and neutralizing the toxic organic substances produced by industrial operations. But there are many alternative hypotheses. Thus Ford[19] believes that conspicuousness is not a great disadvantage in industrial districts, where there are few predators, thus allowing the black varieties, which he and other investigators describe as "hardier", to establish themselves in competition with the less noticeable but more delicate cryptic forms. A third hypothesis is that the contaminated food of the insects in industrial districts induces gene mutations producing melanism. A great deal of work is obviously needed before these questions can be decided.

Some cases are known in which the nature of the larval environment of the individual affects the body-colour of the imago. Thus lepidopteran larvæ subjected to increase of humidity or decrease of temperature usually produce darker imagines. This has little bearing on our problem, as in this order of insects coloration is due to pigment in the scales rather than in the body-wall proper. In the beetle *Leptinotarsa decemlineata*, individuals in which the white stripes were enlarged were produced from larvæ reared in moist air (Tower[20]). This fits in with the rules enunciated above. But other species of beetles and other insects react in the opposite way to changes in humidity. These reactions of the individual are not necessarily relevant to the problem of the adaptation of a species to special ecological conditions. It is generally agreed that characters acquired by the individual are not inherited. The important factors are mutation and selection. The rules already given show the ways in which selection may be expected to act. Mutations producing the colour changes that form the raw material for selection are known to occur in many insect species in Nature. Sometimes the genes reponsible for the darker forms are dominant, sometimes recessive. In Drosophila, as in many other species, it has been proved that great differences in body colour may result from the mutation of a single gene. Different alleles must have become fixed in the different species. In some cases, such as *D. melanogaster*, *D. simulans* and *D. montium*, rather light forms have become established as the normal, and both the very dark forms, like ebony and black, and the extremely light forms, like yellow and tan, are aberrant mutants. On the other hand, there are many dark Drosophila species where the colour mutants are all lighter than the normal

type. Although body colour primarily depends on a very few genes, its stabilization in a species must be determined by many other genetical factors.

The fact that so many kinds of insects, probably the vast majority, are dark, might be put forward as an objection to the above rules. If dark colour is so widespread, why not treat it as the normal thing, instead of formulating rules to account for it in each particular case? But if this view is taken, it is still necessary to account for the existence and distribution of the light-coloured forms, which amounts to the same problem. Handlirsch[7] points out that most of the primitive types within the bigger and higher insect groups are dark. This fits in with the views on the functions of melanism here put forward, if it is assumed that the development of a supporting exoskeleton and the conquest of the air by these creatures is made possible only by heavy chitinization. But any specialization which leads to life in an environment where water supply is plentiful and great mechanical strength is not demanded will remove the necessity for dark coloration and allow the production of pale insects. On the other hand, the primitive orders of insects, the members of which have probably never strayed from a rather damp and sheltered environment, contain many pale forms which are only slightly resistant to desiccation, such as Campodea (Handlirsch[7]).

The rules suggested above will often appear contradictory when applied to the ecology of a given insect species. Some factors in its mode of life will call for dark coloration, others for paleness. The colour actually observed will then indicate what are the controlling factors in the ecology of the species. Take for example the colour gradient of related forms between tropical and colder regions. By rule 1, it would be expected that tropical forms, being more exposed to ultra-violet radiation, would be darker. The opposite is actually observed, showing that protection against evaporation, prescribed in rule 11, is the more important factor. In alpine insects, where increased ultra-violet is associated with decrease of temperature, the two factors operate in the same instead of in opposite directions, and dark colour increases with altitude. There is a similar conflict between the effects on the cuticle colour of increase of size. Because of the need for greater mechanical strength, large insects may be expected to be dark. On the other hand, small insects would seem to need more protection from desiccation, and hence have a darker cuticle than large forms. But the life period of small insects is generally shorter than that of their larger relatives, lessening their need for protection. So on balance it is among the small insects that the majority of non-black forms are found.

There are also numerous cases where several factors in the ecology of an insect act jointly in the direction of a dark (or pale) colour. The dark colour of alpine insects has already been mentioned. In the case of the tsetse fly, the dark colour may be put down to its relatively large size, its diurnal activity in a dry region, its wide range, scattered habitat, or its long life as an imago, all of which, according to our rules, favour pigmentation.

This interpretation of the physiology and ecology of dark chitin, based on its newly detected physical properties, is of course not intended to replace entirely all the conceptions about colour adaptation previously formulated. On the other hand, hypotheses about imitative coloration and the like cannot but gain in certainty and precision when the physical factors are also taken into full account. The groups of organisms the colour of which is not explicable by the above-mentioned consequences of the darkening-hardening process provide the most suitable material for the study of mimicry. Examples of this are the subcuticular colour patterns of aquatic larvæ or nymphs, for example of dragonflies; the wing patterns of Lepidoptera; the body coloration of hemimetabola. Physical and cryptic advantages might also conflict, as in the case of industrial melanism, if Ford's hypothesis is correct, and among the desert populations described by Buxton, consisting of imitative sand-coloured as well as drought-protected dark individuals.

It is hoped that the new rules and considerations suggested in this article will not only provide the entomologist with a new point of view in his endeavours to bring order into his subject, but that they will also be of more general interest. Insect coloration has always been a sort of testing-ground for the theory of evolution; and insects, after all, comprise the majority of all animal species.

OBITUARIES

Mr. William Macnab, C.B.E.

BY the death of Mr. William Macnab, on September 2, at the ripe age of eighty-four, we have to record the loss of one who not only made original contributions to our knowledge of explosives, both as to their properties and manufacture, but who in addition must be considered as a pioneer in the recognition of the importance of chemical engineering in Great Britain.

Coming from Greenock, his father being a shipbuilder there, he took up the subject of sugar chemistry, after a training at the University of Glasgow, where he made a life-long friendship with Ramsay. Fond of travelling, he spent some time in Germany in connexion with sugar and later in Canada and the United States; in Siberia also he passed an adventurous two years engaged in prospecting. He could converse readily in French, German and Russian.

About the age of thirty Macnab took up a consulting practice in partnership with C. Napier Hake and carried this on after his partner had left for Australia to become Inspector of Explosives for Victoria. It was at this period and in collaboration with Napier Hake that he undertook the translation and collation of Berthelot's papers on explosives, publishing in 1892 "Explosives and their Power", which is a handbook constantly referred to by all explosives chemists. This book describes the application of thermochemistry to explosives, gives Berthelot's calorimetric data for explosive reactions over a wide field and deals with many explosive phenomena.

At this time Macnab began his original contributions to the study of explosives, and with E. Ristori published researches on partially gelatinized and on fully gelatinized propellants (*Proc. Roy. Soc.*, 56, 8; 1894). A bomb of the Berthelot type was used; heat values and volumes of gases given off with their composition were measured, together with the metamorphosis undergone by gelatinized mixtures of nitroglycerine with various nitrocelluloses when exploded in the bomb. This work had importance as well as accuracy, as was shown by the agreement of products with original composition of explosive. Pressures were measured in another bomb and these agreed with the values found by Sir A. Noble. Later (*Proc. Roy. Soc.*, 66, 221; 1900) the same authors described attempts to determine the temperature of explosion (apart from its calculation from heat values and specific heats) by a method depending on the use of thermocouples of gradually decreasing diameter, the deflexion of a galvanometer mirror being photographically recorded. Although absolute values for temperature were not obtained, the results placed different explosive mixtures in a comparative sequence. This subject was continued in collaboration with A. E. Leighton (*J. Soc. Chem. Ind.*, 23, 298; 1904) when the heat values were compared with the galvanometer throws, the order of the powders being broadly the same in both cases.

Always interested in chemical manufacture, Macnab played an important part during the War of 1914–18, when he became a technical adviser on Lord Moulton's staff, where full use was made of his experience in the manufacture, as well as knowledge of the properties, of explosives. Working in close conjunction with Kenneth B. Quinan he was intimately associated with the design of factories for high explosives and propellants, as well as with their administration when erected. Impressed by Quinan's method of holding monthly meetings of his factory staffs at which costs and efficiencies were minutely discussed, resulting in notable improvements in technique, Macnab undertook after the War the compilation of an important series entitled "Technical Records of Explosives Supply, 1915–1918" (H.M. Stationery Office), dealing with intermediates and finished explosives. These are valuable studies in which the chemical engineering aspect is emphasized, and serve as text-books for any school in that subject, for they include not only the theory of the processes, but also sketches of designs of plants, instructions for running them, calculations of heat-transfer and loss, and choice of materials of construction. They are so framed as to assist a student engaged in general chemical engineering problems, not necessarily those dealing with explosives.

This methodical approach appealed to Macnab, who lectured on the subject at University College, London, and led to his support in starting the Department of Chemical Engineering there. This movement was strongly urged by Quinan also who had felt the grievous lack of chemical engineers during the War of 1914–18. Some chemical achievements during this time were described by Macnab in his Hurter Memorial Lecture in 1922. For the same reason he acted as one of the founders of the Institution of Chemical Engineers, becoming its president in 1934, the William Macnab Medal of that Institution commemorating his name. Much of the success of the Seventh International Congress of Applied Chemistry in 1909 was due to him. For his work in the War he was made a C.B.E. in 1920.

Of striking appearance, suggesting robust health, with rosy cheeks and pointed beard, always dressed with perfect neatness, he will be remembered for his geniality and unselfish kindliness; and his friends will remember the hospitality of his charming wife and himself at his house on the river, where it was his custom to entertain them, take them out in one of his craft, for he was a master sailor, and to some of them show his experiments in calorimetry with a large bomb that needed his athletic frame to manhandle. In his London house also, his skill at the piano and liking for good music will be remembered by many.

ROBERT ROBERTSON.

NEWS AND VIEWS

Foundation of a Nutrition Society

Workers engaged in research on nutrition in Great Britain have been feeling the need for a scientific society devoted specifically to their subject. In the past no organization has existed to enable investigators in the many and varied branches of the science—clinical, physiological, agricultural and sociological—to find a common meeting-ground for discussion and the exchange of views. Representative workers in all these fields accordingly decided recently to form a Nutrition Society. The new venture owes its conception to a circular letter signed by the following heads of some of the better-known centres for research on nutrition in Great Britain: Sir Joseph Barcroft, chairman, Food Investigation Board; Dr. Harriette Chick, head of the Division of Nutrition, Lister Institute; Prof. J. C. Drummond, scientific adviser to the Ministry of Food, and professor of biochemistry in University College, London; Dr. John Hammond, superintendent of the Animal Research Station, Cambridge; Dr. Leslie J. Harris, director of the Nutritional Laboratory, Cambridge; Sir Frederick Gowland Hopkins, professor of biochemistry in the University of Cambridge; Prof. H. D. Kay, director of the National Institute for Research in Dairying, Reading; Sir Charles J. Martin, formerly director of the Lister Institute of Preventive Medicine; Sir Edward Mellanby, secretary of the Medical Research Council; Sir John Orr, director of the Rowett Research Institute, Aberdeen; Prof. R. A. Peters, professor of biochemistry in the University of Oxford. Later a meeting was held at the Royal Institution attended by representatives from the various institutes, and the following provisional committee was formed: Sir John Orr (*chairman*); Dr. John Hammond (*vice-chairman*); Dr. Leslie Harris (*hon. secretary*); Mr. A. L. Bacharach (*hon. treasurer*); Dr. Harriette Chick, Dr. E. M. Cruickshank, Dr. H. H. Green, Prof. H. P. Himsworth, Prof. A. St. G. Huggett, Dr. Franklin Kidd, Dr. S. K. Kon, Dr. B. S. Platt and Dr. H. M. Sinclair.

It is, of course, not intended that the new Society should compete in any way with existing scientific societies; its functions would be complementary to theirs and would cover a more general and in some ways less specialized field. It is proposed that the main activity of the Society at the beginning should be to hold meetings at various research institutes, at each of which some specific topic should be discussed; several main papers would first be read and would be followed by a general discussion. Arrangements have been made to hold the first conference of this kind at Cambridge on October 18, when the theme will be "The Evaluation of Nutritional Status". Further particulars of the Society can be obtained from Dr. Leslie Harris, Dunn Nutritional Laboratory, Field Laboratories, Milton Road, Cambridge.

Food Values of Eggs and Cheese

Healthy and well-informed public criticism is good for all Governments, particularly when, as was the case in the House of Lords debate on September 30, it is constructive in nature. The debate dealt mainly with the Government food production policy, and a good case was made out for Government support to poultry keepers in their efforts to obtain maximum egg production consistent with the maximum production of crops suitable for direct use as human food. Viscount Dawson stressed the essential value of the egg as a constituent of human dietaries, not only for its use in preventive medicine, but also because of the unique part it plays with milk in maintaining the health and vitality of children and in keeping the active population well and fit in time of war. He maintained that it would be a mistake to penalize egg production in times such as these, and in this view was supported by Lord Phillimore, who hopes that further egg production will be encouraged. That the adoption of such a policy would be in the national interest is substantiated by an article in Nature of September 20, p. 335.

References were also made to the possible utilization of two protein-rich products for animal feeding. The first, a by-product in the production of acetone, has been proved to be of value as a protein concentrate in poultry-rearing mashes, and is characterized by containing not only protein in large amount, but also in addition appreciable quantities of riboflavin and lesser amounts of pantothenic acid. The second, a synthesized vegetable protein, appears to be 'fodder yeast', a product obtained by the fermentation of molasses and ammonium salts by means of *Torula edulis*. This material received the attention of the Royal Society in the War of 1914–18, and Temperton of the National Institute of Poultry Husbandry has shown that this 'fodder yeast' is a suitable substitute for fish meal in egg production rations.

A plea was also made during the debate for the encouragement of the production of ewe milk cheese. The contention that more human food would be produced by converting ewe milk into cheese than by producing mutton is undoubtedly correct; putting it into practice, however, is the difficulty, since it means setting up a new industry as well as introducing complications in the already difficult circumstances in which the arable or grassland sheep farmer is at present working. On technical considerations it is always possible to induce a change of Government policy, since the outsider may often be better informed than the technical advisers upon whose judgment the policy has been based. Criticism, based on quantitative considerations, although well-meaning, is almost always bound to fail, since the full knowledge of the position upon which the policy is based can only be known by the Government.

Dean of the Faculty of Medicine at Birmingham

DR. A. STANLEY BARNES has resigned his post as dean of the Faculty of Medicine in the University of Birmingham after ten years in office. Dr. Barnes, who was a student of Mason College, in addition to being closely associated with the local hospitals, attained an outstanding position as a consultant. About ten years ago he sacrificed his professional practice to become dean of the Faculty of Medicine, in which office he assisted in the planning and building of the City Hospitals Centre and the new Medical School of the University. He was a liberal donor to the building funds of the Medical School, and the perfection of the building and equipment reflects in many directions both his discriminating generosity and constant supervisory care. The Council of the University has recorded its grateful recognition of the valuable and devoted service which he has rendered to the University and to the cause of medical education in Birmingham generally.

Dr. Barnes is succeeded as dean by Dr. Leonard Gregory Parsons, professor of infant hygiene and diseases of children, who has been acting as deputy dean. Dr. Parsons, who was educated at King Edward's School, Aston, and the University of Birmingham, is physician to the United and Children's Hospitals, and was chairman of the Children's Hospital, an office which he resigned in January last, to become Midland Regional Hospital Officer to the Ministry of Health. During 1916–18, serving in the R.A.M.C., Dr. Parsons was officer in charge of the Medical Division 36th General Hospital, British Salonika Force, the Order of St. Sava of Serbia being conferred on him in 1917. He was vice-president of the International Congress of Pædiatrics at Stockholm in 1930 and president of the Children's Section of the Royal Society of Medicine during 1932–33.

Science and World Order

SPEAKING at a meeting convened by the Faculty of Science of Marx House on October 5, Prof. J. D. Bernal summed up the Conference on Science and World Order. The meeting, he said, tended to avoid reference to the difficulties of scientific planning at the present time. The first necessity is to win the War, and the time for planning is now. It is simple to see what we need from science, namely, an environment in which material things are at their best and have the ability to obtain a secure social life. Want and war are the two chief horrors of to-day. Science has pointed the way to remove them and will remove them if the peoples of the world co-operate with the scientific workers.

The attitude of complacency which existed in the higher scientific world is broken. Dissatisfaction is not confined to younger men of science but has reached the senior men. Dr. J. P. Lawrie, speaking at the same meeting, directed attention to the opposition displayed by high political personages when Prof. A. V. Hill organized a liaison between the men of science of Great Britain, the United States and Canada. He is of opinion that any plans made by men of science must secure the backing of the people before they can be put into effect by any Government. This means that men of science must thoroughly instruct the people, and this can best be done through the daily Press.

A Scientific Press Bureau

MR. D. S. EVANS, University Observatory, Oxford, writing with reference to the letter in NATURE of September 27 by Mr. D. L. Johnston urging the need for a scientific press bureau, states that the Association of Scientific Workers has devoted considerable attention to this problem. A scheme has been drafted by the Association whereby each of its more than fifty branches all over Great Britain can act as centres of diffusion for simple and accurate facts on scientific problems of current importance, and it is hoped that this organization will begin functioning in a few weeks. It is an amateur organization, but its possibilities are considerable, and experience will be gained which will be invaluable if, and when, a more formal body is set up. Mr. Evans states that the Association intends to develop this propaganda work for science by every means in its power, and co-operation with other organizations or individuals will be heartily welcomed.

Point is given to the proposal by headlines which appeared in a recent issue of a well-known London evening newspaper. The headlines read "Anti-Gas Serum is Being Sent To Russia"; the accompanying letter-press indicates that the reference is actually to gas-gangrene serum. The mistake is understandable, but nevertheless emphasizes the need for scientific guidance.

Dr. Arthur Gamgee (1841–1909)

DR. ARTHUR GAMGEE, F.R.S., physiologist and consulting physician, was born at Florence on October 10, 1841, the son of a veterinary surgeon and pathologist. From the outset of his career he showed a special interest in physiology, particularly physiological chemistry, as was evidenced by his inaugural thesis at Edinburgh entitled "Contributions to the Chemistry and Physiology of Fœtal Nutrition". From 1863 until 1869 he was assistant to Dr. Maclagan, professor of medicine at Edinburgh, during which time he published several papers showing his outstanding ability to deal with abstruse physiological problems. In 1873 he was appointed the first Brackenbury professor of physiology at Owens College, now the University of Manchester. During the thirteen years he was there he took an active part in the work of the medical school, of which he was dean, and wrote numerous articles on physiology and pharmacology. He was also Fullerian professor of physiology at the Royal Institution during 1882–85, when he left Manchester. Eventually he moved to Cambridge, where he devoted himself to scientific research. Finally, he decided to live abroad and settled first at Lausanne and afterwards at Montreux.

Gamgee's chief publications were "A Text-book of the Physiological Chemistry of the Animal Body, including an Account of the Chemical Changes Occurring in Disease" (1880–1893) and "Physiology of Digestion"

(1893). He also translated Hermann's "Elements of Human Physiology" (1875). In 1902 he visited the United States by invitation to inspect the physiological laboratories there, and in the same year delivered the Croonian Lecture before the Royal Society on "Certain Chemical and Physiological Properties of Hæmoglobin". He died on March 29, 1909; a portrait and bibliography will be found in the *Lancet*, 1, 1141 (1909).

Sir Richard Thorne Thorne (1841–1899)

SIR RICHARD THORNE THORNE, F.R.S., a notable hygienist of the Victorian era, was born on October 13, 1841, at Leamington, Warwickshire, the son of a banker. He received his early education at Neuwied in Prussia and at a Paris *lycée*, and his medical training at St. Bartholomew's Hospital, where he qualified in 1863. Eventually he was elected physician to the Royal Hospital for Diseases of the Chest and to the London Fever Hospital, and about this time he was employed by the Medical Department of the Local Government Board to make various reports. He first became widely known by his work on quarantine and the international relations for the prevention of the spread of disease from one country to another. From 1885 onward he attended many international sanitary congresses as a representative of the British Government, and in 1892 he succeeded Sir George Buchanan as principal medical officer of the Local Government Board. The subjects in which he was most interested were diphtheria, on the natural history and prevention of which he delivered the Milroy Lectures before the Royal College of Physicians in 1891; tuberculosis, the administrative control of which formed the subject of his Harben Lectures in 1899, and the establishment of isolation hospitals for infectious diseases. He was elected a fellow of the Royal Society in 1890 and was also an honorary member of the Royal Academy of Medicine of Rome and a foreign associate of the French Society of Hygiene. His death took place suddenly on December 18, 1899.

Recent Earthquake

A SEVERE earthquake shook Quetta and the surrounding country in Baluchistan at 8.4 a.m. local time (2.34 a.m., G.M.T.) on September 29, 1941. The shock was also felt, though less distinctly, at Sibi, Mach, and Chaman, all in Baluchistan. The shock, which lasted according to human perception for thirty-five seconds at Quetta, was accompanied by heavy rumbling, and caused considerable apprehension. Although telephone and telegraph communications were temporarily dislocated, no serious damage or casualties are reported, and railways were unaffected. This lack of damage might easily be due to the thorough building of the new city after the calamitous earthquakes of May 31 and June 2, 1935. The re-planned city was built to earthquake-proof design according to the best building codes of California as worked out by seismologists and engineers. After-shocks to the 1941 earthquake took place at 2.35 a.m., 2.54 a.m., 4.34 a.m., 5.4 a.m. and 8 p.m. (all G.M.T.) on the same day. It will be recalled that Quetta was levelled to the ground on May 31, 1935, and that an area approximately a hundred miles in diameter was devastated. A severe aftershock occurred on June 2, 1935, and altogether there were about 40,000 casualties (NATURE, June 15, 1935, p. 986 and several subsequent numbers). Severe shocks also occurred near Quetta in September and October 1937.

On September 29 at just after 5 p.m. G.M.T. an earth tremor of some severity rattled crockery and moved furniture at Bethesda, a town of some five thousand inhabitants in Wales. The shock, which lasted according to human perception for about three seconds, did not cause any serious damage or casualties. Two earlier tremors of less intensity occurred early on the morning of September 27. Earth shakes, probably due to mining subsidences and minor fault slips, occur fairly frequently in Wales. One such happened at Pwllheli on December 12, 1940 (NATURE, Dec. 21, 1940, p. 803).

Announcements

M. MAISKY, the Soviet Ambassador, has been offered and has accepted honorary membership of the Athenæum.

THE title of Sir Ernest Cassel reader in commerce in the University of London has been conferred on Dr. Vera Anstey, in respect of the post held by her in the London School of Economics.

DR. FREDERIC JOHN NATTRASS, lecturer in therapeutics and clinical teacher in medicine in King's College, Newcastle-upon-Tyne (University of Durham) has been appointed professor of medicine in the College.

THE Minister without Portfolio has appointed an Inter-Departmental Committee, under the chairmanship of Lieutenant-Colonel Sir Francis Shelmerdine, director-general of civil aviation, to make recommendations as regards the reconstruction, organization and development of civil aviation after the War.

THE fourth Hinchley Memorial Lecture of the Institution of Chemical Engineers will be delivered by Sir Richard Gregory, who will speak on "Scientific Knowledge and Action". The address will be given in the Institution of Civil Engineers on October 24 at 2.30 p.m.

The autumn meeting of the National Academy of Sciences of the United States will be held at the University of Wisconsin during October 13–15.

PROF. W. E. S. TURNER, professor of glass technology in the University of Sheffield, will deliver a lecture before the London Section of the Society of Glass Technology on "Glass as a Substitute Material" on October 15 at 4.30. The meeting will be held at the Electric Lamp Manufacturers' Association, 2 Savoy Hill, London, W.C.2.

Number of Primes and Probability Considerations

THE probability that a number chosen at random is divisible by p is $\frac{1}{p}$ and consequently that it is not so divisible is $1 - \frac{1}{p}$. On simple probability considerations, that is, provided that these probabilities are independent of one another, the chance that a number is simultaneously not divisible by a group of primes is therefore $\Pi\left(1 - \frac{1}{p}\right)$. Hence the probability that a number in the neighbourhood of N^2 is prime should be $P(N^2) = \overset{p_N}{\Pi}\left(1 - \frac{1}{p}\right)$ where p runs through the gamut of the primes from 2 to p_N the largest prime less than N. This product has the value $\frac{e^{-\gamma}}{\log p_N}$ where γ is Euler's constant.

If P is the probability of a number in a given region being prime, the number of primes in an interval Δ in this region must be on the average $\Delta . P$. Hence the number of primes in an interval Δ in the neighbourhood of N^2 should approach $\frac{\Delta}{e^{\gamma}} \frac{1}{\log p_N}$.

For large values of N, we may substitute $\log N$ for $\log p_N$, since the interval between successive primes is of the order $\log N$. Hence the number of primes in an interval Δ in the neighbourhood of N^2 should tend to $\frac{\Delta}{e^{\gamma}} \frac{1}{\log N}$. The correct answer, of course, is $\frac{\Delta}{2} \frac{1}{\log N}$, that is, about 11 per cent smaller.

It is curious that simple elementary probability considerations should give an answer so nearly right, but just failing by such a small fraction. It seems to imply that the probabilities are not strictly independent, that there is a slight tendency of factors to avoid one another; in other words, that after all the numbers in an interval divisible by $p_1, p_2, p_3 \ldots p_l$ have been eliminated, the chance that one of the remaining numbers should be divisible by another prime p_m is rather greater than $\frac{1}{p_m}$.

Perhaps a reader of NATURE can throw light on this question.

Effect of Negative Groups on Reactivity

RECENT experimental and theoretical studies of bond strength[1] have shown that our forecast[2], according to which in the series of gas reactions $Na + XR = NaX + R$ (X = halogen, $R = R_1, R_2 \ldots$) the reactivity is inversely related to the bond strength C–X, holds true for hydrocarbon radicals R_1, $R_2 \ldots$ containing no negative groups. But the great acceleration caused by the presence of such negative groups ($X_1, X_2 \ldots$) in reactions of the type $Na + XRX_1 = NaX + RX_1$ is as yet unexplained. The presence of these groups is not usually considered to weaken the bond strength C–X. In fact, it has been suggested by Pauling that, when $X_1, X_2 \ldots$ are halogen atoms attached to the same carbon as X, the strength of all the halogen bonds is rather increased than decreased by resonance[3]. Moreover, observations on the bond energy of acetyl iodide[1] failed to reveal any such weakening of the carbon halogen bond by the negative substituent (=O), which could explain that acetyl chloride reacts much faster with sodium vapour than does C_2H_5Cl [4].

A specific effect of negative substituents on reactivity can be deduced from the fact that in the presence of a negative substituent the transition state will resonate between three structures instead of the usual two. We shall have:

1. (a) $Na \ldots XRX_1$
   (b) $Na^+X^- \ldots RX_1$
   (c) $Na^+ \ldots XR \ldots X_1^-$

the component state c being due to the presence of the negative substituent X_1.

Take the case of a number of halogen atoms $X, X_1, X_2 \ldots$ in the molecule. A sodium atom approaching a polyhalogenated alkyl will interact simultaneously with each of the halogen atoms $X, X_1, X_2 \ldots$ in the sense of the transfer of an electron: $Na + {>}C{<} - X = Na^+ \ldots {>}C{<} \ldots X^-$ and likewise for ${>}C{<} - X_1$, ${>}C{<} - X_2 \ldots$ Each of these transfers may be considered as leading to an alternative final state, producing a different alkali halide molecule with the pairs of ions ($Na^+ \ldots X^-$, $Na^+ \ldots X_1^- \ldots$) separated by various distances. All these alternative final states will resonate jointly in any transition state arising in a reaction of a sodium atom with a polyhalogenated alkyl, and will depress the activation energy.

This resonance will increase steadily with the number of halogens $X_1, X_2 \ldots$ present in the molecule and also with their specific tendency to react with the sodium atom. The first part of this statement is patently confirmed by the observed cumulative accelerating effect which halogen atoms have on the reaction rate[4]; the second part may be analysed and tested as follows. Let us first think of all X's as being the same halogen, say, chlorine. The energy of the alternative transfer of the electron to the different Cl atoms increases with the electrostatic energy of the pair $Na^+ \ldots Cl^-$, which is inversely proportional to the distance at which the halogen is situated from the Na atom at the moment of reaction, that is, in the transition state. Hence the reactivity of di-chloro compounds should increase

with the mutual proximity of the two Cl atoms; and we should find, in particular, that *cis* di-chloro ethylene reacts faster than the *trans* isomer. All this has been confirmed by experience[4]. Moreover, the accelerating effect of halogen substitution should increase in the series F, Cl, Br, I, which represents the sequence in which the tendency to react with sodium increases; which also has been confirmed over a wide range of observations[4].

In the electron transfer discussed above the attachment of the electron to the halide molecule is clearly a manifestation of the *electron affinity* of the latter particle. The accelerating influence of a negative substituent on the reactivity of a molecule is thus seen to go parallel to the substituent's contribution to the electron affinity of the latter.

The observed parallelism in the influence of negative groups on the rate of sodium reaction as compared with the rate of substitution by a negative ion[4,5] can be explained by the presence of additional resonance in the transition state, similar to that which we derived for the sodium vapour reaction. In a substitution reaction $X^- + RX_1X_2 = XRX_2 + X_1^-$ the transition state will have the *threefold* resonance:

$$2. \quad \begin{array}{ll} (a) & X^- \ldots RX_1X_2 \\ (b) & XRX_2 \ldots X_1^- \\ (c) & XRX_1 \ldots X_2^- \end{array}$$

where the component state *c* is due to the presence of the negative group X_2.

The latter type of resonance can be related to the mechanism postulated by A. Lapworth in his classical studies on the formation of the cyanhydrine anion from RCO and CN^-. In this sense we could write, for example, the accelerating effect which C = O has on the substitution of acetylhalide by halogen ions, as being due to the tendency $X^- \ldots \underset{X_2}{C} = O$. We could even extend this to represent the rapid reaction of the acetylhalides with sodium vapour in the sense

$$Na \ldots \underset{X}{C} = O.$$

Structures of Thallium

THALLIUM at room temperature has a close-packed hexagonal structure, but this transforms at 230° C. into another structure which is given in the literature as face-centred cubic. This is based on the work of Sekito[1], who used specimens quenched from the melt and specimens containing other elements; his results cannot therefore be considered decisive, particularly since he does not give the purity of his materials.

We have taken photographs of Hilger thallium No. 7011 (99·995 per cent Tl) in the Debye-Scherrer camera described by Wilson[2]. At room temperature photographs of the hexagonal structure were obtained. Above 230° C. the photographs were not very satisfactory owing presumably to grain growth, as the metal is too soft to be finely filed. The lines present, however, did not fit in with the face-centred cubic structure, and measurement of a photograph taken at 262° C. with copper *K*-radiation showed that the pattern was mainly that of a body-centred cubic structure with $a = 3{\cdot}874 \pm 1$ A. Some of the hexagonal structure also was present. In the accompanying table a description of the photograph is given, and the observed and calculated positions of the lines are compared. Allowing for a systematic difference due to absorption, it will be seen that the evidence for the body-centred cubic structure is quite conclusive.

Indexes and Radiation	Intensity	$\sin^2\theta$ Obs.	$\sin^2\theta$ Calc.
110 β	medium	0·0645	0·0643
110 α	strong	0·0791	0·0789
$10\bar{1}1$ α	medium	0·0847	0·0848
$10\bar{1}2$ α	very weak	0·1427	0·1412
200 α	medium	0·1582	0·1578
211 β	medium	0·1945	0·1929
211 α	strong	0·2383	0·2366

Propagation of Lightning Leader Strokes

THE interesting suggestions recently put forward by Bruce[1] with regard to the mechanism of leader strokes are largely based on data relating to glow-to-arc transition. However, laboratory experiments indicate that such transition is a cathode-dependent phenomenon, a fact specifically stated in two of the articles[2] cited by Bruce. The current at which the glow develops into an arc is a most variable quantity[3] and is governed by the shape and material of the cathode.

Most authorities[4] seem agreed that, in the glow discharge, electrons are liberated from the cathode by positive ion bombardment or by photo-electric effect, and also in the gas by collision processes or by

photo-ionization; transition to an arc takes place when the conditions *at the cathode* are such as to initiate a much more copious source of electrons, namely thermionic emission or auto-electronic emission.

The propagation of a leader stroke depends on ionization processes in the gas. There seems no reason to suppose that a sudden transition will take place in the leader channel at a value of current which relates to the glow-to-arc transition between metal electrodes, where all evidence points to the importance of cathode mechanisms. Thus I consider that the experimental data on glow-to-arc transition are not directly applicable to the leader stroke, which is a gas-dependent phenomenon.

A feature of the propagation of leader strokes is their development in fields of relatively low gradient. The leader stroke must therefore carry forward as it advances a localized intense field about its tip in order that its progress may be maintained. To create such a field an excess charge of the appropriate sign is required in the channel. I would then suggest that one of the criteria relating to the propagation of a leader stroke is that the gradient along the ionized channel should be such that the electron drift speed is sufficient to ensure the continuous creation of this excess charge as the leader advances. The manner in which this excess charge is produced is probably as follows:

(1) *The negative leader stroke.* The average electron drift speed u cm. per sec. along the leader channel is in the same direction as the average speed v of advance of the channel tip. If n is the number of ion pairs created per cm. advance of the leader stroke, the number of electrons in the channel is $\frac{n\,v}{v-u}$ per cm., while the number of positive ions is n per cm. (the positive ions may be considered as virtually stationary in comparison with the more mobile electrons). There is then an excess of electrons in the channel, namely, $\frac{n\,u}{v-u}$ per cm., which maintains the negative character of the advancing leader.

(2) *The positive leader stroke.* The direction of electron drift in the leader channel is in the reverse direction to that of advance of the leader. The number of electrons in the channel is $\frac{n\,v}{v+u}$ per cm., while the number of positive ions is n per cm., so that there is a resultant excess $\frac{n\,u}{v+u}$ positive ions per cm. of channel.

Further details relating to the amount of excess charge required in a leader channel will be published in due course.

Magnetization of Matter by Ultra-violet Radiation

I HAVE attempted to repeat the interesting experiments reported by Ehrenhaft and Banet[1] on the effect of ultra-violet radiation on "non-magnetic" and annealed pieces of iron. They stated that, with the simplest apparatus (for example, a cheap compass needle), they showed that poles were induced in various pieces of annealed iron, the poles being mainly north magnetic. The specimens were placed perpendicularly to the geomagnetic field and irradiated for periods varying from minutes to several hours. The poles, they state, were present in many specimens after several days.

My experiments were carried out under similar conditions, and, within the limits of sensitivity of the magnetometer used, they were entirely negative. This sensitivity was about 9,000 mm. at 1 metre per œrsted, and was such that a pole strength of 0·01 C.G.S. unit (or a magnetic moment of 0·05 C.G.S. unit) on the specimen tested could be detected clearly. A small compass needle was found to be less sensitive and reliable. In the various tests I used two types of ultra-violet source, direct exposures to within 10 cm. of the source and also at the focus of a quartz lens, exposure times ranging from minutes to several hours, various angles from 0° to 90° between radiation beam and specimen, and many specimens of the kind mentioned by Ehrenhaft and Banet. In no case was there a significant increase in magnetization. An occasional specimen, accidentally dropped, became magnetized by the earth's field.

It was shown that the weak poles (of order 0·01–0·1 C.G.S. unit) induced by placing a specimen in the earth's field and tapping it could be detected with certainty by the magnetometer, and often by the compass needle.

The first ultra-violet lamp used by me was an Osira, 125-watt, high-pressure type (General Electric Co.). Its glass globe had been removed, and the ultra-violet flux density in the region 3132 A. and less had been determined in previous work[2] (39 microwatts per cm.^{2} at 61 cm. horizontally from the source). The second source was a Mercra lamp, 125-watt, with ultra-violet filter bulb (British Thomson-Houston Co.).

I would like to know if anyone else has tried these experiments, and their results.

Distillation 'Constants'

WE have become interested in the relationships existing between some of the older 'distillation constants' and the more recent concept of relative volatility (α of Walker, Lewis *et al.*[1]). To find the rate of change with composition of total vapour pressure (P) of a binary mixture Rosanoff, Bacon and Schulze[2] put forward the general equation (deduced empirically)

$$\frac{dP}{dx} = \frac{1}{K}\log\,[p_1(1-x)/p_2x]. \quad . \quad . \quad . \quad . \quad (1)$$

p_1 and p_2 were the partial vapour pressures (at a particular temperature) of the components, the

molecular fractions of which in the liquid were x and $(1-x)$. The constant, K, held for all cases and was evaluated as follows: When in a particular case where Raoult's law held, that is,

$$[p_1(1-x)]/p_2x = P_1/P_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and

$$P=p_1+p_2=P_1x+P_2(1-x)=(P_1-P_2)x+P_2\,; \quad . \quad (3)$$

then $$\frac{dP}{dx} = P_1-P_2= (1/K)\log\,[p_1(1-x)/p_2x]$$

$$= (1/K)\,\log\,P_1/P_2\,; \quad . \quad . \quad . \quad . \quad (4)$$

whence $K = (\log P_1 - \log P_2)/(P_1-P_2)$. . . (5)

P_1 and P_2 were the vapour pressures of the pure components (at the temperature in question). Rosanoff *et al.*[2] evaluated K for a number of pairs of liquids and extended their considerations to obtain liquid-vapour equilibria points from measurements of total vapour pressures, etc.

A relationship between K and α can be deduced as follows: Since by definition (Walker *et al.*[1])

$$\alpha = p_1/p_2\left[\frac{1-x}{x}\right], \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

equation (1) becomes

$$\frac{dP}{dx} = \frac{1}{K}\log\alpha\ (\text{or } \alpha = e^{\,K.dP/dx})\,; \quad . \quad . \quad . \quad (7)$$

whence

$$K = \log\alpha/\frac{dP}{dx}\,; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

and for pairs of liquids which obey Raoult's law—equation (2)—and in general,

$$K = \log\alpha/(P_1-P_2) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

At a later date the relationship between α and other distillation constants[3] will be discussed.

Incidentally, the equation of Rosanoff *et al.* relating E_0 and x_0, the initial weight and initial molar fraction of a component in a binary mixture, with E and x, the quantities remaining in the mixture after a finite partial distillation, namely:

$$\ln\frac{E}{E_0}=\int_{x_0}^{x}\frac{e^{\,K.dP/dx}}{(e^{\,K.dP/dx}-1)\,(1-x)\,x}\,.dx \quad . \quad . \quad (10)$$

can be written in the form

$$\ln\frac{E}{E_0}=\int_{x_0}^{x}\frac{\alpha}{(\alpha-1)\,(1-x)x}\,.\,dx, \quad . \quad . \quad . \quad . \quad (11)$$

which on integration, provided α is constant, gives

$$\log\frac{E}{E_0}=\frac{\alpha}{\alpha-1}\left[\log\frac{x_0}{x}+\log\frac{1-x}{1-x_0}\right]. \quad . \quad . \quad (12)$$

A similar equation may be written for the other component[4].

Reilly and Kelly[5] have shown that the distillation constant, k, for pairs of liquids used by Virtannen and Pulkki[6], is the same as α on the condition that Raoult's law holds. It is hoped to show in a later publication that this condition is not necessary. It would therefore appear that the technique of Virtannen and Pulkki[6] can be applied to determine α for pairs of liquids which form azeotropes. It should be noted that components which form an azeotrope deviate from Raoult's law. Even if Raoult's law has to be obeyed by the components for k and α to be the same, there would still be a possibility of the above method being applied to azeotropic components. Hildebrant[7] points out, in another connexion, that, in certain cases, it does not take much deviation from Raoult's law for an azeotrope to form. However, it would appear at the moment that the only criterion necessary for the similarity of k and α is that the relative volatility of the two components should be constant (or approximately so) through the temperature range of the small partial distillation necessary to determine k. In practice, a series of small partial distillations, or a single distillation into several small separate portions of distillate, is carried out to determine k for different compositions. Walker *et al.*[1] point out that, in general, relative volatility does not vary rapidly with temperature. Consequently, as a general rule, k should approximate to α in a given partial distillation. For an infinitesimally small partial distillation, k would become identical with α.

A pair of liquids mixed in the exact azeotropic composition has a value of α equal to unity. For other compositions α varies from values greater than unity to less than unity depending on which component is present in excess of the azeotropic composition in the mixture. The determination of k can be carried out quickly (even if using the more elaborate technique of Rosanoff, Bacon, and White[8] for distillation into separate portions of distillate) and the values of k for a range of compositions rapidly ascertained. If k approximates to α then a curve relating k with a range of compositions should have an inversion point, where an azeotrope is formed, at about the co-ordinates of k equalling unity and composition equalling that of the azeotrope.

In another connexion some of us have been examining the extraction of nicotine from aqueous solution[9]. On turning attention to the distillation of aqueous nicotine solutions some interesting results have been obtained. A preliminary determination of values of k for a series of dilute (one liquid phase) solutions of nicotine in water indicates that the curve relating k with composition shows an inversion point (as described earlier). Accordingly, the existence of an azeotrope of nicotine and water would be probable. This work is being completed and the liquid-vapour equilibrium curve for nicotine and water will be constructed to confirm the existence of an azeotrope.

Oogenesis in Adult Mice and Starlings

It has long been the general assumption that, at least in the higher vertebrates, the stock of oogonia and oocytes laid down in the ovaries during embryonic life is never afterwards increased, and that in the adult the waves of maturing eggs are derived from this stock which lasts the animal throughout its active sexual life. In 1923 this theory was challenged by Allen[1], who had observed in the ovary of the adult

mouse (*Mus musculus* L.) the formation of new oogonia from the mitotic divisions of the cells of the germinal epithelium. Depending on the plane of division, these mitoses resulted in the production either of new cells in the germinal epithelium or of new oogonia. Although the original theory is still widely held, much evidence confirming Allen's observations has now accumulated, and a review of present knowledge has been given by Swezy[2].

Investigations have been made which endorse Allen's statement that the mitotic activity of the germinal epithelium of the adult mouse ovary is a cyclic phenomenon. More mitoses are evident, and therefore more oogonia are produced, during the œstrous period than in any other period of the normal œstrous cycle. Allen did not, however, fully demonstrate how very intense and short-lived is this period of maximum production of new oogonia. In the strain of mice used in this laboratory, œstrus, as recognized by the typical vaginal smear, lasts for about forty-eight hours, and about thirty-six hours from the beginning of this period ovulation occurs. Œstrus is therefore divided into a long pre-ovulation period and a shorter post-ovulation period, the latter being equivalent to what Allen termed early metœstrum. Counts were made of the number of mitoses in the germinal epithelia of the ovaries of a series of normal mice in all phases of the œstrous cycle, and the results are given in Table 1.

TABLE 1.
Average numbers of mitoses in the germinal epithelia of ovaries of adult mice.

Period	Diœstrus 1st day	2nd day	3rd day	Pro-œstrus	Œstrus pre-ovulatn.	Œstrus post-ovulatn.	Met-œstrus
Mitoses	8	12	19	25	27	408	24
Number of mice	4	4	4	4	4	5	4

It is seen that a very sharp peak of mitotic activity is characteristic of the period immediately following ovulation, although there are also slight increases in the number of mitoses in both the pre-ovulation œstrous period and in metœstrus.

TABLE 2
Average numbers of mitoses in the germinal epithelia of ovaries of one-year-old starlings.

Month	April		May		June		July
Mitoses	0	5	30	8	0	0	0
Numbers of starlings	1	2	3	1	2	2	3

Oogenesis in many adult mammals is now an established fact, but little is apparently known about oogenesis in adult birds. During a study of the reproductive cycle of the starling (*Sturnus vulgaris* L.)[3] it was found that new oogonia are produced by the cells of the germinal epithelium, and further examination has indicated the presence of a cycle of mitotic activity similar to that of the mouse. The female starling when one year old usually lays one clutch of eggs, but when two or more years old it may breed twice in one season. Counts were made of the mitoses in the germinal epithelium of both first-year and older birds, and it was found that during the greater part of the year the germinal epithelium is quiescent. Mitoses, resulting in the production of new oogonia, are, however, common in the breeding season, and Tables 2 and 3 show the number of mitoses seen in the ovaries of starlings taken each fortnight from the beginning of April to the beginning of July.

TABLE 3.
Average numbers of mitoses in the germinal epithelia of ovaries of starlings of two or more years of age.

Month	April		May		June		July
Mitoses	0	4	34	11	22	2	0
Numbers of starlings	3	3	4	2	4	3	3

Ovulation takes place about the last week in April, and the greatest number of mitoses was observed immediately afterwards. In older birds, some of which ovulate a second time in early June, the counts of mitoses shown in Table 3 were made.

In addition to the wave of mitoses in early May, there is a second shorter and less intense wave coinciding with the end of the second ovulation in early June. By the end of June all activity of the germinal epithelium has ceased, and there are large numbers of small oogonia just below the tunica albuginea. These form a stock from which many of the next year's eggs are derived.

From these results it is evident that, both in the mouse and the starling, the mitoses of the germinal epithelium, resulting in the production of new oogonia, are at a maximum during very limited periods of the reproductive cycles, and in this respect the short cycle of the polyœstrous mammal is comparable with the yearly cycle of the bird. In both cases there is a sharp maximum of activity of the germinal epithelium in a short post-ovulation period. It appears probable that some factor which stimulates mitosis, and which is of an internal secretory nature, comes into full operation during this post-ovulation period. Further research on these lines is proceeding.

Function of Pyrenoids in Algæ

THOUGH attempts have been made from time to time to explain the function of pyrenoids in Algæ, exact knowledge on the point is lacking. Usually starch is deposited around the pyrenoids in a good many Chlorophyceæ, and G. M. Smith[1] holds that pyrenoids synthesize starch. In starch-free diatoms G. Karsten[2] remarks that one has scarcely seen the actual formation of oils in connexion with pyrenoids. But by growing *Rhopalodia gibba* and *Synedra affinis* var. *fasciculata* in 2 per cent glucose medium, fatty acid and glycerine medium, etc., I could get distinct grouping of oil-drops around the pyrenoids (Fig. 1), the first-formed oil-drops in these diatoms being invariably deposited round the pyrenoids. Similarly, by growing green filaments of Spirogyra in fatty acids and glycerine medium, oil is synthesized in the course of three days in the form of drops (Fig. 2) around the pyrenoids within the starch-sheath. Chemical analysis confirms the utilization of acids in the process as the amounts of acids decreased during the process. Filaments of Spirogyra undergoing decomposition, either in Nature or in artificial

culture, show the first formation of oil-drops around the pyrenoids within the starch-sheath as well as surrounding the sheath; here the starch-sheath becomes narrower and thinner—evidently oil is secondarily formed from the primarily formed starch-grains in the sheath.

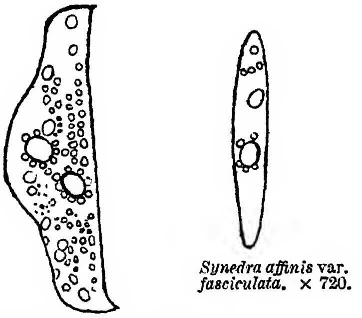

Fig. 1.

Thus, from these experiments it is held probable that pyrenoids serve as receptacles of appropriate enzymes for the syntheses of various food substances in such plants.

Fig. 2.

SPIROGYRA SP. PHOTOMICROGRAPH UNDER OIL IMMERSION LENS AND EYE-PIECE No. 5; OIL-DROPS AROUND THE PYRENOIDS WITHIN THE STARCH-SHEATH ARE MARKED BY WHITE LINES.

The central portion of the pyrenoids gives the protein test with Millon's reagent, where a very faint pinkish stain is visible under the oil-immersion lens. In plants (both lower and higher) lacking in pyrenoids pinkish vacuoles are always found inside the plastids, and food substances are usually deposited in connexion with them. These pinkish vacuoles are not found in old, disorganized or plasmolysed cells.

It is hoped to publish the details of the work soon.

Biography of W. H. Wollaston

IN 1931 I appealed in NATURE[1] for information for a biography of William Hyde Wollaston. Since then, probably all printed information of any importance has been supplemented by a large amount of unpublished material. In the collection of the latter, much of which is of great interest, I have received very generous help from many sources.

Various circumstances have delayed the work, but in a way I do not regret the delay, because from time to time fresh material has come to light. Only a few weeks ago a large collection of letters from Wollaston to E. D. Clarke (1769–1822), professor of mineralogy at Cambridge from 1808, was reported in a bookseller's catalogue, and is now in my possession. It is possible that other Wollaston material which readers of NATURE may know of is unknown to me. The dossier collected by Henry Warburton after Wollaston's death for the purpose of a biography was "lost", although I believe I have found a small fraction of it.

I am writing to record thus that the work is still in progress, and to issue one more appeal for information. Documents would be gratefully received by me, and would be returned by registered post as soon as copied; or, if correspondents would prefer that their documents were inspected under the ægis of an important library, Dr. T. Richards, librarian of the University College of North Wales, Bangor, where the section to which I belong of the Chemistry Department, University College, London, is enjoying hospitality, has kindly consented to take temporary charge of such papers.

L. F. GILBERT.

Men of Science as Administrators

IN a letter to NATURE (May 31), R. A. Jones has well expressed the molluscan tendency of men of science to grow a shell and stay in it, and the difficulty of acquiring the arthropod ability to moult into an administrative stage. This difficulty exists in Canada also, but to a lesser degree, I think, than in England. The reaction to strong criticism may often be an invitation to "come and do it yourself, you who know so much".

It seems to be agreed that the peaceful penetration of government departments by men of scientific training and experience is desirable. I submit that for men of science engaged in 'near-economic' work such penetration is not difficult, given the will and political conscience to do so. Men of administrative experience are vulnerable on the side of economic development. As to the lack of administrative experience among men of science, which, as Mr. Jones points out, is considered a serious obstacle, it seems to me that if a classical education is looked upon as a sound foundation for the conduct of the affairs of the native populations of Africa, then a knowledge of the quantum theory should be as good equipment for the administration of civilized communities.

CONFERENCE ON INDUSTRIAL RADIOLOGY

ON September 24 the Industrial Radiology Group of the Institute of Physics held the first meeting since its inauguration, this taking the form of an afternoon conference at the Royal Institution, presided over by Prof. J. A. Crowther. The Conference was opened by Sir William Bragg who first spoke of the early days of X-rays, almost fifty years ago, before commenting on the many industrial uses to which the radiations are now put. He welcomed the formation of a group of workers interested in radiology and hoped it will be a success in sharing experience and knowledge and also in stimulating further interest in the subject.

Three papers were read before the conference, forming the basis for the following discussion. The first of these, given by Dr. W. Betteridge, and entitled "The Application of X-Rays to Industrial Problems", was a general review of the subject. The physical properties of X-rays important in radiology were briefly described, and led to a consideration of the factors involved in the production of a radiograph. The points to be considered in the choice of the different variables such as tube voltage, tube to film distance, etc., were considered, and the importance of blocking off, the use of filters, intensifying screens and diaphragms were briefly described.

Various fields in which radiology has proved of service were then enumerated—the examination of castings and welded joints was mentioned but left for the following speakers to treat in more detail, and the miscellaneous uses of the rays were then described under grouped headings. The examination of assembled structures was considered to be the most important use after the two already mentioned, these being examined for the presence and correct alignment of component parts. Radio valves, small ammunition, shell fuses, electric heater elements, sparking plugs, etc., were mentioned as examples and slides shown illustrating the types of defect looked for. Such examinations are frequently carried out by fluoroscopic means. The routine examination of food products, fire bricks, arc carbons, etc., was also mentioned, and stereoradiography for the location of defects and the measurement of wall thickness was described. The observation of objects in a furnace was illustrated among uses in a research laboratory, and microradiography was dealt with. This latter consists of the radiography of a very thin metal sample on fine-grain film with soft radiation, subsequent optical magnification of the radiograph giving the equivalent of a photomicrograph, and showing the presence of different phases by the different degrees of absorption; it was described as of particular value in the study of coring and segregation in a solid solution. The use of γ-rays in the examination of thick sections of heavy metals was mentioned.

A final section of Dr. Betteridge's paper dealt very briefly with the application of X-ray diffraction methods to industrial problems, reference being made to the recent symposium published in the *Journal of Scientific Instruments*. The Debye-Scherrer powder photograph was used to illustrate the different types of problem which could be dealt with, determination of the crystal structure, or its comparison with standards, being described for the identification of unknown materials in very small quantities, and the use of accurate parameter measurements for the analysis of alloys in solid solution and the measurement of elastic stresses was also mentioned. How the appearance of the diffracted lines could be used to yield information as to grain size, state of cold work or preferred orientation, and for the study of relaxation and recrystallization formed the closing section of the paper.

The next paper, by J. J. Gillespie, dealt with "The Applications of Radiography in the Inspection and Control of Welds". After a short description of the practice of welding and the bodies to which it is frequently applied, Mr. Gillespie dealt more fully with the methods used in the examination of welded joints in boilers and other pressure vessels. The need for careful preparation of the weld before examination was emphasized, in order that surface defects should not mask the internal faults for which search was being made; and it was pointed out that the marking out of the body before radiography should be systematically and permanently done, so that at any future date the radiograph of a particular section could be located. Dark-room technique must be maintained at a high standard since an otherwise perfect radiograph can easily be spoiled by faulty processing. The common types of defect were then enumerated, the chief classes being porosity, slag inclusions, lack of penetration and cracks, and slides were shown to illustrate the different degrees and forms in which these faults could occur. It was stated that a certain amount of uniformly distributed porosity or slag inclusions can be tolerated in a weld, particularly if the metal is of fairly thick section, but lack of penetration and cracks are more serious defects likely to result in stress concentration, and a high standard of acceptance has to be maintained. Mr. Gillespie stated that a generally agreed standard of acceptance is becoming a necessity.

The third paper, on the "Application of X-Rays to the Examination of Magnesium Alloy Castings", was contributed by P. M. Bailey. It was first stated that fluorescent screen inspection of magnesium castings is unsatisfactory, as it is, in general, quite impossible to detect microshrinkage, the characteristic fault of these alloys, and the minimum size of fault detectable is about seven times as great as that shown on a radiograph. The type of X-ray film found most suitable for this work has a fine grain, and the highest contrast is not found desirable; for this reason filters with an absorption up to 50 per cent of that in the casting itself are frequently used, although in general, filters are unnecessary for magnesium. Emphasis was laid on the use of a suitable viewing lantern, and modifications to commercial lanterns found necessary, such as the addition of blinds for reducing the area illuminated and the introduction of high-power lamps, were described.

Typical defects of magnesium castings were described, microshrinkage, which can reduce the tensile strength of the material from about ten to five tons per square inch, being paramount. The incidence of blow-holes and dross inclusions, both often due to faulty foundry technique, was mentioned, and it was pointed out that cracks, which, in the case of die castings, are

usually due to poor dies, can easily be missed if the direction of the X-ray beam lies far from the plane of the crack. The necessity of close collaboration between radiologist and foundry manager was emphasized, and the procedure followed by Mr. Bailey himself was described. The breaking-up of castings in order to confirm and supplement radiographic inspection is essential, especially for the detection of microshrinkage; this is helped by heat-treating the castings before breaking, the oxidation resulting making the microshrinkage more readily visible.

A lengthy discussion followed these papers and was contributed to by many speakers. Practical details, both difficulties which have been encountered and hints to overcome them, were mentioned, among the latter being the use of rubber cassettes which can be evacuated to hold intensifying screens in close contact with the film, the advantage of these being their flexibility, enabling them to be adjusted to close contact with irregularly shaped bodies; and the use of mercury for blocking off holes in an otherwise uniform plate. The most important point raised during the discussion, however, was the need for standardization of the acceptable limit for given types of fault. It was generally agreed that standards for welds would not be too difficult to formulate, particularly since welds are usually in material of uniform section and regular shape, but it would be much less easy to arrive at similar standards for castings. The responsibility for the determination of standards was discussed and there was agreement that the final decision should rest with the designer of a component, the function of the radiologist being to interpret the radiographs to the designer.

It was decided that the Radiology Group of the Institute of Physics is not in a position to undertake the preparation of radiographic standards, but Dr. L. Mullins, the secretary of the Group, pointed out that standardization is very necessary in other fields, and hopes, for example, that the Group will be able to put forward suggestions which will result in a reduction of the many different types and sizes of camera used in X-ray diffraction work.

TECHNICAL ABILITY AND THE WAR EFFORT

A PRIME necessity in a war-time economy is for the maximum and most efficient use of all the country's resources. Particularly necessary in this War is the full use of technical man-power. After two years of war, when it is implied by Government spokesmen that we still lack sufficient material to contemplate an offensive against the enemy, it is disquieting to learn that there still exists a widespread misuse of technical man-power.

At a national conference for members in engineering and aircraft industries, held at Birmingham on September 7 under the auspices of the Association of Scientific Workers, delegates stated that many industrial scientists and technicians are still working on peace-time problems. Others with insufficient work to do are being kept together as teams and find the Essential Work Order used to prevent release from their present firms and the transfer of their ability elsewhere. Delegates made it clear that this situation has arisen from the concern of some industrial firms with the problems of post-war competition. Speakers criticized the absence of any proper pooling of information. They spoke of production being held up while technicians completed designs or solved problems already dealt with by a parallel organization, and of the withholding of full technical information from designers of apparatus.

There was criticism of the scientific ability of some persons at present in charge of technical staff. A delegate from the aircraft industry spoke of technical leadership being in the hands of former racing drivers.

Many speakers felt that the combination of inefficient management, the concern of firms for private interests, the scheduling of overtime as a pretence of activity when there is insufficient work to do and similar experiences have given rise to a general apathy regarding production and that it is necessary for this to be broken down by close co-operation between management and employees.

The remainder of the conference dealt with working conditions in these industries. Cases were put forward of qualified men receiving less remuneration than workmen under their supervision. Strong exception was taken to the system whereby university graduates rated as student apprentices are put on to ordinary production work at nominal salaries. Speakers clearly felt that little improvement in the status of scientific workers would be effected unless the Association of Scientific Workers could establish a minimum salary scale for all grades of scientific and technical staff.

The Conference therefore passed the following resolutions:

(1) All technical staffs not fully engaged on the war effort or engaged on development in preparation for post-war competition should be transferred to other departments.

(2) Real pooling of technical information and facilities should take place between firms producing similar articles, and between Government departments and firms producing for them.

(3) All scientific and technical work should be under the direction only of persons with adequate technical experience and qualifications.

(4) There should be genuine co-operation between managers and workpeople to secure greater enthusiasm for the war effort.

(5) An attitude of vigilance should be adopted regarding the working of the Essential Work Order, so that it shall not be allowed

(*a*) to hinder the war effort by permitting managements to retain staff when their transfer would be in the national interest;

(*b*) to serve as an instrument of victimization of active trade unionists.

To carry this programme into effect the Conference proposed several points of action for the consideration of members of the Association, full details of which can be obtained from the Association of Scientific Workers, 30 Bedford Row, London, W.C.1.

THE NATIONAL RESEARCH COUNCIL OF CANADA

THE review of activities of the National Research Council of Canada for the year ending March 1940, which has now appeared, includes the report of the president, together with reports of the divisions and sections and reports of co-operative investigations, including the associate, joint and special committees.*

The president's report, referring to the re-alignment of work through the effect of the War, points out that many of the studies that were being carried out in peace-time proved of equal or greater importance in war-time, and the change over to a war-time programme involved very little departure from existing procedure. The Aeronautical Committee since the outbreak of war has been occupied almost exclusively on urgent military aviation problems, while the Radio Committee has undertaken a greatly enlarged and intensive programme directed exclusively by military considerations. With the outbreak of war, the Metrological Laboratory was considerably expanded to undertake the standardization of munition gauges. Scientific work of the Department of National Defence for the Services has included problems relating to the mechanical equipment, and other problems, of naval craft, such as the design and performance of hulls and the investigation of means of offence and defence in sea warfare. Research work for the Militia Service has covered war supplies, munitions manufacture, the examination of explosives and the provision of supplies for the troops, while for the Air Force the facilities of the Aeronautical Laboratories are used to determine the practicability of new designs of aircraft and engines, improvement in technique in construction and flight, engine performance and the effect of modifications in fuels and lubricants, etc. Other laboratories are being constructed outside Ottawa, and larger wind tunnels, both horizontal and vertical, are to be built, while a new model-testing basin will provide more adequate facilities for the study of ship and float design.

The National Research Council also maintained direct contact with similar scientific bodies in Great Britain, and since the beginning of the War the practice of exchanging scientific officers between Great Britain and Canada has been extended. The Section on Codes and Specifications is responsible for the preparation of commodity standards for Government Departments and for the development of a National Building Code as well as for general specification studies. The Research Plans and Publications Section, in addition to the maintenance of the Library, is responsible for the publication of the *Canadian Journal of Research*, the preparation of bibliographies on scientific subjects, and translations, and also conducts a research advisory service. With the recall of the president, Major-General A. G. L. McNaughton, to active military service, Dean C. J. Mackenzie took over the duties of acting-president in October 1939.

Dealing with the work of the main research divisions, the Division of Biology and Agriculture continued its work on plant growth factors, including the hormone treatment of seeds. These tests, carried out in co-operation with a number of organizations across Canada, indicated no appreciable benefit from such treatment of seeds when the hormone chemicals were incorporated in organic mercurial disinfectants or talc. Indolylacetic acid, however, proved effective in reducing injury by formaldehyde to germination in soil, and the dust method of applying synthetic hormone chemicals to plant cuttings had a further beneficial effect when the substances were used in combination with nutrient salts, sugar and organic mercurial disinfectants. Other work has been concerned with the propagation of forest trees from cuttings. Satisfactory results have been obtained with plant hormones applied as dust or in a mixture of equal volumes of sand and peat humus. Further work has been carried out on the standardization of the experimental baking test as well as studies on malt quality and the modification of malt. Among the work carried out on food storage and transport, the investigation of the canning of poultry and the development of rancidity in frozen pork during storage, as well as the curing of bacon by smoking in view of the dearth of refrigerated shipping space available, may be mentioned. Other work has been concerned with the control of storage conditions and also with the storage of blood for transfusion purposes. Statistical studies have been made of the effect of dust seed treatment with indolylacetic acid on the growth and yield of barley under closely controlled conditions.

In the Division of Chemistry, a major project was concerned with the preparation of ethylene oxide by direct oxidation of ethylene by air over catalysts, and some catalysts have been prepared which show sufficiently high activity and specificity to indicate that the process might be more practical than the chlorohydrin process for the manufacture of ethylene glycol. A new laboratory has been equipped for the study of synthetic resins and plastics, while the electrochemical laboratory has continued work on the corrosion of metals by used lubricating oils, the corrosion of metals and coatings by 'leaded' petrol under storage conditions, and a preliminary investigation of the corrosion of metals by hot and cold domestic tap waters and by softened laundry water. Investigations in the field of detergency as applied to laundering and dry-cleaning have been continued, as well as research on the possible harmful effects of certain textile finishing agents and methods of determining sizing and finishing compounds on cotton fabrics. In the Paint Laboratory, increasing attention has been given to protective coatings for use on aircraft, military vehicles and other equipment for war purposes.

The Division of Physics and Mechanical Engineering has been concerned with investigations on fatigue in aircraft propellers, the temperature control of refrigerator cars, development work on photographic apparatus for the Royal Canadian Air Force, and on the application of spectrochemical methods of analysis to agricultural problems.

Of the associated and joint committees, the Associate Committee on Aeronautical Research has been responsible for further work on the cathode ray compass tests, on the oil dilution system for cold-weather starting of aeroplane engines, the development of the apparatus to study vibrations in aircraft structures, fatigue of metal propellers and aircraft ski research.

Under the Advisory Committee on Field Crop Diseases, research in Alberta has indicated that seed

* National Research Council of Canada. Review of activities for the year ended March 1940. N.R.C. No. 976. Pp. 155. 75 cents.

treatment with formaldehyde is ineffective for preventing smut contamination. Copper carbonate and chloride were more effective, but the organic mercurial dusts were the best protectors. Research in Manitoba on liquid and dust fungicides for smut control showed that dust failed to control smut in oats and barley although the failure may have been due to the method of treatment given. Satisfactory control in wheat was obtained with solutions of organic mercurial compounds.

In work under the Associate Committee on Grain Research at the University of Alberta preliminary comparisons of the relatively injurious effects of the three organic mercury dusts, New Improved Ceresan, Laytosan and Lunasan, on wheat indicated that the first was more likely to cause injury in overdoses than the others. Further evidence was obtained indicating that treatment of seed wheat with formaldehyde renders it more susceptible to mould damage than untreated wheat, although the damage was apparently reduced by addition of certain fungicidal dyes and organic mercurial compounds to formaldehyde solution.

Progress has been made with breeding projects aimed at the development of drought-resistant varieties of wheat. Work on the development of rust-resistant smooth awned barley of good malting property has continued.

Under the Associate Committee on Medical Research a study is being made of the relation of certain food factors to the development of cancer, and attempts to prepare a synthetic chemotherapeutic agent for the treatment of tuberculosis and studies of the relation of certain dietary deficiencies and physical factors to the development of arthritis are in progress.

Two meetings have been held of the Canadian Committee on Oceanography, established in March, 1938,. while under the Associate Committee on Parasitology studies of the enzyme inhibitors of Ascaris and of the anthelmintic action of phenothiazine have been carried out. In addition to the studies of the anthelmintic action of phenothiazine in sheep, a method of administration has been worked out by critical testing and a test is being conducted on its effect on a flock of cull lambs.

THE HELIUM METHOD FOR DETERMINING THE AGE OF ROCKS

By N. B. KEEVIL,
DEPARTMENT OF PHYSICS, UNIVERSITY OF TORONTO

THE potentialities of radioactive methods of determining the ages of rocks, minerals and meteorites are so great that much time, money and effort have been expended in age research during the past decade. The supplement to the chemical method of the more elegant physical method of lead age determination from isotopic abundances has done much to establish confidence in the lead time-scale; but more hope has been held for the helium method because of its promised application to a great variety of geological materials rather than to a limited group of rare minerals.

It is now evident that the 'apparent age' or helium index calculated by the helium method is usually considerably lower than the age expected from geological and lead age data. Only in rare cases does the helium index seem to be concordant with the lead time-scale. This would not be so serious geologically if helium indexes were reasonably consistent, for it is not so much the absolute age as the sequence and relative time intervals which are of importance in geological problems. However, a survey of one hundred and fifty determinations on rocks has shown that there is only a one-to-one chance of finding the age of a basic rock within one geological period, that there is a still smaller chance of determining the age of a granitic rock, and that the results obtained for porphyries and lavas are meaningless from the point of view of age.

The discovery that differing values of the helium index are obtained for the different minerals constituent in rocks[1] led to the theory that the low results were due to selective loss of helium in minerals. Results recently obtained for one hundred and fifty minerals have shown a variation in the ratio of experimental age (helium index, I) to the expected age, A, from mineral to mineral and from rock to rock. No one mineral has been found to give uniform results. Since more than ninety per cent of the four hundred age determinations made to date show lower values than expected, the explanation that the variations are due largely to non-uniform loss of helium seems a logical one, and hence I/A may be termed the helium retentivity.

The results summarized in Table 1 show that the retentivity varies by a factor of 2500, but if the high values are excluded, most of the average values, and the probable values of retentivity obtained from distribution curves, fall within the range 0·3–0·6.

TABLE 1. HELIUM RETENTIVITIES OF ROCKS AND MINERALS

Type of sample	No. of samples (Keevil)	Helium retentivity			No. of samples (others)
		Range (Keevil)	Average* (Keevil)	Average† (others)	
Granitic rocks	34	0·02–0·86	0·25	0·35	6
Basic rocks	18	0·10–1·93	0·44	0·45	69
Porphyries and lavas	22	0·01–1·08	0·12	0·36	9
Quartz	14	0·04–1·22	0·25		0
Magnetite	10	0·24–12·3	0·46	0·93	18
Oxides	6	0·11–0·59	0·32	0·25	17
Feldspar	25	0·02–0·46	0·20	0·25	2
Femics	37	0·05–3·84	0·57	0·45	4
Silicates	22	0·12–3·63	0·41	0·34	29
Oxy-salts and halides	12	0·03–24·6	0·45	0·38	10

* Excluding 14 values indicating excess helium.

† Excluding 18 high values from data by Strutt, Holmes, Dubey, Kano, Davis, Lange, Urry, Goodman, and Hurley.

No significant disagreement exists between my results and data obtained by other observers. Rocks containing a glassy matrix are not comparable with crystalline rocks, since helium diffuses through glasses

much more readily, and the discrepancy in the case of magnetite is discussed below.

Attempts to apply corrections on the basis of average helium retentivities have made little improvement in the accuracy of dating, although such correction does tend to place the helium ages calculated for different types of specimens on a more common basis. At the present time it seems that such corrections do not provide 'ages' of sufficient accuracy for use in geological correlation. A consideration of the local effects of metamorphism, and a more general plot of retentivity against expected geological age, show the discrepancies to be due in part to the variation in retentivity of minerals with geological history. It is fairly definite that low values of I/A are caused by metamorphic changes, deuteric action, some mineralization processes, and by weathering. In a series of Algoman hornblendes from one area, a relationship between the degree of alteration and helium index was found. It is also apparent that loss of helium may be caused by crystal imperfections, localization of the radioactive elements, and by interruptions in structure.

Two possible alternatives remain: first, the use of perfect minerals, if such can be found, and secondly, the correction of helium indexes by means of characteristic equations or curves for each mineral, such as retentivity-alteration curves. I have had some success with the second method, but it is doubtful whether a generally useful method can be developed. It is also uncertain whether any crystal can be said to be perfect so far as retaining its radiogenic helium is concerned; and the chance of its containing excess helium renders the result subject to error in any case.

Although it has been suggested that magnetite generally retains most of, if not all, its helium, and so gives reliable helium ages[2], results obtained in this laboratory indicate magnetite to be no better than some other iron minerals. Although some samples have appeared to give ages consistent with the lead time-scale and geological data, others have shown pronounced loss of helium, and a few have shown evidence of large amounts of extraneous helium. Furthermore, age determinations on other minerals separated from magnetite-rich samples have shown discordant results in all cases, the helium indexes frequently being higher than those for magnetite. The few examples given in Table 2 show the unreliability of using helium indexes of magnetite as criteria of age.

TABLE 2. SOME RESULTS ON MAGNETITES

Locality	Helium index, I	Expected age, A	"Retentivity", I/A
Magnet Cove, Ark. ...	42	150	0·28
Bushveld Complex, Africa	39,200	575	6·53
Port Henry, N.Y. ...	230	600	0·37
Franklin, N.J.	181	600	0·29
Yellowknife, N.W.T. ...	2,640	575	4·6
Yellowknife, N.W.T. ...	16,500	575	28·7

At the present time, insufficient is known of the causes of the discrepancies to permit correction of helium indexes, and while some mineral specimens give a value of I/A of unity, one cannot be confident from preliminary examination of the mineral that the 'correct' age will be obtained. It must therefore be concluded that the helium method in its present stage of development is not generally reliable as a means of geological correlation.

FORTHCOMING EVENTS

MONDAY, OCTOBER 13

THE FARMERS' CLUB (at the Royal Empire Society, Craven Street, London, W.C.2), at 3 p.m.—Mr. James Mackintosh: "Feeding Livestock under War Time Conditions".

TUESDAY, OCTOBER 14

ILLUMINATING ENGINEERING SOCIETY (at the E.L.M.A. Lighting Service Bureau, 2 Savoy Hill, London, W.C.2), at 2.45 p.m.—Mr. W. J. Jones: "Light and Lighting—A Forward Outlook" (Presidential Address).

WEDNESDAY, OCTOBER 15

INSTITUTE OF FUEL (in the Connaught Rooms, Great Queen Street, Kingsway, London, W.C.2), at 2.30 p.m.—Mr. W. M. Selvey: "The Hundred Thousand, an Engineer's Philosophy" (Presidential Address). Dr. Clarence A. Seyler: "Recent Progress in Coal Petrology" (Melchett Lecture).

THURSDAY, OCTOBER 16

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Prof. I. M. Heilbron, F.R.S.: "Some Aspects of Algal Chemistry" (Eighth Hugo Müller Lecture).

FRIDAY, OCTOBER 17

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at the Literary and Philosophical Society, Newcastle-upon-Tyne), at 6 p.m.—Annual General Meeting. Mr. W. A. Woodeson: Presidential Address.

SATURDAY, OCTOBER 18

NUTRITION SOCIETY (at Cambridge).—Conference on "The Evaluation of Nutritional Status". (See page 433 of this issue.)

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

PRINCIPAL of Melton Mowbray and District County Technical College—W. A. Brockington, Esq., Grey Friars, Leicester (October 14).

PSYCHOLOGIST—The Hon. Secretary, Cheltenham and County Child Guidance Clinic, Education Department, Municipal Offices, Cheltenham (October 15).

LECTURER IN THE DEPARTMENT OF PHARMACY—The Principal, Central Technical College, Suffolk Street, Birmingham 1.

ASSISTANT CONTROLLER OF TELECOMMUNICATIONS (ENGINEERING) for the Malayan Postal Service—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M/9795).

LECTURER IN PRINCIPLES OF EDUCATION at Victoria College, Belfast—The National Froebel Foundation, 2 Manchester Square, London, W.1.

INDUSTRIAL CHEMISTS (preferably with works experience)—The Director, British Launderers' Research Association, The Laboratories, Hill View Gardens, Hendon, London, N.W.4.

ASSISTANT MISTRESS TO TEACH ELEMENTARY SCIENCE AND MATHEMATICS—The Headmistress, Day Technical School for Girls, Fort Pitt, Chatham.

FIRST CLASS HONOURS GRADUATE IN CHEMISTRY, WITH SUBSIDIARY PHYSICS—The Principal, University Correspondence College, Burlington House, Cambridge.

NATURE

SATURDAY OCT. 18, 1941

FOUNDATIONS OF A NEW WORLD ORDER

THE Atlantic Charter has rightly been recognized as a political offensive of the first order. It is the starting-point for far-reaching and greatly intensified political warfare. Even more important, there is scarcely one of the eight points that is not a challenge to clear, fundamental and constructive thinking. That in certain respects most of the eight points require elaboration, if not elucidation, does not detract from the significance and value of the charter they constitute.

The many attempts already made to outline the basis of a new order which affords an adequate reply to that which the Nazis seek to impose on a prostrate Europe must therefore be given careful consideration. Two such recent efforts may be commended to the attention of scientific workers for their contribution to clear and constructive thinking. The first of these, by Prof. E. H. Carr, in the Democratic Order series of pamphlets*, deals particularly with the issues involved in the principle of self-determination and nationality, and should help to clarify thought about the second and third points of the Charter. The second, Mr. C. B. Purdom's "The New Order"†, goes even deeper into the social and economic changes involved in the establishment of any new order which worthily embodies the ideas of the fourth, fifth and sixth points of the Charter.

Prof. Carr's pamphlet derives its main value from its critical exposition of some of the fallacies which have initiated policy in the past, although he concludes with various constructive suggestions. He directs attention to the limited validity of the supposed coincidence between the principle of nationality and that of self-determination. Generally speaking, this is valid only for the limited area of western Europe, and self-determination should accordingly be carefully disentangled from those misleading associations with nationalism which nineteenth-century thought fastened upon it. It must be recognized in future that the self-determination of small nations is incompatible with unbridled economic power and complete economic independence.

Furthermore, Prof. Carr points out that the development of military technique and the conditions of modern warfare have broken down the conception of the independence of small States based on the principle of self-determination. In modern conditions of warfare, a small State cannot defend its independence against a great Power except by methods which in themselves constitute

* The Future of Nations: Independence or Interdependence? By E. H. Carr. (The Democratic Order, No. 14.) Pp. 64. (London: Kegan Paul and Co., Ltd., 1941.) 1s. net.

† The New Order. By C. B. Purdom. Pp. xvi+286. (London: J. M. Dent and Sons, Ltd., 1941.) 7s. 6d. net.

a surrender of military independence. Interdependence has become an inescapable military necessity. Neutrality has been virtually nullified for small nations in proximity to the theatre of war, both in the military and in the economic sphere. The small Power can in fact only survive by seeking the permanent alliance of a great Power.

Prof. Carr maintains that the failure of the settlement of 1919 was due, first to disregard of the economic factor, and secondly to neglect of the way in which military conditions had thus qualified self-determination. Moreover, many factors already introduced in the present War tend further to complicate the question of self-determination and independence. The offer of Great Britain to form a union with France, and also the Atlantic Charter, are the most striking examples of the extent to which nations have been prepared for close military and economic co-operation for the tasks of peace. The Inter-Allied meetings in London, a composite army, a navy and an air force in which units of different nationalities are embodied under a single command, the possession by one country of naval or air bases on the territory of another—all these are arrangements which need not disappear with the war. The Eight Points show that the democratic leaders have no intention of returning to the anarchy and confusion that marked the life of the world between the two wars.

Tentatively, Prof. Carr concludes, therefore, that we must discard the nineteenth-century assumption that nation and State should normally coincide, and lay far less stress on the absolute character of the right of self-determination and far more on its necessary obligations. Neglect of these correlative obligations was one of the cardinal errors of 1919, and Prof. Carr indicates how from this flow two lines of development towards international order: recognition of the need for a larger unit than the present nation for military and economic purposes and, within this unit, for the largest measure of devolution for other purposes, and recognition that the right of national self-determination can be valid only within the limits of this necessity for military and economic concentration.

Acceptance of these principles clearly involves a revolution in our whole thinking about neutrality, economic policy and defence, and that revolution must commence before the fighting ends. The lines of policy suggested by Prof. Carr are in fact well calculated to gain time for such a transformation of thought to occur. First, he urges the vital importance of maintaining, for the organization of peace, the forms of co-operation already established by those united in the struggle against Nazism. This machinery of interdependence and co-operation should be extended to other countries by an empirical process based on practical needs and possibilities. In the same way the constitutional forms of such co-operation must be determined, not theoretically according to some *a priori* conception of league, alliance or federation, but empirically as the outcome and expression of a practical working arrangement. The establishment and maintenance of *de facto* co-operation are far more important than the drafting of constitutional rules to regulate. At the present stage, interdependence is the practical problem of surrendering the habit of framing our military and economic policy without regard for the needs and interests of other countries.

In spite of the entirely different approach, Mr. Purdom's much more ambitious study gives a strikingly similar outline of a new order. The greater part of his book is indeed occupied by a comparatively detailed outline of a new order in Britain, but like Prof. Carr, he insists in the first place on the need for a new attitude, for a revolution in thought and the readiness to sacrifice old prejudices and ways of thought and living. The new order he outlines is built up of nations or States in which this changed outlook has already occurred, and the evolution of international institutions, whether in Europe or in the world at large, proceeds from the nation as model and as unit.

The structure of the new order conceived by Mr. Purdom is association in the State, society and nation, and it is to be built up through the recognition of the functional principle. International co-operation becomes practicable through the creation of functional organs within the nation and through the removal of sovereign power. The conversion of the British State into a functional organ involves the separation of economic and cultural from civic and political objects, those functions of the State now concerned with industry and trade being entrusted to an economic organ and those concerned with education, health, art and science to a cultural organ. The State would then be concerned strictly with its ancient functions of legislation, justice and order.

Mr. Purdom's proposals for the transformation of British institutions into a functional social order are detailed, and involve new conceptions of politics, of city life and of the value and significance of local government, as well as a new emphasis on cultural institutions; the removal of trading services and education from civic government gives a new aspect to regionalism. In the structure tentatively outlined, there are three functional chambers, of which the Civic Chamber would continue the specific characteristics of the House of Commons for legislation and retain its name and rules and forms. The House of Lords would be transformed into the Senate, its members appointed

for life from among men and women distinguished in religion, science, art, letters, education, medicine, economics and civic affairs, and there would also be a Senate of Women and a Senate of Youth with consultative and advisory functions only.

The main element in the economic life of this new order would be the Economic Chamber, to which all the economic and industrial functions of the State would be transferred; it would be responsible for the reorganization of the economic life of the community, and the creation and supply and distribution of the goods and services required. This Economic Chamber would be concerned with all industries, primary and secondary, with power, transport, postal communications, agriculture, fisheries, shipping, distribution and banking. The individual, competitive, or monopolist units in every industry and service would be replaced by guilds composed of all engaged in the industry or service in whatever capacity. Through this system Mr. Purdom considers a new sense of vocation could be developed and a new standard of scientific production attained. Besides the guilds, the Chamber would work through a series of economic boards which would deal with proposals affecting the guilds or the Chamber, and consider and review regulations made by the guilds or legislation affecting them.

Parallel with the Economic Chamber, Mr. Purdom proposes a Cultural Chamber responsible for the bodily, mental and spiritual welfare of the community. This Chamber would consist of representatives of the churches and the various cultural guilds covering science, art, education, recreation, publication, etc., for which councils would also be formed through which the Chamber would work. These cultural organs, which unlike the economic organs, would not be limited to those less than forty-nine years of age, are intended to overcome the defects of specialization while enabling science and other cultural factors to exert their full humanizing influence on society.

Both in the economic and in the cultural sphere these institutions are visualized as reaching down into a system of co-ordinated local guilds in which the individual and the locality have full opportunity to make their own contribution. Similarly, while a Central Planning Board under the Minister of Planning as chairman, and formed jointly from the Economic Planning Board and the Board of Cultural Planning, would take care of the central planning required to avoid overlap and ensure consideration of all factors in national planning, it is from these same individual economic or cultural units that Mr. Purdom visualizes the beginning of effective international co-operation. The structure he contemplates for Britain would have its counterpart in the Dominions, from the political, economic and cultural chambers of which there would be formed three distinct federations: a Commonwealth Political Federation, a Commonwealth Economic Federation and a Commonwealth Cultural Federation. In addition, a Commonwealth Planning Council would be concerned with the higher direction of Commonwealth policy. The Colonies might be brought into the system as a commonwealth responsibility under a Commonwealth Colonial Council.

These Commonwealth federations are Mr. Purdom's model of the new world institutions. Functional federation on such lines, including a federal union of States with a federal defence council, federal court, currency council, colonial council and political planning council, a federal economic union, a federal cultural union, embracing a scientific council, a council for art and a planning council for culture, and federal planning institute, first for Europe and then extending to a world union on the same lines, offers, he considers, the most hopeful solution of establishing a European and a world order giving full satisfaction to human aspirations and ideals, and in which liberty and individuality would be reconciled. It offers, too, a solution of the problem of the place of Germany in a new Europe, and many of the changes he suggests can be built on developments or institutions already brought into existence by the War.

Mr. Purdom's proposals are no doubt ambitious—many would say visionary—but there is more to commend them than even the fact that some of his suggestions are taking crude shape under the stress of war. By far the most successful international co-operation of the last two decades has been on functional lines, and by concentrating on such developments, encouraging through them the development by education, through world planning and through cultural or economic contacts, of a widespread world consciousness, while preserving, as Prof. Carr insists, the institutions of co-operation established to serve our immediate tasks of defence or offence, it may be possible to move forward to a more concrete and formal organization when the time is ripe. Meanwhile, Mr. Purdom's proposals at least merit serious and critical examination. They indicate one way in which the points of the Atlantic Charter might be translated into action. Whether the particular proposals he details are adopted or not, no new order embodying the spirit of that declaration and safeguarding the four freedoms of mankind will ever be elaborated save by utilization of creative energy, and by readiness to face change and to accept sacrifice and responsibility. It is in that spirit alone that the immense opportunities that the War has brought can be seized and turned to the building of a new order, a new society of free men and free peoples.

REASON AND THE 'NEW ORDER'

Ideals and Illusions
By L. Susan Stebbing. Pp. xiii+206. (London: Watts and Co., Ltd., 1941.) 8*s*. 6*d*. net.

THIS book, which is written by a philosopher, deserves to be widely read. It could be used by 'advanced groups' studying the problems of the post-war world. It is suitable also for the isolated student and especially, I think, for the scientifically trained and for religious people.

It is not a very easy book to read. Some re-arrangement of the chapters might clarify the argument, but the difficulty arises rather from the nature of the subject than from faults in authorship.

The object of the book is to examine one of the three important causes that have led to the present "profound failure" of civilization. The method adopted is that of rational or Socratic criticism. The part played in Plato's Dialogues by his acquaintances is taken by a large number of leaders of modern life: political, economic, philosophical and religious. One by one, they are brought into the discussion by means of extracts from their books or speeches. Interesting results follow the rational criticism of their words.

The argument of the book is based upon the dictum that there are "three important factors that determine social change: economic structure, the possession of power—especially naked power—and ideas".

Prof. Stebbing deals only with the last of these factors. "The modern world over-emphasising power has neglected the significance of ideals." An ideal is described as being "something considered to be worth having", an idealist as "one who is influenced in his actions by his ideal". No description is given of an illusion, but it appears that an ideal that will not withstand rational criticism or is impractical, does not influence conduct, or is evil in its social consequences, is an illusion.

The close connexion between good ideals and good social conduct is repeatedly stressed—at least by implication: the need for a sound criterion of the rightness or wrongness of an action —the need, that is to say, for a sound basis for morals—is emphasized again and again.

Some people attack idealists because they believe them to be utopians and visionaries, but the attack may be due to verbal misunderstandings or to the careless use of words. Again, misunderstanding may arise from a confusion between ideals and illusions. Even the most ardent of the realists, from Machiavelli to Hitler, have possessed and have pursued ideals. It is an illusion to suppose that realists have no ideals: the question is whether their ideals are good or bad. Another illusion is to hold "that unless there be a goal for man beyond and outside the historical process, our lives are without significance and futile" and, in that case, that there "remains no basis for morals". But "many spiritual excellencies are valuable for their own sake" and do not depend upon a future life.

Everything points therefore to the "need for reflection" in order that we may be able to distinguish ideals from illusions. "The unexamined life is not a life worth living for a human being", said Socrates.

The modern tendency to disparage reason is considered. The 'retreat from reason' is found to be due, in part, to a longing for certainty and for absolute moral standards. Certainty is an illusion; in seeking for it we "always over-simplify our real problems".

Next we consider the "democratic ideal". A starting-point is found in a sentence in the American Declaration of Independence, "that Freedom and Happiness are the inalienable right of all men". The ideals of freedom and happiness are examined. The divergent ideals of democrats and totalitarians are made more clear to us. After that we consider an illusion, that happiness is irrelevant to the good life since, as some Christians have asserted, poverty, pain and suffering are disciplines for the soul. But "if our sensibilities are unblunted, we cannot ignore the tragic happenings in our world. Not to ignore them is to be forced to do something about them; and to do something, it is first necessary to make clear to ourselves our political ideals." Another common illusion is to suppose that democracy can be achieved simply by "playing the game".

Once again we examine the conflicting ideals of the democrat and the totalitarian, and as we do so we encounter the illusions that arise from the careless use of abstract words like war and poverty. At this point the author suggests a device by means of which some of our illusions may be evaded. She suggests that the main abstract word in a sentence should be translated into an "equivalent sentence" composed of corresponding but less abstract words. When this has been done, it is usually not difficult to discover to what extent our thinking has been confused by the abstract words. In this manner we shall learn to speak plainly and think more clearly. Abstract words such as 'conscience' and 'conscientious' are next examined.

Finally, we return to a point raised earlier in the book. This is what the author calls the "Last

Illusion", namely, the idea that morality is dependent (as most, but not all, Christians hold) upon a belief in *personal* and *conscious* immortality. This last chapter seems to me to fall below the standard set by the rest of the book both in clarity and significance. The argument aims at showing that a belief in personal immortality is an illusion and that a rational basis for morals can be found without invoking this belief. But it may be asked whether a *rational* basis for morals is sufficient for our present tragic circumstances. It seems to me that what is chiefly necessary is a sound *conative* basis for morals, that is to say, an adequate and an enduring 'drive' towards right conduct. May it not be that, even if a sound rational basis for morals can be found within the time-space order, adequate and persistent moral *drives* can only be found within an eternal order? A. N. Whitehead has said: "What Plato thought, Christ did." Within the difference that existed between Plato and Christ is to be found (as it seems to me) the 'drive' that the modern world needs. Dr. Stebbing asserts that a sound basis for morals can be found in "metaphysical materialism". I venture to doubt it. At least we should require an "equivalent sentence" for these highly abstract words before forming an opinion. Perhaps paper economy is responsible for the vagueness of her final chapter—or it may be that my illusions or her illusions are responsible for it.

I regret that the book has no index, not even an index of quotations. This last omission seems to be a serious fault in a book of this kind. But I hope that I have sufficiently commended a valuable discussion of an important topic.

HOWARD E. COLLIER.

PLASTICITY IN METALS

The Metallurgy of Deep Drawing and Pressing
By Dr. J. Dudley Jevons. Pp. xvi+700+164 plates. (London: Chapman and Hall, Ltd., 1940.) 50*s*. net.

THE modern use of metals and alloys is dependent to a very large extent on their plasticity, which allows them to be worked into useful forms in the solid state, at ordinary or at raised temperatures, by methods causing plastic flow. It is not only in course of manufacture that this plasticity is useful, since the same property is a safeguard against sudden fracture under stress. Possibly the most striking example of the importance of plasticity in metals is the hot-rolling of vast quantities of steel into many different forms, but the pressing of metal sheet into finished shapes at atmospheric temperatures is also now a great and expanding industry. To give one example, the present-day motor-car body is essentially an assemblage of sheet steel pressings.

In the past, the hot and cold working of metals were both looked upon as primarily the province of the engineer, no doubt because of the engineering knowledge demanded in the design, construction and operation of the powerful rolling mills, hydraulic presses and other machines used. More recently, the metallurgical problems arising have received a larger share of attention. Organized co-operative investigations are now in progress in Great Britain on the rolling and on the deep drawing of metals. Prof. H. W. Swift, who has written a foreword to this book, has for some time been conducting a section of these researches on deep-drawing problems, and has, in particular, made advances in methods of determining the capacity of metal sheet for undergoing deep-drawing operations satisfactorily. "Deep" drawing imposes severe plastic deformation on sheet metal by means of a punch and a die in a press. The production of a brass cartridge case from a flat disk in successive drawing operations, with intermediate annealings to restore the plasticity lost in the hardening caused by cold work, illustrates the extent to which such cold-working operations can be carried in deep drawing.

Dr. Jevons has made the subject of deep drawing peculiarly his own and has taken full advantage of his special opportunities for investigating its application on the large scale. He has produced a comprehensive treatise in which none of the metallurgical aspects of deep drawing is neglected. He has indeed gone outside this field in giving excellent concise descriptions of the manufacture of the two chief materials of deep drawing, brass and steel sheet. While far more adequate accounts of, for example, the iron blast furnace are naturally to be found elsewhere, those engaged in deep drawing, for whom the book is mainly written, will be helped by the descriptions of the manufacture of the materials the properties of which are so important to them. Mild steel of the softest grades and annealed brass such as 'cartridge brass' containing about 70 per cent copper, 30 per cent zinc are specially suitable for deep drawing because of their very high plasticity.

The cold pressing of flat sheets into various forms is such a quick, convenient and economical way of

producing relatively intricate shapes that it is often applied to the utmost limit of the deformation the sheet will stand. Thus there is a never-satisfied demand for still better deep-drawing properties. Dr. Jevons has rightly given much space to the questions, less simple than might be thought, of what constitutes good deep-drawing properties in the various materials used, how these properties may be controlled, measured and specified, the many causes of defects and failures occurring in drawing or as a consequence of it, and means of overcoming these troubles. In this section special chapters are devoted to the season-cracking of brass resulting from internal stresses remaining after drawing (a trouble which should occur less frequently than it does as methods of prevention are well established) and stretcher-strain markings in steel. These markings, a form of 'Luder's lines', caused by local 'necking' under the tensile stress imposed by drawing, constitute a difficulty in the drawing of mild steel which is not easily surmounted. Presses, tools, lubricants, new applications of deep drawing, and the deep drawing of metals other than brass and steel are the headings of other chapters each dealing adequately with its subject. The avoidance of defects and failures by improvement in design of the pressing, in pressing operations or in the drawing qualities of the metal sheet is discussed in an impartial and authoritative manner.

Plasticity in metals is a property of the individual crystal. Dr. Jevons attaches full weight to such factors as size and orientation of the crystals and discusses 'directionality' in an illuminating way. The mode of deformation of metals, even in relatively simple and well-defined conditions, and the effects of such permanent deformation still present many obscurities. The scientific study of the severe and intricate plastic flow involved in deep drawing, of the changing conditions of stress and strain, and of the complex effects resulting, is full of difficulties, and practice rests mainly on empirical knowledge. Nevertheless, Dr. Jevons considers that there is urgent need for a much wider application to deep drawing of scientific investigation and control, which have already solved serious problems in this field.

Although the book is a very substantial volume Dr. Jevons has compressed his encyclopædic knowledge of the subject into manageable compass and has contrived to make it thoroughly readable. All the industries concerned and all those who have occasion to take a scientific interest in any aspect of deep drawing have reason to be grateful to him for this masterly treatise. Its appearance during the War has been most opportune because of the extent to which deep drawing is employed in the manufacture of aircraft, ammunition, transport vehicles and innumerable other war requirements. The lavish illustrations add to the value of the book, and the way in which it is produced is worthy of the excellence of its contents.

THE BARTRAMS: BOTANISTS AND EXPLORERS

John and William Bartram, Botanists and Explorers: 1699–1777, 1739–1823

By Ernest Earnest. Pp. vii+177+2 plates. (Philadelphia: University of Pennsylvania Press; London: Oxford University Press, 1940.) 12*s*. net.

THIS book is delightful reading. It tells of pleasant people in happy times, for it is mostly about Philadelphia in Benjamin Franklin's day. John Bartram, member of the Society of Friends and poorly educated in a village school, bought a piece of rough land on the Schuylkill River, hard by the city, in the year 1728; there he built his house, drained his land and won his way to prosperity. Meanwhile he planted a garden and learned botany, became a friend of Benjamin Franklin, and signed his name next to Franklin's own on the Founders' Roll of the American Philosophical Society. He came in close touch with Peter Collinson, and was the chief source of new and rare American plants for him and his many gardening friends; sent pine-cones to the Duke of Norfolk and seeds to Philip Miller and dozens more; was dubbed king's botanist for the American Colonies by George III, made a member of the Royal Academy of Sciences of Stockholm, and called by Linnæus the greatest natural botanist in the world.

He was indeed a remarkable man, and his son William was no less remarkable in his own way. When "Billy" was a schoolboy—"botany and drawing are his darling delights", said his father, "and I'm afraid he can't settle to any business else". The forecast came true. But William Bartram learned to draw exquisitely, knew his plants and his birds, was loved and trusted by the Indians, travelled far and wide and constantly, and at last wrote a famous and beautiful book. To write English undefiled was no rare accomplishment in the Quaker city, but Bartram wrote his "Travels" in such a style as influenced Chateaubriand and delighted Wordsworth and Coleridge himself. From Bartram, Wordsworth took his Indian scenes for "Ruth", and Coleridge

got his sacred river, with its "caverns measureless to man". As Coleridge says in his "Table Talk", "the book was written in the spirit of the old travellers". Wordsworth's "pulse of the machine" was Bartram's own "pulse of nature"; and what Bartram conceived as an "impulse" controlling the life of the plant grew in Wordsworth to "One impulse from the vernal wood May teach you more of man . . .".

Mr. E. Earnest has done his work admirably well; but he might have told us a little—for he tells us nothing—about the many plants which the Bartrams discovered and sent to England.

D'ARCY W. THOMPSON.

CHEMISTRY IN WAR

Annual Reports on the Progress of Chemistry for 1940

Vol. 37. Pp. 525. (London: Chemical Society, 1941.) 15*s*.

THERE is a proneness to designate this as a physicists' war in contradistinction to that of 1914–18, which was widely called a chemists' war. Then Great Britain was short of trained men, knowledge and the manufacturing equipment to make many materials essential for the State and the people; broadly speaking, the same applies this time to physics, which has changed during the last decade from a largely theoretical to a definitely applied science.

Though less is heard of the chemist it does not mean that he is stagnant: in fact both science and industry took the lessons of the War of 1914–18 very much to heart, perhaps more so than any other section of the community. A steadily increasing stream of highly trained students—chemists and chemical engineers—flows from the universities, while the industry has become both highly organized through its trade association, conscious of the value of more and more research, up to date in its methods of manufacture. As a result the outbreak of war found it able to supply the national needs of essential chemicals and medicinals and to undertake without much delay the manufacture of a few substances protected by patent and hitherto imported.

It is common knowledge that there is now increased pressure for every single thing that can be produced at home, and even this greatly enhanced demand for chemicals has been largely met. Substitutes usually mean synthetic materials in which chemicals are involved, and now that the stage has been reached of making substitutes for substitutes it is more than ever a question of more chemicals. Thus the very fact that little if anything is heard in public of the chemical industry, of the shortage of this or that chemical, of the need for trained men, is a tribute to the prevision of the industry and to its pre-war organization. We write "pre-war" in order that we may repudiate the term as indicating preparation: the industry was organized to supply the nation and the export trade with an expanding need for each and every chemical at competitive prices in normal times of peace. It has no interest in war chemicals as such; in war it diverts explosives from the mines to the guns and has to make so much more of this and that taken away from their multitudinous ordinary everyday uses. Those who are pleased to rant about the prostitution of science to war sometimes speak in ignorance.

The individual chemists are likewise playing their part, and the research workers, now a great army, are for the most part engaged in solving the nation's problems. In spite of this the scientific journals still contain original papers and abstracts of work in other lands; there is more than enough to form the subject of annual reports even more crammed with undigested material than usual.

These reports were originally issued in 1905, when Sir William Tilden was president of the Chemical Society, to present an epitome of the principal definite steps in advance "in order that specialists in any one department of the science may obtain without difficulty information as to the nature and extent of progress in other branches of the subject to which they have not paid special attention".

Judged from this criterion, the individual reports are a disappointment. The older man, the industrialist, the specialist in one field, as we nearly all must be nowadays, will not find it easy from them to discover the state of knowledge in other fields. In fact, the reports are written by a specialist in a field for others in the same field, described in the notation or shorthand, sometimes termed jargon, used in that particular subject, and therefore as incomprehensible to outsiders as the shorthand notes of their secretaries.

Surely it is possible for our future chemists to write clear statements in English about a subject of which they are masters. The Chemical Society should say whether it has departed from its original intentions: as they are to-day the "Annual Reports" appeal to specialists only.

E. F. ARMSTRONG.

SCIENCE AND HUMAN NEEDS

AMONG the many subjects that were discussed at the Conference on Science and World Order held during September 26–28, there was none that met with more support and general agreement than the need for an increase in the standard of living, especially as regards nutrition. Gone are the days of 'subsistence standards', that would give the necessary number of calories to keep body and soul together.

The right of every individual to the means of attaining his full inherited capacity for health and physical fitness, said Sir John Orr, of the Rowett Research Institute, Aberdeen, should rank equal with his right to religious and political freedom. We have now an authoritative standard of dietary requirements for health, but when diets in common use are compared with this standard, it is found that, even in the wealthiest countries, the diet of the poorest third of the population does not come up to the standard. This rough estimate gives an indication of the extent to which mankind can be freed from much of the burden of disease, poor physique and resulting suffering which formerly was thought to be due mainly to heredity and, therefore, inevitable.

In the decade preceding the outbreak of the War, some Governments realized the importance of the new science of nutrition for human welfare and took measures to improve the diet of the poorest. These measures have had striking results. The great decrease in deficiency diseases, the reduction in both infant mortality and tuberculosis death-rate, the increased stature and better physique of school-children which have taken place in Great Britain in recent years, are due mainly to the great improvement in the diet of the poorest. This gratifying and rapid improvement in national health shows how easily average health and vigour can be raised.

If we are going to plan for human welfare, we should begin with a food policy based on nutritional needs. This would do more to promote health and happiness, and alleviate the worst effects of poverty, than any other measure. If every family knew that, in any circumstances, they would have sufficient of the right kind of food to give their children full opportunity for the enjoyment of a healthy life, the worst fear of want would be eliminated.

Mr. Herbert Morrison, the Home Secretary, while careful not to commit the Government, expressed himself in equally unequivocal terms. Within the last generation, he said, science has given us a new body of exact knowledge about human and social needs. Social scientists have told us that in Great Britain nearly half the population, a few years before the outbreak of war, had a diet below the minimum needed for health. The great experiment made possible by the War has demonstrated that a people living on a diet more restricted in bulk and variety, need not suffer in health—indeed may even show some improvement as measured by epidemic statistics—when steps are taken to ensure that the food they get contains the right proportions of those ingredients needed for healthy living.

Our satisfaction about national health during the War must not blind us to the fact that we are, partly through ignorance, partly through poverty, still well below an optimum food standard; health, growth and expectation of life will all be greatly improved if we can attain that standard.

Turning to the question of housing and town-planning, Mr. Morrison pointed out that systematic study of the effect on health of immediate environment, and analysis of housing standards, have indicated that a certain minimum individual allowance of space, privacy, fresh air and sunlight is an essential for health. Yet, judging by the Government standard of overcrowding, which is by no means strict, more than 340,000 houses in England and Wales are found wanting. In one of our great cities nearly a third of the population are living in a state of overcrowding. The death-rate in the slums of one city is 28 per thousand, as against 18 per thousand in municipal houses.

As to clothing, the Board of Trade has given a flying start to exploration of this field, by the system of rationing now in force. We can accept sixty-six coupons, and what they will procure, as a useful first approximation to a minimum—not, of course, an optimum—welfare standard in clothing.

Dr. Agnes Hamilton, of the London County Council, dealt with the needs of a specific group, the housewives. She expressed the hope that time-saving appliances and fittings, now found only in the more expensive modern dwellings in Great Britain, will become available to all. The chromium sink, the electric mixer, the refrigerator, Bakelite fittings, and central heating and hot-water arrangements, if made available normally for the woman in the home, could revolutionize her life and that of her family. Not only could the home-keeper dispose of her household chores in a time limited enough to permit her to follow a career, if she wants to do so, but work in the house would also become a skilled profession, such as can enlist the services of regular workers who have the talent

for it that does not belong to every woman as such.

An account of some of the recent social work carried out in the United States for the relief of malnutrition and improvement of health was given during the session on world planning by Prof. Alvin Hansen, professor of political economy in Harvard University and special economic adviser to the Federal Reserve Board. In 1934, he stated, surplus farm products were purchased by the Federal Government for distribution to needy families and for use in school lunch programmes. In 1939 the Food Stamp Plan was inaugurated. That plan is now reaching about four million families and distributing foods worth 120 million dollars a year. Most of the foods so distributed are protective foods needed by under-nourished families. Free lunches are now available to about four million school-children. Low-cost milk is being distributed in several large American cities.

The Conference on National Nutrition for Defense, held in Washington last May, recommended vigorous and continual research in nutritional problems, more widespread education of medical men, dentists, social service workers and teachers, in the newer knowledge of nutrition; also the mobilization of motion pictures, the radio, the Press, and home and community demonstrations to spread knowledge of nutrition among the people.

The programme of nutrition should be attacked from an international angle. Arrangements could be made for international exchange of surplus products to be used for free school lunches, since the means exist now, for the first time in history, to produce abundant food for all mankind.

The level of health in the United States to-day, Prof. Hansen said, is higher than ever before, but it is none the less true that large sections of the people do not share in the general high health-level, and it is only just beginning to be realized that to ensure available treatment to all is a basic public concern. In 1934 President Roosevelt appointed a Committee on Economic Security to study, among other things, the country's health needs, and after the passage of the Social Security Act in 1935, he appointed the Inter-departmental Committee to co-ordinate health and welfare activities. This Committee, in its report, envisages a gradually expanding programme, reaching its peak by the end of the tenth year. The programme includes the creation of public health organizations and facilities for combating special diseases, and for maternal and child health services; also the expansion of present hospital facilities and medical care for the medically needy.

Lord Hailey, in his address at the session on world planning, discussed the needs of the peoples of the British and other colonies. We must see that they have the type of nutrition that will establish the necessary measure of resistance to disease. They must have access to medical facilities for dealing with physical disorders, epidemics and other sickness; and access to such measure of popular instruction as will enable the mass of the people to adjust themselves to the needs of new economic and cultural conditions. It is only in the last few years that we have inaugurated a general survey of nutritional conditions in the Colonies, and the extent of popular education was for long dependent upon missionary initiative.

Several of the papers presented to the session on post-war relief also dealt with problems that are of a permanent nature. Prof. Julius Löwy, of the University of Prague, mentioned that delicate and convalescent children are in need of mountain and sea air, and that industrial workers suffering from systematic poisons must be placed in suitable climatic conditions. Dr. Anni Noll pointed out that regular periodic health overhauls of family units, such as are carried out at the Peckham Health Centre, London, are essential.

Mr. Noel-Baker, M.P., supported earlier pleas for a balanced diet: "We know how much protective and energy-producing food every child and adult ought to eat, in other words, we know what our food policy ought to be. We know with mathematical certainty that if we could give every one a minimum standard for maximum health, the community as a whole would be richer, healthier and happier in every way, and we know that if we plan right, we could produce the food. Mr. McDougall Inglis, who is a very high authority, says that we could do it for North America and Australasia in five years, for the whole of Europe in eight or ten years, and for the whole world rather longer."

Returning to Sir John Orr's address, which set the tone to many of the subsequent utterances, it may be pointed out that he referred to several diet standards: the British Medical Association's "minimum", the League of Nations' "optimum", the American Agricultural Department's "moderate" and the American National Nutrition Council's "lowest" standard. He might have added to these Cadbury's "suggested" diet and the Engineers' Study Group "desirable" standard. Sir John did not go into the differences between these standards—and perhaps it is unnecessary to do so at this stage. The following article dealing with post-war relief makes it sufficiently clear that the diet-level in Europe and elsewhere is already very low, and likely to be at a starvation-level at the end of the War. It will not be practicable therefore to begin with the highest level, and we shall have perforce to pass through the stages represented by the several 'balanced' dietary standards.

SCIENCE AND POST-WAR RELIEF

OUT of the present terrible conflict there will arise upon its termination widespread calls for succour and help, said Dr. Wellington Koo, the Chinese Ambassador, at the Conference on Science and World Order, in opening a discussion on post-war relief. The need of care for the sick, food for the hungry, nourishment for the young, housing for the homeless, prevention of epidemics, and many other forms of assistance will be pressing. All this requires planning, and science can do much to facilitate it.

An example of the work which will have to be done was given by Mr. R. Allen, of the American Red Cross, who has recently returned from relief work in France. He described how they had found hospitals in Occupied France completely denuded of all supplies, the Germans having taken over not only the buildings but also all medical materials, and left the French to set up hospitals in churches and schools. The American Red Cross was able to help them with medical supplies without interference from the German military authorities, and in Unoccupied France distributed milk to children under fourteen, with excellent results.

Mrs. H. Priestman-Breal, of the Friends' Relief Mission, who was engaged in relief work after the War of 1914–18, showed much human understanding in her analysis of the problems of relief and reconstruction. These, she said, offer a great opportunity for international friendship and understanding, but one that might easily be misused, even with the best of intentions. Skill and knowledge are needed in such matters, otherwise some of the results might be the very opposite of what is intended, because the people one means to help, though they might be better off materially, might nevertheless feel sore, humiliated and indignant, no matter how irrational such a feeling on their part might appear.

Mrs. Priestman-Breal gave an outline of some of the work done in Poland after the War of 1914–18. In her opinion, merely handing out relief seems unsatisfactory, as it encourages certain people to beg. She has found various schemes for encouraging the initiative of the people to be helped which gave good results : in spring and summer, ploughing columns and seed distribution were started, in autumn and winter, timber hauling for rebuilding houses was organized, and spinning, weaving and embroidery, in exchange for food rations, was encouraged.

A superior attitude on the part of the relief worker would be fatal. One must remember that while it is pleasant to give presents, it is sometimes less pleasant to receive them. In such countries as France and Germany the danger of giving offence would perhaps be greater, and any superior attitude might be even more resented.

Sir John Russell, of the Rothamsted Experimental Station, delivered one of the most vivid speeches of the Conference, in discussing the steps that will have to be taken towards "restoring the scorched earth". The Russian and Ukrainian peasants, he said, are following their traditional policy of burning their villages and destroying all crops and animals which they cannot remove to safety. The inevitable consequence is famine and pestilence, and large-scale relief will be necessary. Agricultural reconstruction will be, if anything, more important.

Fortunately, the destruction of the soil is not likely to be serious. The conditions in the Ukraine do not favour soil erosion such as occurred in the 'Dust Bowl' of the United States, in spite of the high proportion of cereal cropping—always a predisposing cause.

The reconstruction of agriculture will, however, be very difficult. Russian plant breeders have produced numerous varieties of crops specially suited to their different regions. Drought has always been a serious problem in the U.S.S.R. ; indeed the yields of grain are more dependent on favourable rain and snow fall than on any other factor. Rain- and snow-fall are out of human control, but in all countries the search for drought-resistant varieties is recognized as the surest way of coping with the problem. Russian men of science have been very successful in that field, and it would be a tragedy if the varieties produced as the result of so many years of labour should be lost. It would greatly facilitate reconstruction if selected varieties could be sent to western Canada and multiplied there in readiness for the time when the seed will be needed.

The reconstruction of the Soviet livestock population will be more difficult. It took five or six years to recover from the low level of 1933, which brought great distress to the U.S.S.R. Recovery would now be more rapid if the pedigree stock could be saved by sending animals eastwards out of harm's way. Selection and improvement have been steadily going on, and the technique of artificial insemination whereby a high-class male animal can fertilize a much larger number of females than is otherwise possible would be very helpful.

The destruction of trees is pathetic because it takes so long for them to grow again, but the British could help in regard to fruit trees, not by sending British varieties, which would not be at all

suitable, but by carrying on the Russian varieties, so as to ensure that the patient work of their fruit experts should not be lost. Very little material is needed, and it could be carried by air.

All these problems of reconstruction in the U.S.S.R., Sir John said, will arise in Poland also, but they will be intensified by the circumstances that Poland has no hinterland into which pedigree seeds or animals can be sent for safety, and the cutting down of the forests in the north will lead to soil destruction. We can greatly help agricultural reconstruction by maintaining British pedigree flocks and herds so as to supply breeding stock. After the War the planning of agriculture will become essential and special responsibility will devolve upon us as the largest buyers of agricultural produce. We must plan so as to safeguard British agriculture and to ensure that the distribution of British imports yields the maximum of benefit both to the producers of the materials and to ourselves.

Dr. E. Kodicek, formerly lecturer in psychology in the University of Prague, gave the warning that the organization of post-war relief will have to be based on a wide scheme of total post-war reconstruction rather than on charity. All attempts of the latter kind after the War of 1914–1918 were unable to deal adequately with the great tasks with which they were confronted, nor can they hope to do so after this War. To deal with these problems an efficient organization of scientific experts and politicians is needed which would have to possess sufficient executive powers to implement the plans upon which they decide.

There will be nutritional deficiencies in Europe in the west as well as in the east, and immediate measures will have to be taken to prevent a major disaster. But even more important is a constructive food policy for building up a post-war Europe. The relief programme will be the starting-point for mutual understanding and collaboration between nations. Plans for food distribution, food-growing, exchange, stocks of vitamin concentrates, care of mothers, children and the sick, and many other problems, will have to be organized from the wider outlook of nation-wide needs. The help of the separate Governments will be necessary, working in collaboration with each other and under an international organization.

The same considerations apply to health organization. Medical relief will have to be organized on the basis of State medical services, but will also have to pay regard to *inter*national as well as *intra*national requirements. Such services require to be directed by a central organization with executive powers. The immediate help needed after the War will include : medical supplies of all kinds, such as therapeutic sera and vitamin concentrates, the distribution and training of doctors to be sent to the distressed areas, etc.

As Mr. Hugh H. Smith, of the Rockefeller Health Foundation, pointed out, among the multiplicity of urgent problems which will face the post-war world that of health will be of prime and pressing importance. In no field will the 'good neighbour' policy be more necessary. Since no effective barrier can be raised against the entrance of many infectious diseases, each nation must concern itself with the health conditions of all other nations. Workers properly trained in the principles of epidemiology, supported by essential laboratory facilities, must be employed in the field. International effort must be co-ordinated and information must be collected by central agencies, for distribution to all.

Another urgent need of post-war reconstruction in the first days after the War, emphasized by Dr. Kodicek, is the planning of housing and the possibility of securing constructive work for the people. An international settlement of this kind would remove potential causes of discontent and unrest internally and internationally. The psychological re-education and enlightenment of people, who during the past few years have lost their faith in the pledged word, must be started now and intensified a hundredfold immediately after the War. Such re-education will be best helped by practical measures to be put into operation at the earliest moment. The simple force of the objects so achieved, together with the underlying idea of world understanding, repeated and again repeated by all methods of propaganda, would do much to persuade and convince people of the sincerity of Britain's aims.

The great opportunity offered by a concerted action in the matter of international post-war relief cannot be better expressed than in the words of Mr. Philip Noel-Baker, M.P., who recalled that President Roosevelt and Mr. Churchill have emphasized the need for building up a stock of food for post-war distribution. "The Allied Council has drawn up plans for the assembling, transport and distribution of such stocks. We know that Europe will be bankrupt, that this work will have to be done on lease-lend lines. It would be the greatest deed of charity in the history of mankind, ending the hunger of the people, saving scores of thousands of threatened lives.

"If the Government would treat relief as the first step in a long-term policy of world-wide scope, if they would hand it over to international control, if they would use that opportunity to replan for a new system, and mobilize behind it all the dynamic power of opinion that supports the Atlantic Charter, a new perspective of human welfare would indeed be opened up."

HUMAN LIFE AND DEATH AT HIGH PRESSURES

By PROF. J. B. S. HALDANE, F.R.S.

MEN are exposed to high pressures in a number of circumstances. They may be working in compressed air in a caisson or diving-bell, working under water in a diving dress, or attempting to escape from a sunken submarine. In the latter case it is obviously necessary that the air pressure inside a part of the ship should be equal to that of the water outside before a man emerges. This can be achieved either by flooding a small escape chamber holding only two men, or a whole compartment of the ship. Men have escaped by both these methods. They can rise through the water either holding their breath or breathing from a Davis submarine escape apparatus. The former method is not to be recommended, but it is not quite so hazardous as it sounds, for a lung-full of air at 5 atmospheres contains as much oxygen as a lung-full of oxygen at atmospheric pressure, and will allow a man to hold his breath for more than twice the normal time. The Davis submarine escape apparatus consists of a rubber bag and a soda-lime canister to absorb carbon dioxide. The bag is filled with oxygen from a small cylinder of the compressed gas. It has the advantage over air that it can be used almost to the last dreg. We shall come to its disadvantages later.

In June 1939, H.M. Submarine *Thetis* was sunk with civilians as well as naval officers and ratings. The Amalgamated Engineering Union and the Electrical Trades Union asked me to attend the investigation of this disaster, as some of their members had been killed. I was only able to carry out some very rough experiments during the course of this inquiry, but they made it clear that certain physiological factors concerned in escape from submarines had not been fully considered. I was therefore asked by Admiral Sir Martin Dunbar-Nasmith's physiological sub-committee on escape from submarines to undertake further research on this question, and it has very kindly permitted me to publish certain results. Messrs. Siebe Gorman and Co. put their plant and staff at my disposal. All the experiments described here were carried out in a small steel chamber at their works, which holds two, or at a pinch, three people in a sitting position. The experiments were conducted by Dr. E. M. Case and myself, on ourselves and twenty volunteers, including not only physiologists such as Dr. J. Negrin, the former Spanish Prime Minister, and Dr. B. M. Matthews, but also a number of working men. Four of our subjects were women. An account is in the press.

The physiological dangers fall under six different heads. The literature concerning (A) and (F), with a full discussion, has been given by Haldane and Priestley[1].

A. MECHANICAL EFFECTS

During rapid compression violent ear-ache, and even rupture of the tympanum, may occur if the pressure on the two sides of the tympanic membrane is not equalized. Most people can easily be taught to do this. Four working men who had never been in compressed air before were compressed to 10 atmospheres (corresponding to 300 ft. of sea water) in 5 minutes. A trained subject was compressed to 7 atmospheres in 90 seconds, and this rate could certainly be exceeded. About one subject in five cannot be taught to equalize the pressures rapidly.

During decompression there is less pain, but more danger to life. A number of men have died from rupture of the lungs, which forced air or oxygen into the pulmonary circulation, so that the circulation was blocked by air embolism. This was probably caused by a rapid rise of intra-pulmonary pressure, due to the subjects holding their breath while rising through the water. Any obstruction of the valve by which excess air leaves the escape apparatus would have the same effect. We have had no cases of embolism, but one of our subjects, Mr. J. M. Rendel, developed a pneumothorax.

At 10 atmospheres the density of the air is very striking. The voice becomes nasal, and the increased resistance of the air is obvious even when the hands are moved, and still more so when attempts are made to stir it. The resistance in breathing apparatus may be greatly increased, since the volume of air breathed is unchanged, but the mass increases tenfold, and turbulence may develop, increasing the resistance still further.

B. NITROGEN INTOXICATION

Behnke, Thomson and Motley (1935)[2] made the remarkable discovery that nitrogen is a narcotic at high pressures. We confirm their findings. In air at 10 atmospheres all our subjects felt very queer, and many behaved in an irresponsible manner. Manual dexterity was little affected, but arithmetical performance fell seriously in most cases. Some subjects became hilarious; others were greatly alarmed, and thought they were dying. Few could cope with several tasks at a time. There were, how-

ever, great individual variations. One subject, H. Spurway, though subjectively affected, was so resistant that her arithmetical performance was actually slightly improved at a pressure corresponding to 250 ft. The symptoms disappear when hydrogen or helium is substituted for nitrogen.

Behnke and Yarbrough (1939)[3] found that argon is rather more narcotic than nitrogen. These results are of importance for the general theory of narcosis, and further experiments with gases such as krypton, xenon and methane, which are regarded as physiologically indifferent, will be of great interest. It is also likely that at sufficiently high pressures, say, 20 atmospheres or more, hydrogen and helium will become narcotic. These gases would also perhaps reach the threshold concentration for taste or smell, as nitrogen and oxygen do for many people at a partial pressure of about 7 atmospheres.

C. Carbon Dioxide Intoxication

If a compartment of a submarine contained 1 per cent of carbon dioxide, this would not be noticed at atmospheric pressure. If, however, the compartment were flooded at 200 ft., the partial pressure would rise to 7 per cent of an atmosphere. This would make many people unconscious in less than five minutes, although fine work, such as gas analysis, is quite practicable in air containing 7 per cent of carbon dioxide at atmospheric pressure. The effects of carbon dioxide and nitrogen are additive. We investigated this question on a number of subjects. Their attitude may be exemplified by the notes made by Dr. H. Kalmus, a Czechoslovak refugee, just before losing consciousness at 10 atmospheres with a partial pressure of 6·5 per cent of carbon dioxide: "This is enough. This is enough.—Not necessarily too much." Consciousness was rapidly regained on decompression, and there were no appreciable after-effects.

D. Oxygen Intoxication

Paul Bert (1878)[4] found that oxygen is a convulsant at high pressures. At 7 atmospheres the convulsion comes on with little warning. There is a slight feeling of anxiety, which would, however, be disregarded under Service conditions. The clonic convulsions are very violent, and in my own case the injury caused by them to my back is still painful after a year. They last for about two minutes and are followed by flaccidity. I wake up into a state of extreme terror in which I may make futile attempts to escape from the steel chamber, whereas, like others, I am quite calm on recovery from carbon dioxide-nitrogen narcosis. Behnke, Johnson, Poppen and Motley (1935)[5] found that convulsions or syncope developed in men after about forty minutes at 4 atmospheres. We find that all of seven subjects could breathe oxygen for five minutes at 6 atmospheres. At 7 atmospheres, five minutes exposure is about the limit tolerated. It is obvious that convulsions of this sort would be fatal if they occurred while a man was wearing an escape apparatus under water.

E. After-effects of Carbon Dioxide

J. S. Haldane and J. L. Smith (1899)[6] reported vomiting on breathing ordinary air after breathing air containing a high percentage of carbon dioxide for some time. Alexander, Duff, Haldane, Ives, and Renton (1939)[7] reported vomiting and severe headache in several subjects after breathing air containing 6–7 per cent of carbon dioxide for an hour or longer. The same symptoms may occur if oxygen is breathed. We have not found such effects after breathing 6–7 per cent of carbon dioxide for so short a period as half-an-hour. Only one of the numerous subjects who lost consciousness when breathing air containing added carbon dioxide at 10 atmospheres even retched appreciably, and this was before losing consciousness, not on recovery.

It is clear that vomiting would be fatal during an attempted escape from a submarine, and it may have accounted for some of the deaths in the *Thetis*. It can be avoided by purifying the air, or by breathing oxygen or pure air for some minutes before attempting escape; this will give time for vomiting to occur if it is going to do so. On the other hand, this danger would not arise after a short exposure to a high partial pressure of carbon dioxide, such as is discussed under heading (C).

F. Bubble Formation during Decompression

This has been the principal physiological danger to divers in the past, and has been fully studied. The tissues take up nitrogen at high pressures. On decompression they become supersaturated and bubbles may form. With very rapid decompression, capillaries in the lungs and brain may be blocked with froth. This causes asphyxia and death unless the subject is at once recompressed. However, such embolism cannot occur if the blood has a reasonable opportunity of unloading its surplus nitrogen. The pressure should never be halved in less than a minute or so, which gives the blood from most organs an opportunity to release its nitrogen in the lungs. With slower rates the main symptoms are 'bends', that is to say, pain referred to the joints and bones, and other nervous symptoms such as paralysis and paræsthesia. These

are due to the formation of bubbles in the white matter of the central nervous system, and perhaps in the synovial fluid and bone marrow. Nitrogen is a good deal more soluble in lipoids than water, and this may account for the symptoms in question.

J. S. Haldane introduced stage decompression as a prophylactic, and Sir Robert Davis (1935)[8] found that this could be greatly accelerated if oxygen were breathed in the later stages. Even when oxygen is used, decompression lasts for an hour after 15 minutes exposure to 10 atmospheres. Unfortunately, no published figures exist on the limits of safety after very rapid compression to high pressures, followed by rapid decompression, such as occurs during escape from a submarine. We have obtained some data on this important problem. As regards decompression after longer exposures, some of our subjects have had slight symptoms when following the official tables, but these have never been serious. Others can be decompressed much more rapidly without any pain. We do not know the cause of this individual variation. Fatness may be a slight handicap, but I am fairly fat, and have had no trouble when following Sir Robert Davis's schedules of decompression, while thinner men have had 'bends' while doing so. Nor do we know the cause of the itching which is almost universal during decompression from high pressures, the rash which sometimes accompanies it, and the rarer symptom of nose bleeding.

Helium has been recommended as a preventive of decompression symptoms, and is used for this purpose in the United States. There is no question that it is of value at high pressures, as it completely does away with nitrogen intoxication. But I am much more doubtful of its value against 'bends'. Last December I was decompressed according to the Davis schedule after breathing a helium-oxygen mixture at 10 atmospheres. I developed severe pain over a good deal of my body which lasted for an hour or so, and which was followed by itching and 'pins and needles' over the area of the skin supplied by the 4th and 5th sacral roots. This was probably due to a bubble of helium in the conus, the tip of my spinal cord. Even after seven months I prefer a cushion to a hard chair, and may perhaps be excused for scepticism of the alleged prophylactic value of helium.

This failure of helium to prevent 'bends' throws a good deal of doubt on the current theories as to their causation. Helium is less soluble in water and fat than nitrogen; and whereas nitrogen is more soluble in fat than in water, helium is less so. For this reason it was erroneously concluded that it would be less likely than nitrogen to produce 'bends'. The whole problem demands a systematic experimental study with a number of gases. The experiments could be made on animals, whereas experiments on the narcotic effects of gases must be made on men. Animals give very unclear results in this case. Thus a canary flew normally in air at 10 atmospheres, while Drosophila refused to do so even when stimulated.

G. COLD

Even when the surface water is fairly warm, the sea may be below 40° F. at a depth of 200 ft. Among the questions which we investigated in this connexion was whether cold increases the narcotic effects of nitrogen and nitrogen + carbon dioxide. Dr. Case lay in a bath of melting ice until, after 12 minutes, he began to shiver violently. He was then compressed to 10 atmospheres, but retained his faculties sufficiently to multiply 47 by 13 in his head. I propounded this question, but was unable to solve it correctly, being more susceptible than he to nitrogen intoxication. A still more drastic experiment showed some adjuvent effect of cold, but it does not seem that any measures need be taken to combat it which would not be justifiable at ordinary pressures.

The main physiological problem to be tackled in planning escape from submarines at depths of 100 ft. or more is how to steer, so to say, between the Scylla of nitrogen poisoning and 'bends', and the Charybdis of oxygen poisoning. The detailed solution must depend on the details of construction of submarines and escape apparatus, so a full discussion is impossible at the present time. However, it also involves physiological investigations such as those here summarized, some of which will be published in greater detail elsewhere. I am convinced that physiologists have been far too negligent in investigating the limits of human existence, or at least of human consciousness. Physicists often find that mathematicians have already provided them with methods which they need for a theoretical account of their findings. It would be well if physiologists were to investigate the effect of abnormal conditions on human beings before, rather than after, these conditions have killed numerous people, whether in war or in industry.

CENTENARY OF QUEEN'S UNIVERSITY, KINGSTON, CANADA

By Dr. R. C. Wallace
Principal and Vice-Chancellor

On October 16, 1841, a Royal Charter was granted to Queen's College, to be established in Kingston in Canada. The Presbyterian Church of Canada, resentful of the position which had been taken by the Anglicans in the management of higher education, felt that it was necessary to have a college at which men might be educated in arts and theology for the ministry of the Church, and made application for the charter. Thus Queen's began as a denominational college, and remained under denominational control until 1912, when the Presbyterian Church relinquished all connexion with the University. A Theological College then was established under separate administration, though closely connected with the University, and was associated with the Presbyterian Church until 1925, when, on the Union of Presbyterians, Methodists and Congregationalists in Canada, the Theological College became affiliated with the United Church of Canada, and still maintains that affiliation.

From the beginning the College took a liberal view of its responsibilities. It established teaching in the humanities, mathematics and theology, but almost immediately decided to embark on the teaching of medicine. The Faculty of Medicine was eventually established in 1856. Applied science came later, when the need developed for mining engineers and metallurgists to guide the growing mining industry in Canada. The School of Mines was set up in 1893, and when its activity had widened it was incorporated as a Faculty of Applied Science in 1916. Courses in commerce, banking and chartered accountancy, which had been carried on in association with the Faculty of Arts for several years, were organized under a School of Commerce in 1937.

These are the dry bones of detail of organization. They are not the things that are most in mind when one thinks of the hundred years which have passed over the head of the embryo Queen's College of 1841. Some of the more intangible elements of the story of Queen's University deserve mention, for they have much to do with the remarkable sense of loyalty and devotion which the graduates of Queen's show to their Alma Mater.

The most striking fact in the history of Queen's University is the constant struggle against difficulties, financial and otherwise, with which the institution was faced. Few universities are free from financial worries, but Queen's in her history has had more than her share. In time of difficulty students as well as staff took off their coats and worked, until the situation was relieved. Out of this sharing of hard times together there developed a sense of co-operate responsibility which has welded Queen's people into a solid community.

A second fact of importance in giving the University its own individuality has been the personality of the teachers. The older graduates, when they gather together, recall the days under the outstanding administration of George Munro Grant, when a galaxy of men, such as it has been the good fortune of few university heads to gather together, moulded the intellectual life and character of those who were fortunate enough to sit at their feet. Grant was a great Canadian statesman, who gave Queen's the status of a national university; and Watson, McNaughton, Jordan, Dupuis, Shortt and Cappon were names to conjure with. We like to feel that Queen's has not departed from the tradition. It is, *par excellence,* a teaching university.

Its service to teaching and to education found a special method of expression. Queen's instituted a system of extramural correspondence courses, by means of which students who could not take the winter terms at the University were able by correspondence work and summer sessions to complete the work for the degree, the condition being that more than half the work must be taken intramurally. This system, in which Queen's was the pioneer and is still the chief exponent, has been of very great service to the teaching profession throughout the Dominion. In normal years, in a student body of 4200, some 2400 are taking courses under the extra-mural system, and are sitting for the regular university examinations for the degree in arts, or the special examinations of the Institute of Chartered Accountants or the Canadian Bankers' Association.

The University has made a special contribution to the public services. Under the direction successively of Shortt, Skelton, Clark, Norman Rogers, McArthur and Mackintosh, all of whom have given distinguished service to the public administration, a long list of Queen's students have gone into the public life of Canada. Ottawa has leaned heavily on Queen's for men, and continues to do so; while in the provinces, and more particularly in

Ontario, the Civil Service has drawn in large measure from those who received their inspiration from the men who served Queen's on the teaching staff, and served their country later in significant administrative capacities.

Though the emphasis has been on teaching, Queen's has not failed in contribution to knowledge during these years. John Watson was for more than thirty years the exponent of speculative idealism on the American continent, and he exercised a very real influence on philosophical thought. Jordan and Scott led a school of liberal interpretation of theological dogma. Cappon, sparing in writing, was recognized to be one of our ablest Canadian literary critics. Shortt had proved himself to be an authority on banking and currency before he undertook to reorganize the Civil Service system at Ottawa. Skelton, in like manner, had become known for his researches in Canadian political history before he went to Ottawa to build up the Department of External Affairs. The economic studies of Mackintosh, and the studies in Canadian history of McArthur, Trotter and Graham, maintain for Queen's a high place in the social sciences.

In the physical and natural sciences, the University has gained a reputation in geology, for which Brock and Miller laid the foundation, now maintained by Bruce and his fellow-workers. The practical problems in the Canadian Northland, from the metallurgical point of view, have been faced by Kirkpatrick, who made an important contribution to the recovery and utilization of cobalt. Clark has done much work on the critical state of fluids, and Gray is well known for the contributions he and his co-workers have made to knowledge of atomic structure. One need only name the work of Humphrey in psychology, Vlastos in social ethics, Miller in pathology, Sinclair and Boyd in lipids, Reid in gas gangrene, Hebb in intelligence testing, McRae in organic synthesis, Ettinger in physiological reactions, to refer only to a few of the present-day workers, to show that in variety and—may I add—in quality of scientific research Queen's is playing its part.

Queen's celebrates its centenary by reviewing the progress of thought during the last hundred years. To that progress universities have made important contributions. In the development of knowledge during the next hundred years the universities will have an even greater part to play.

OBITUARIES

Dr. Walter Gardiner, F.R.S.

The name of Walter Gardiner, whose death occurred on August 31, will always be remembered by botanists and physiologists for his epoch-making histological researches and discoveries on the continuity of protoplasm. Owing to many years of ill-health, he was unknown to recent scientific workers, except by his classic papers.

Born on September 1, 1859, he died on the eve of his eighty-second birthday and was one of the veteran fellows of the Royal Society—only three now living having been elected before 1890, the year of his election, at the early age of thirty and a half years.

He was the younger son of Mr. Stephen T. Gardiner and was born at Burwell, on the edge of the Fens, between Cambridge and Newmarket. He was educated at Bedford and was a scholar of the Royal Agricultural Society during 1874–1876, and proceeded with a scholarship to Clare College, Cambridge. In 1881 Gardiner obtained first class honours in the Natural Sciences Tripos and took his B.A. degree in 1882 and M.A. in 1885, in which year he was elected to a fellowship at Clare College; afterwards he was made an honorary fellow of the College (1915). In 1883 he was appointed science lecturer at Girton College and the following year, University demonstrator in botany. This post he held until 1888 when he was promoted University lecturer. He resigned the lectureship in 1897. He was elected bursar of Clare College in 1895.

Gardiner was associated with the Cambridge Botany School during the last years of Prof. C. C. Babington's professorship, when botanical teaching and research was at a low ebb and was being conducted mainly on uninspiring descriptive lines. The appointment of S. H. Vines, however, as reader in botany in 1883 and his conjunction with Francis Darwin, opened a new era in Cambridge botany. Into this new atmosphere Gardiner threw himself with energy, giving remarkable lectures to the advanced students, building up the Museum—founded originally by Prof. J. S. Henslow—and carrying on his own histological researches, in which he was influenced and greatly encouraged by Michael Foster and by Thiselton-Dyer, then assistant director of Kew.

Botanical teaching in Great Britain being so unsatisfactory, as Prof. F. O. Bower has pointed out in his "Sixty Years of Botany in Britain", Gardiner, like several other young botanists, went to Germany and he worked in the Botanical Institute at Würzburg during the summer of 1882 under Prof. J. von Sachs, for whom he had a profound admiration. At

Würzburg he started his work on protoplasmic continuity, demonstrating its occurrence in the pulvini of *Mimosa pudica*. He was also able to prove the existence of connexions between the cells of the leaf of Dionea, between the parenchyma cells of the stamens of Berberis, and in many endosperm cells and in ordinary vegetable tissue. These results were given in several communications to the Royal Society, the Cambridge Philosophical Society, and the *Quarterly Journal of Microscopical Science* 1882 and 1883, and in the *Arb. a.d. Bot. Institut Würzburg*, Bd. III, in 1884. His best-known paper, with figures showing the connecting threads, is that in the *Philosophical Transactions of the Royal Society*, Part 3, 1883, pp. 817–63, with three plates. His earliest paper was on the development of the water glands in the leaf of *Saxifraga crustata*, illustrated by his own drawings (*Quart. J. Micro. Sci.*, 21, 417; 1881). Vegetable tannins, the constitution of the cell wall and middle lamella, and the mucilage-secreting cells of Blechnum and Osmunda (with Tokutaro Ito) (*Ann. Bot.*, 1, 1; 1887) were among the other subjects on which he published important papers. Protosplasmic continuity, however, was his dominant research, and he was indefatigable in attempting to perfect his methods and to demonstrate the existence of the fine protoplasmic connexions across the pit-closing membrane of all vegetable cells. Nothing but the best would satisfy him, and weeks might be spent—as the writer well remembers—before a result which he would pass could be obtained.

I was singularly fortunate in being asked by him in 1898 to work in his own laboratory, and here several happy years were spent with him in perfecting methods and demonstrating continuity between the cells of every plant subjected to investigation. Much of this work has never been published, but our joint papers on "The Histology of the Endosperm of *Tamus* during Germination" (*Proc. Camb. Philos. Soc.*, 11, Pt. 6; 1902) and on the connecting threads in *Pinus sylvestris* and other allied species (*Phil. Trans. Roy. Soc.*, 194; 1901) embody important aspects of his work.

Walter Gardiner was a remarkable lecturer and spared no pains fully to illustrate his lectures in an unusual and arresting manner. His afternoon lecture on "The Plant in the War of Nature" at the Royal Institution in 1888, and his evening lecture at the British Association meeting at Newcastle, 1889, on "Plants in the Struggle for Existence", were specially memorable.

Gardiner was awarded the Rolleston Prize by the University of Oxford in 1888, he and William Bateson being declared equal. In 1898 he received the Royal Medal from the Royal Society and in 1905 the degree of Sc.D. was conferred upon him by the University of Cambridge.

A keen naturalist, with a highly developed artistic sense, Gardiner had a very extensive knowledge of his subject, which was enhanced by his frequent visits to Kew, where he did much of his early work in the Jodrell Laboratory. Histological research in Great Britain suffered a great loss when he was incapacitated by illness from continuing his studies.

He married Miss I. W. Campbell, a great-niece of Sir Joseph Hooker, in 1893, to whom, and to their son, Mr. Alan Gardiner, F.L.S., and their daughter, we extend our sympathy. Arthur W. Hill.

Prof. Otfrid Foerster

Prof. Otfrid Foerster, one of the most prominent neurologists of the day, whose recent death has been announced, was born in Breslau on November 9, 1873. After receiving his medical education at Breslau, Kiel and Freiburg, he qualified in 1897. He studied under Prof. Dejerine at La Salpétrière, and then became assistant to Prof. Wernicke in the psychiatric clinic at Breslau, where he was appointed professor of neurology and psychiatry in 1921.

Foerster is perhaps best known for the operation to which his name is attached for the treatment of spastic paralysis and tabes, but his most important work consisted in his studies of the motor cortex and peripheral nerves. His principal publications were on the physiology and pathology of co-ordination (1902), co-ordinated movements in health and nervous and mental disease (1903), the essence of choreic motor disturbances (1904), contractures in pyramidal lesions (1906), diseases of the central and peripheral nerves (1923), hyper-ventilation in epilepsy (1925), and the paths of conduction of pain in flaccid and spastic paralysis (1927). He was, formerly, co-editor with Prof. O. Bumke of the "Handbuch der Neurologie" and on the editorial board of the *Deutsche Zeitschrift für Nervenheilkunde*.

Foerster was a good European and therefore no friend of the Nazis, which may account for his name not appearing in *Wer Ist's*, the German *Who's Who?* A eulogy of him, however, appears in the *Deutsche Zeitschrift für Neurologie* of 1933, on the occasion of his sixtieth birthday, by Prof. Max Nonne of Hamburg. He was well known in Great Britain, where, in 1927, he was elected an honorary member of the Section of Neurology of the Royal Society of Medicine, before which he delivered the ninth Hughlings Jackson Lecture in 1935, published in *Brain*, 59, 135 (1936), his subject being "The Motor Cortex in Man, in the Light of Hughlings Jackson's Doctrines". He was elected an honorary fellow of the Society in 1933. J. D. Rolleston.

We regret to announce the following deaths:

Baron Mataro Nagayo, formerly president of the Tokio Imperial University, director of the Japanese Foundation for Cancer Research, and editor of *Gann*, the Japanese journal of cancer research, on August 16, aged sixty-three years.

Prof. Rudolf Schoenheimer, associate professor of biochemistry in Columbia University, formerly head of the Department of Pathological Chemistry in the University of Freiburg, known for his work on the application of isotopes for the study of intermediary metabolism, on September 11, aged forty-three.

Mr. M. M. Ussishkin, president of the Jewish National Fund and chairman of the Zionist General Council, one of the founders of the Hebrew University, Jerusalem, on October 2, aged seventy-eight.

NEWS AND VIEWS

The Declaration of Scientific Principles

MR. H. STRAUSS, M.P., has written stating that the wording of Clause 4 of the Declaration of Scientific Principles presented at the British Association meeting on September 28 (see NATURE, Oct. 4, p. 393) is capable of misinterpretation. The British Association, through Prof. Allan Ferguson and Dr. O. J. R. Howarth, has acknowledged that it does not wish to prescribe any documentary statement as final, and that it is fully prepared to alter the wording of the Declaration in the light of friendly and constructive criticism, while leaving the spirit of the pronouncement unchanged. So far as science is concerned, the formulation of basic laws is undoubtedly profoundly influenced by the structure and state of the civilization in which the laws are formulated, but the shorthand statement, the so-called *law*, possesses neither sanctity nor finality. It is a policy rather than a creed. It is accordingly proposed to amend the wording of Clause 4 to read: "That the service of science requires independence combined with co-operation and its structure is influenced by the progressive needs of humanity."

International Youth Rally

AN impressive and stimulating International Youth Rally for Victory was held in London on September 11. A message from H.M. the King emphasized how clearly the young men and women of to-day appreciate the true meaning of the present struggle and the gravity of the task which the years of reconstruction will lay upon their shoulders. As Mr. Bevin, the Minister of Labour, pointed out, the Allied Governments are fortified in their present tremendous tasks by the support of the masses of the people, and are reinforced by the vision, enthusiasm and energy of the youth who are engaged on the battlefield, in the air, on the seas, in civil defence, in transport, in the workshop, and in the fields; to this might well be added the laboratory. "It will be yours to rebuild and shape the new world" said Mr. Bevin, so it is to be hoped that youth of the present and future will be given every opportunity to do so when that time comes.

That more than twenty nations took part is of more than casual significance. Youth are awake to their responsibilities, and are clearly anxious to give their all in the present struggle; they must be encouraged to give of their best in the long period of reconstruction which will follow the victory towards which they are now contributing the majority of practical effort. The very fact that such a rally was held was indicative of the desire of youth for new sources of inspiration and for genuine bases for co-operation between the youth of all nationalities in order to prepare them for their future responsibilities. The movement is deserving of every encouragement. Youth must be given greater chances, they must be given more sympathetic hearing, they must be represented to greater degree on all national and international counsels (including science) than they have in the past. Youth have often felt and sometimes expressed a feeling of frustration, a feeling of being overlooked or even overruled merely because of their youth. Such feelings must not be manifest in the youth of the future, if they are to play their just part in the world of to-morrow.

The Faraday Society and the U.S.S.R.

AT the annual meeting of the Faraday Society held on September 26, the following letter, signed by Prof. E. K. Rideal (president) and Mr. G. S. W. Marlow (secretary), to the Physical and Chemical Society of the U.S.S.R. was read and heartily approved by the members for dispatch: "At their first meeting after the invasion of Russia, the Council of the Faraday Society desires us on their behalf and on that of the Society to send greetings to our colleagues in the Union of Soviet Socialist Republics. Our two countries proudly stand allied as guardians of the freedom of the World against wanton aggression. By restoring such freedom to the temporarily enslaved peoples of Europe and Asia we shall enable the work of our men of science to bless mankind. The work of Russian men of science has assuredly shown to all the world what splendid results can be achieved. Russia's heroic resistance against the ruthless aggressor is a source of immense pride to her ally and will ever be remembered in history. We look forward with confidence to the day when the aggressor will be conquered and in the blessings of peace and freedom the members of our two Societies can meet in fraternal comradeship as allies in the peaceful quest of the laws of nature, just as now we are allies in the war on barbarian man."

Legislation on Town and Country Planning

IN the House of Lords on October 7, replying to a question from Viscount Samuel as to when the proposed legislation on town and country planning would be presented to Parliament, Lord Reith repudiated the suggestion that no progress has been made and that departmentalism is still obstructive. Lord Reith stated that the Council of Ministers has already produced a Bill which is in an advanced stage and excellent reports have already come from the interdepartmental committee associated with him on reconstruction problems. His statement, however, that as a result the Ministry of Health has appointed regional planning officers for all the regions to deal with problems that might arise and that the Minister of Works and Buildings is himself about to appoint regional authorities for propaganda purposes and to encourage local authorities to establish joint committees where they do not already

exist, was much less reassuring from the point of view of the central planning recommended in the Uthwatt report and endorsed from all quarters. Much is being done, however, said Lord Reith, with regard to the preparation of designs, and the supply of materials for post-war use, by standardization, economy of design and the use of alternative materials. He hopes to give an account of such activities and to make a more definite statement later, but assured the House that the need and urgency of the problem is realized and that the Government shares his view that the problems of peace are much more serious than the problems of war.

Chemical Society: New President

Dr. W. H. Mills, recently elected president of the Chemical Society, has for a long time been one of the outstanding figures in the scientific world: his influence on chemistry at Cambridge has been profound. An independent thinker, his researches bear no resemblance to those of his teachers: he founded a 'school', but he never had a 'team'. A paper by Mills is something to be read not only for instruction, but also for the intellectual pleasure it gives. His work on the cyanines, the photographic sensitizing dyes, was largely responsible for settling their chemistry, to which his former student, Dr. Hamer, has added so much. But it is for his stereochemical work that Mills is best known. In 1910 and 1914, with Miss Bain, he demonstrated the configuration of the doubly linked nitrogen atom, adding compelling evidence in 1923, with Schindler, and in 1931 with Saunders. The proof, with Warren, of the tetrahedral configuration of the ammonium ion compares for elegance with the proof, with Quibell and Lidstone, of the planar configuration of the 4-co-ordinated platinous and palladous atoms. The resolution of an allene, with Maitland, was also a remarkable achievement.

Mills's stereochemical investigations, in succession, of restricted rotation in naphthalene, quinoline and benzene derivatives, with Elliott, Breckenridge, Kelham and Dazeley are highly important. Reference must also be made to the 'Mills-Nixon' effect; to the mechanics of the Beckmann change; to a theory of absolute asymmetric synthesis; and to Mills's supreme skill with molecular models, by means of which he never fails to entrance an audience.

Dr. Dorothy Wrinch

Dr. Dorothy Wrinch has been appointed to a research professorship jointly by Smith, Mt. Holyoke and Amherst Colleges, in Massachusetts, to conduct a lecture and seminar course for advanced students on structure problems in the biological sciences. Dr. Wrinch is widely known for her exploratory work in mathematics, physics and biochemistry. During the past six years she has been working as a research fellow of the Rockefeller Foundation and has made an extensive study of the chemistry and physics of the proteins, the results of which have been published from time to time in Nature and in other scientific journals. Her research work on the structure of proteins, especially their two- and three-dimensional patterns, has attracted much attention. A distinctive feature of the new approach to the problem of protein structure which is employed by Dr. Wrinch is that it is based on the study of live proteins, while most previous structural studies have been conducted with dead proteins such as hair and silk, or with proteins which have lost their native configuration. Dr. Wrinch's views on the structure of globular proteins, based on the cyclol hypothesis, have provoked intense controversy, and while they are still by no means generally accepted, the discussion of their implications has provided a valuable demonstration of the interrelations of biology, chemistry, physics and mathematics.

Evaporation in the Sugar Industry

The first meeting of the session of the Newcomen Society was held on October 8. Two papers were read, the first by Messrs. N. Deerr and A. Brooks dealing with the "Development of Evaporation in the Sugar Industry", and the second by Mr. S. Withington on "Automobiles in 1830". There were three phases in the progress of the practice of evaporation, it was said, the first reaching back to the time when evaporation was conducted over a direct flame, the second phase being marked by the use of steam-heated appliances and the boiling of syrup under reduced pressure, while from this was developed the present practice of multiple-effect evaporation in a series of vessels. The review of Messrs. Deerr and Brooks ranged all over the world, and reference was made to many inventors, manufacturers and plants. One outstanding event was the patenting in 1813 by the Hon. Edward Charles Howard (1774–1816), a cadet of the ducal House of Norfolk, of the vacuum pan, a master patent appearing complete and successful in operation in its first trial. The first crude idea of multiple-effect evaporation was to be found in a patent of 1826. One of the chief improvers of the practice was Norbert Rillieux, who was born at New Orleans in 1806 and died in Paris in 1894. In 1934 persons connected with the sugar industry all over the world placed a tablet to Rillieux in the State Museum in New Orleans. Multiple-effect evaporation is to-day used not only in the sugar industry but also in others in which large quantities of liquids are dealt with.

Influence of War on Surgery

Mr. V. Zachary Cope gave a Chadwick Lecture on October 7 in which he discussed the influence of war on surgery. Surgery, or the handicraft of healing, he pointed out, has always been an art, but only recently a science. In pre-historic and historic times up to the time when Harvey discovered the circulation of the blood, surgery was a crude art, and for the most part surgeons learnt their lessons on the battle-field. When first there began to be an anatomical and physiological basis for surgery, it was upon the battle-field that trials of various discoveries were made. Antiseptics were given their first big trial in the Franco-Prussian war. Modern wars are upon

so large a scale that they provide unparalleled opportunities for the trial of new remedies, and the intensive research necessitated by the demands of war may concentrate within a year what would usually take ten years to do. The War of 1914–18 led to great advances in surgery. The prevention of tetanus by prophylactic administration of specific serum was standardized, and the treatment of shock and hæmorrhage by blood transfusion made readily available.

Moreover, the treatment of wounds underwent great changes during 1914–18. Antiseptics put into a wound were found to have little effect, and it was soon shown that the best results were obtained by excising the damaged parts of a wound. There is no doubt also that the same war was the chief means of putting thoracic surgery upon its present sound foundation. Even more striking was the rapid and wonderful development of plastic surgery whereby hideous deformities of the human face were remedied. In the recent Spanish Civil War, the main contribution to the advance of surgery was the discovery by Trueta that wounds treated by excision and encasement in plaster of Paris healed better than those which were treated by splinting and daily dressing. This was a useful application of the Winnett-Orr treatment and could be applied to simple wounds, to wounds of joints, and to open fractures. The present War has already provided some important contributions to surgery. The work of Colebrook on the local antiseptic action of the sulphonamide group of drugs, and the experimental results of Zuckerman's researches on the effect of blast, are noteworthy.

Vitamin B_1 in Buds of Trees

LARGE quantities of vitamin B_1 have been found in the buds and leaves of many common American trees by Prof. P. R. Burkholder and Prof. E. W. Sinnot. Using a constant-temperature tissue culture laboratory, they found heavy concentrations of the substance in the buds of oak, red maple, horse chestnut, elm, sycamore and white pine trees. Although vitamin B_1 is now produced by synthetic chemical processes, this discovery points to a large natural source of vitamin B_1, and this finding may offer a clue to the source of essential vitamins for many forest animals, according to Prof. Burkholder. The vitamin seems to be formed in the young leaves and growing points of the shoot, whence it is transported to the roots and various portions of the plant.

Experiments in which basswood and maple trees were ringed in the spring show that almost no vitamin B_1 has appeared below the ring in midsummer. Yet huge quantities of the vitamin have been found above the ring. This seems to indicate that ultimately a ringed tree may die not only from lack of food but also from vitamin starvation. These researches show that most green plants contain sufficient amounts of the vitamin for their normal growth. The amount of essential minerals in the soil and sunlight apparently influence the amount of B_1 which green plants are able to produce. Vitamin B_1 is heavily concentrated in the buds, according to Prof. Burkholder, just as it is in grain.

Health of Paraguay

IN the July issue of the *Boletín de la Oficina Sanitaria Panamericana,* Dr. Ricardo Odriosola, Minister of Health for Paraguay, states that organized public health work in his country began on August 16, 1889, with the creation of the National Health Council, which was merged in 1917–18 with the National Public Assistance and Welfare Commission (created in 1915) to form a Department of Health and Welfare. This was succeeded on June 15, 1936, by the present Ministry of Health, with its five departments—Public Health of the Capital, Rural Hygiene, Hygiene, Child Welfare and Odontology. Paraguay's most serious problems at present are surveys of the causes of death and the system of school lunches, to which 15 per cent of the municipal income has been assigned, and which are now being supplied in eighty towns. Leprosy comes next in importance. Compulsory vaccination against typhoid fever has been introduced. Malaria has become increasingly severe, and fourteen sanitary commissions have been organized to combat it by distributing quinine, oiling breeding-places of mosquitoes and draining swamps. Hookworm disease is also being combated.

Announcements

DR. A. EICHHORN, director of the Animal Diseases Station, Beltsville, Maryland, has recently visited Great Britain for consultations with the Ministry of Agriculture and Fisheries and the Agricultural Research Council. He has visited several institutes concerned with problems of animal health, and discussed with members of the staff the experience in Great Britain and in the United States in the control of various diseases of livestock. It is hoped that the liaison thus established between American and British veterinary scientists will be continued and extended.

THE following appointments have recently been made in the University of Sheffield: Miss A. R. Murray, assistant lecturer in chemistry; Mrs. Margaret G. Happey, assistant bacteriologist; Mr. H. I. C. Page, assistant demonstrator in radio physics.

THE following appointments and promotions have recently been made in the Colonial Service: D. J. Billes, agricultural superintendent, Gold Coast; P. L. Bradley, agricultural officer, Nigeria; H. M. Tickler, agricultural officer, Northern Rhodesia; M. S. Parry, assistant conservator of forests, Tanganyika; J. McCulloch, veterinary officer, Nigeria; G. C. Weatherhead, veterinary officer, Uganda; A. B. Killick (deputy director of agriculture, Tanganyika), deputy director of agriculture, Kenya; G. W. Lock (agricultural officer), senior agricultural officer, Tanganyika.

ERRATUM. In the letter entitled "Constitution of a Sulphonamide" in NATURE of October 4, p. 409, Mr. M. A. Phillips referred to "a tautomeric mixture of the forms II and III"; this should read "forms I and II".

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.*

An X-Ray Criterion for Distinguishing between Lattice Curvature and Fragmentation

Asterism in Laue photographs and the arc-shaped smears in monochromatic X-ray photographs show that, in plastically deformed crystals, regions of different orientation are present. This may be due either to local curvatures of the lattice[1,2], or to its

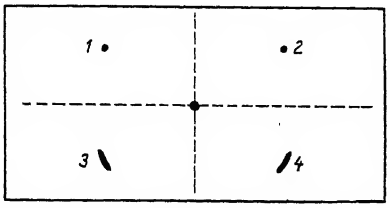

Fig. 1.

disintegration into a mosaic of small fragments the orientations of which are independent of those of their neighbours[3,4]. It has been considered that X-ray methods could only reveal the existence of regions of different orientation, but could not give information as to how these regions were joined

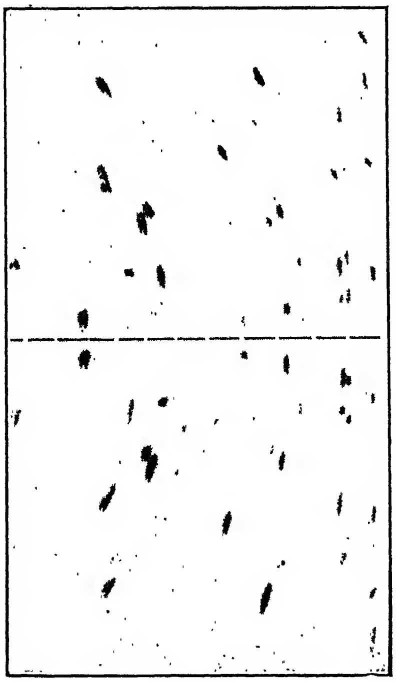

Fig. 2.

Part of a rotation photograph, enlarged 1·62 times. Cd crystal, about 1 mm. thick; extension about 2 per cent. The dotted line is the equator. CuK_α-radiation; camera radius 3·0 cm.

together, and thus could not tell which of the two alternatives, curvature or fragmentation, was present.

Rotation photographs of moderately extended cadium crystals have shown, however, that in many cases X-ray methods are capable of deciding this question. Such photographs often contain remarkably sharp spots (sometimes sharper than the spots obtained before distortion). Whenever a spot 1 (Fig. 1) is unusually sharp, the corresponding spot 2 on the same side of the equator (reflected by the same lattice plane) is equally sharp, but the two corresponding spots 3 and 4 (reflected by the other side of the same plane) are smeared out to arcs. Fig. 2 shows this effect on an enlarged portion of a rotation photograph.

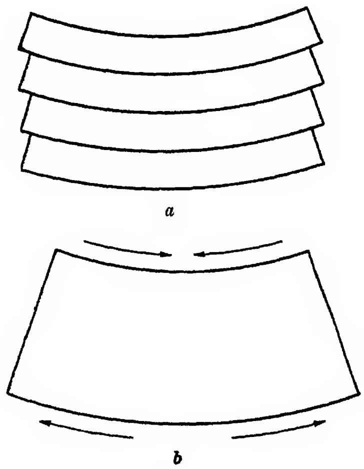

Fig. 3.

To explain the dissymmetry of corresponding spots above and below the equator, we have to assume that the lattice plane is curved and the beam emerging from the pin-hole is focused on the film as if it is reflected from the concave side of the plane; in this case a particularly sharp spot results. If, on the other hand, the beam falls upon the convex side of the plane, it is reflected with strong divergence, and a smear is produced.

The lattice planes from which the spots in Fig. 2 were reflected were plotted in a stereographic net, and the degree of dissymmetry between the reflexions from the two sides of the planes indicated by markings. The dissymmetry was a maximum for the basal plane (reflexions (0004) and (0006)) and for planes inclined at small angles to it (for example; (10$\bar{1}$6) and (10$\bar{1}$5)); with increasing angle it decreased, and became small and of rather irregular variation for planes approaching the zone of the hexagonal axis. Since the curvature of the glide plane in an extended single crystal is approximately cylindrical, with the cylinder axis perpendicular to the glide direction, it was to be expected that lattice planes perpendicular to this axis remained plane. It did not seem to make any difference, moreover, whether or not a plane was

nearly perpendicular to the cylinder axis; the dissymmetry of the reflexion diminished for all planes with increasing angular distance from the basal plane. This may be attributed to a disintegration of the bent crystal into glide lamellæ (Fig. 3*a*). Such a process is bound to occur, as otherwise bending would produce extremely high tensile stresses on the convex side, and extremely high compressive stresses on the concave side of a thick block (Fig. 3*b*). If the crystal consists of thin bent lamellæ, lattice planes perpendicular to these will show no dissymmetry of the X-ray reflexions, since initially plane sections perpendicular to the surface of a lamella remain approximately plane in elastic bending.

In the case of polycrystalline metals, the mutual interference of neighbouring grains will give rise to particularly sharp curvatures and thin lamellæ. The dissymmetry effect cannot be observed if the focal length of the curved lattice planes becomes too small compared with the radius of the X-ray camera, but the reflexions will show the diffusion and broadening (Scherrer effect) usually attributed to random fragmentation. With increasing deformation, the elastic energy of the bent lamellæ and their mutual surface energy become high enough for recrystallization to occur. This is strikingly illustrated by observations of Andrade and Chow[5], who found that the tails in Laue photographs of distorted iron crystals broke up into distinct spots at sufficiently high temperatures; with sodium and potassium, this process took place at room temperature, but continuous tails were observed at very low temperatures. All metals may recrystallize at room temperature if the distortion is severe enough. At a given temperature, therefore, local curvatures of the lattice and its splitting up into lamellæ, with the accompanying diffusion of X-ray reflexions, increase only up to a critical distortion at which recrystallization begins[6]. The existence of such a limit to the amount of diffusion has been observed by Gough and Wood[4].

Photo-Electric Alloys of Alkali Metals

IN order to obtain very thin photo-electric layers, P. Görlich[1] investigated alloys of alkali metals with other metals and found that very thin layers of cæsium-antimony and cæsium-bismuth alloys are sensitive to visible light. I have made some further experiments with these alloys and obtained some results which are summarized below; a more detailed description will be published elsewhere.

The most sensitive alloys of cæsium and rubidium with bismuth and antimony correspond to the stoichiometric formulæ BiM_3 and SbM_3, M representing the alkali metal.

The alloy layer with the highest photo-electric quantum yield is $SbCs_3$. At the optimum wavelength of 4600A., one electron is emitted for only five incident light quanta.

The electric resistance of the antimony-cæsium alloy rises sharply with increasing Cs : Sb ratio. The specific resistance of pure antimony is 4×10^{-5}, the specific resistance of $SbCs_3$ is $1 \cdot 6 \times 10$. The alloys of lower photo-electric sensitivity have a lower specific resistance than $SbCs_3$. The rise of resistance during the formation of the photo-electric alloys is accompanied by the disappearance of metallic reflection. The alloys of the $SbCs_3$ type can therefore be regarded as semiconductors. They represent borderline cases between metallic alloys and ionic crystals, as is to be expected from the position of bismuth and antimony in the periodic system.

It has been impossible to obtain antimony-cæsium alloys in which the ratio of cæsium to antimony is greater than 3 : 1. The same is probably true for corresponding alloys.

Superficial oxidation of the alloys increases the photo-electric sensitivity to light of longer wavelengths. This effect can be explained by the lowered work function of the surface.

From theoretical considerations one would expect that a semiconductor with low surface work function, as represented by the $SbCs_3$ alloy, would be a good photo-electric emitter. But to explain the exceptional properties of the $SbCs_3$ alloy, as compared with the other alloys of the same type, the structure of these alloys would have to be investigated in more detail.

Influence of the Synthetic Œstrogen Triphenylethylene on the Growth and Egg-laying Capacity of Poultry

Robson and Schönberg[1] have shown that triphenylethylene, a synthetic substance which is easily prepared and now commercially obtainable, will induce œstrous changes in the genital organs and mating in ovariectomized mice and hypophysectomized rabbits. The effect in mice may last for several months. Robson[2] has reported on the induction of œstrous changes in the monkey and bitch by triphenylethylene. He stated also that no toxic changes were observed in these animals or in mice injected with large doses of triphenylethylene[3].

We have investigated the action of triphenylethylene on the growth of poultry and on their egg-laying capacity. The experimental part of this work was carried out by one of us (A. G.) at the Animal Nutrition Experimental Station, Faculty of Agriculture, Giza, Cairo. So far as could be ascertained, no experiments of this kind have hitherto been reported.

The average weight of a hen during the period September 1938–November 1939 was increased by 74·23 per cent after receiving 0·7 gm. triphenylethylene in comparison with 64·54 per cent increase of those not receiving triphenylethylene. The egg-laying capacities of hens are practically unaffected by triphenylethylene as regards either weight or number of eggs.

The average weight of the male turkey chicks was almost uninfluenced by triphenylethylene, in contrast to females, which increased their average weight by 311·5 per cent after receiving 2·73 gm. triphenylethylene a head. Female birds to which no triphenylethylene

was given increased their weight by 244·6 per cent only (compare table at end).

(1) *Experiments with white native (Baladi) hens.* Experiment *A T* was carried out on 25 hens. Triphenylethylene (0·5 gm.) was given with the morning ration for every ten hens three times a week, on Saturday, Tuesday and Thursday, during March 14–April 13, 1939 (0·7 gm. per hen per month). Experiment *B* was carried out on 26 hens to which no triphenylethylene was given. Feeding and age (4 months and 10 days at the beginning of the experiment) were the same for Groups *A T* and *B*. The results are given below.

	Group *AT*	Group *B*
Average weight of hen at the beginning of the experiment	939 gm.	939 gm.
Average weight of hen at the end of experiment . . .	1636 gm.	1545 gm.
Average increase in weight .	74·23 per cent.	64·54 per cent.
Total number of eggs laid per hen in 15 months (Sept. 38–Nov. 39)	115·08	123·67
Average number per month per hen	7·67	8·24
Average weight of an egg (Sept. 38–Nov. 39)	39·2 gm.	39·33 gm.

It seems, therefore, that triphenylethylene had little or no effect on the number or weight of eggs laid, as Group *B* was a little better than Group *A T* before, during and after the period during which triphenylethylene was given.

The ration for the white native hens consisted of: maize, 28; barley, 28; beans, 13; bran, 20; sesame cake, 8; fish powder, 1½; meat powder, 1½ per cent. In addition, we added for every 100 kilos, 1·5 kgm. fish powder (instead of bone powder, which was not available) and 0·5 kgm. sodium chloride.

The starch equivalent of the ration was 63·41 per cent, and the digestible protein 13·00 per cent. The daily ration was 90 gm. a hen. This quantity was given in two parts: (*a*) the mixture of bran, sesame cake, meat powder, fish powder and sodium chloride was given in the morning, slightly wetted; (*b*) the mixture of barley, maize and beans was given at noon. In addition to this daily ration, a hundred grams of barsim clover (*Trifolium Alexandrinum*) was given to each hen.

(2) *Experiments with turkeys.* The turkey chicks were put in four groups: *MT*, *FT*, *M* and *F*. In Group *MT* there were five males weighing 7·900 kgm.; in Group *FT*, eight females weighing 8·360 kgm.; in Group *M*, four males weighing 6·780 kgm.; and in Group *F*, eight females weighing 9·720 kgm.

Four equal quantities of the following mixture were prepared and put in different bins: maize, 29·5; barley, 29·5; beans, 12·0; bran, 20·0; sesame cake, 7·0; fish powder, 1·0; meat powder, 1·0 per cent. In addition to this, 1·5 kgm. shell powder and 0·5 kgm. sodium chloride were added.

The starch-equivalent of the ration was 67·82 and digestible protein 12·00 per cent.

Each bin was allotted to one of the groups of the chicks, and they were allowed to eat from this as much as they could every day by putting plenty of food before each group. The quantity of the ration consumed every fortnight was found by weighing that which remained in each bin.

3·8 gm. of triphenylethylene was added in the morning three times a week, on Saturday, Tuesday and Thursday, to the food of Group *MT* and Group *FT* during the whole experiment; no triphenylethylene was added to the food of Groups *M* and *F*. The total amount of triphenylethylene given to Groups *MT* and *FT* was 19·335 and 21·856 gm. respectively.

In addition to the above-mentioned food, barsim clover (*Trifolium Alexandrinum*) or green maize was also given to saturation. The quantities consumed daily were the difference in weight between what was put in front of each group in the morning and what remained in the afternoon. The total green diet consumed in every fortnight was recorded with the dry diet.

At the end of every fortnight, the chicks of every group were weighed to obtain the growth of each group.

These operations have been repeated during the whole of the experiment, which began on August 24, 1940, and ended on February 7, 1941. The summary of the experiments is tabulated as follows:

	Males		Females	
	Group *MT*	Group *M*	Group *FT*	Group *F*
Weight in kgm. on 24/8/40	7·900	6·780	8·360	9·720
Weight in kgm. on 7/2/41	38·450	31·970	34·400	33·500
Total growth . .	30·550	25·190	26·040	23·780
Percentage increase in weight	386·70	371·53	311·48	244·65
Food per kgm.—				
Grains and bran . .	176·805	161·428	232·860	230·348
Green maize . . .	140·910	118·212	203·028	191·932
Barsim clover . .	100·500	100·500	108·500	113·000
Total starch value during the experiment (kgm.) . . .	133·799	122·130	175·414	173·368
Kgm. starch value for every kgm. growth .	4·380	4·848	6·736	7·291

Siderocytes in Man

SIDEROCYTES are erythrocytes in which the presence of some non-hæmoglobin iron can be demonstrated by the Prussian blue reaction[1]. They occur in the embryos and new-born young of normal rats and mice, and are greatly increased in numbers in the blood of mice suffering from the transitory anæmia associated with the gene for flexed-tail and belly-spot.

It has been suggested[2] that siderocytes in small numbers may occur in normal human babies at birth, but on account of their scarcity no definite decision was possible. Material has now come to hand which leaves no doubt that siderocytes are a normal embryonic feature in man, as in rodents. A 14-weeks-old fœtus (therapeutic abortion, heart-blood) had 94·3 per cent normocytes, 1·25 per cent normoblasts, and 4·45 per cent siderocytes ($n = 2{,}000$). Data on premature and full-term fœtuses are summarized in the accompanying table. The two 36-weeks-old

fœtuses are fraternal twins. The amount of siderotic material per siderocyte is generally small; in most cases a single granule is found, except in the earlier stages, where up to four granules per siderocyte are common. It seems safe to predict that a feature common to mouse, rat and man will be found to be widely spread among higher mammals.

Age in weeks of pregnancy	Sex	Siderocyte Percentage	Cells counted
33	♂	3·65	2,000
36	♀	1·15	2,000
36	♂	0·14	5,000
40	♀	0·10	2,000
40	♀	0·25	2,000

It is perhaps worth pointing out that in this case the study of an inherited disease of the mouse has led to the discovery of a normal embryonic feature of apparently wide distribution, including man.

I am greatly indebted to Dr. H. H. F. Barns, of University College Hospital, London, for the blood films on which this report is based.

Pterygoquadrate Connexions in the Embryos of *Ichthyophis glutinosus* (Apoda)

THE pterygoquadrate in the embryos of *I. glutinosus* Linn. shows the ascendens and the otic processes; in the orbitotemporal region the basal process is not developed, and, therefore, the union of it with the basitrabecular process as seen in Siphonops (70-mm. larva, Edgeworth , Fig. 386) is absent. The relation of the processus ascendens with the orbital cartilage has been variously described. According to Edgeworth[1] and Winslow[2], a connexion is established in embryonic stages, while Peter[3], who examined a slightly older stage than that of Edgeworth, does not show it. Prof. E. S. Goodrich suggested to me (*in litt.*) that this difference may be due to the two authors examining two different species of Ichthyophis, but this may not be so, for both secured their material from Dr. F. Sarasin. In my sections of a 30-mm. embryo of *I. glutinosus* at any rate the ascendens connexion is not present, thus resembling Hypogeophis.

On the other hand, the uniform occurrence of the otic connexion in Ichthyophis (the processus oticus of the pterygoquadrate uniting with the stapedial process of the stapes) is noteworthy, though Edgeworth[1] and Goodrich[4] quoted to the contrary. This connexion is noticed in all the embryos examined by me, and in the adult it becomes a joint. In Hypogeophis also Marcus, Stimmelmayr and Porsch[5] described a transient otic connexion. But according to de Beer[6], the definite chondrocranium in Ichthyophis with no connexions of the pterygoquadrate with the cranium conforms to the primitive autodiastylic type, whereas in Hypogeophis, with the temporary otic connexion, the larval cranium is 'amphistylic'. As an otic connexion was also noticed by me in all the embryos of *I. glutinosus* examined[7], the chondrocranium does not conform to the autodiastylic type.

A New Antibacterial Agent produced by a Mould

IT has been shown in this department that penicillin, a substance produced by the Penicillium discovered by Fleming[1], has very remarkable chemotherapeutic properties[2]. Consequently, it became of interest to see whether other species of moulds produced substances with similar properties. Of a considerable number of air-borne moulds studied, two were found to produce substances very similar to penicillin, both in its chemical and biological behaviour. Recently, however, a mould, probably belonging to the genus Aspergillus, was found to produce a powerful antibacterial agent with chemical properties different from penicillin and with an antibacterial range considerably greater than that of penicillin. In addition to the Gram-positive organisms known to be inhibited by penicillin, the growth of a number of Gram-negative organisms, such as *Bact. coli*, *B. dysenteriæ* (Shiga), the typhoid and paratyphoid bacilli and *Vibrio choleræ*, is inhibited by the culture filtrate, of this mould. An extract of this new antibacterial substance has been prepared from the culture filtrate, and it was found that it inhibited the growth of both the Gram-negative and Gram-positive organisms in a dilution of approximately 1 : 200,000. It remains to be seen whether this substance bears any relation to the bactericidal agent in culture filtrates of *Aspergillus flavus*, described by E. C. White[3].

Rotifer vulgaris and Tetanus Toxin

DURING an estimation of anti-tetanic serum, 0·02 c.c. of a filtrate of a meat broth culture of *Clostridium tetani*, 0·01 c.c. of which filtrate, injected intraperitoneally, had previously killed a mouse in eighteen hours, was slowly added to 0·03 c.c. of water from a rain-gutter

containing five *Rotifer vulgaris*. All the rotifers were dead at the end of four minutes. In one specimen observed, addition of 0·01 c.c. of the filtrate caused retraction of the ciliary wreath, and some slowing of bodily movement, though the jaws remained active. Addition of the remainder caused the jaws to slow, and the body gradually contracted, without convulsions, into a double mass with a central constriction. The other four rotifers presented the same post-mortem appearance. Small monads also present in the water showed no diminution of activity after fifteen minutes.

Epidermal Papillæ and Dermal Bones of the Chick Sclerotic

THE article in NATURE by Moy-Thomas[1] and Westoll's comments[2] discuss the interesting relation existing, in fish, between certain structures of ectodermal origin and certain dermal bones. It seems appropriate to report briefly upon a similar relation which I have recently studied in the embryonic chick. A more complete account will be published elsewhere. It is well known that the fowl has fourteen dermal bones in its sclerotic, forming a ring round the pupil, and that the same number of epidermal papillæ develop in the conjunctiva at about seven days of incubation but disappear before hatching. Nussbaum[3] and Dabelow[4] both studied the papillæ, but as their descriptions are in several respects unsatisfactory, I have examined these structures, and especially their relation to the dermal bones, afresh.

The papillæ first appear as flat thickenings of the epidermis. Later, on the eighth and ninth days, the central part of each thickening increases greatly and projects downwards as a conical mass of epithelial cells into the underlying mesenchyme, against which it is bounded by a basement membrane. I call this downward projection the 'tongue'. The papilla also projects slightly above the general epidermal level. There is a condensation of mesenchyme cells below and around the tongue; these cells are the *Anlage* of the future scleral bone. Careful study shows, in sections stained with azan, that very delicate blue-staining collagen fibres run off from the basement membrane of the papilla, and especially from its tongue, among these mesenchyme cells. Even while it is forming, degeneration sets in among the epithelial cells at the base of the tongue and in its substance. This continues during the ninth and tenth days, and the result is the liquefaction of the greater part of the cells forming the tongue, which gradually retracts and finally disappears. At the same time the elevation of the papilla above the general level of the epidermal surface increases and the papilla is transformed from a solid mass projecting principally downward into the mesenchyme, into a hollow, more or less filiform structure, projecting upwards from the epidermis and joined to it by a rather narrow neck. Its cavity is open to the mesenchyme below, and contains mesenchyme cells.

Meanwhile, the cells of the mesenchyme condensation, originally grouped round the 'tongue', stream from this position downwards and outwards, and become arranged as a flat sheet of cells below the papilla and separated from it by mesenchyme which at last shows little or no condensation. The first collagen fibrils of the developing bone are now deposited among these cells, which take the histological character of osteoblasts. A connexion with the papilla is, however, maintained. The delicate collagen fibrils, mentioned above as running from the papilla among the mesenchyme cells around the tongue, have increased in number and thickness, and when the histological differentiation of the bone is beginning they form a very obvious strand of fibres running from the cavity of the hollow papilla, down through the intervening unspecialized mesenchyme, to the bone, with the developing collagen fibrils of which they are continuous.

The papillæ disappear completely before hatching, and it is difficult to imagine what function they can serve if it is not concerned with the development of the scleral bones with which they are so closely connected. Experimentation must wait until eggs once again become available for purposes other than food; but it will be as surprising as Moy-Thomas's results if the relationship proves to be without morphogenic significance.

Poultry as Food Converters

THE article by Mr. E. T. Halnan in NATURE of September 20 threw an interesting light on the problem of achieving the maximum efficiency in livestock farming from the point of view of war-time food production. He made out a good case for giving prior right to the hen in the distribution of available feeding-stuffs, over meat-producing animals. The milk-cow easily takes first place as an efficient food converter, and its performance is still more amazing when one considers that, besides utilizing concentrated feeding-stuffs such as hens and pigs need, it also utilizes cheap, home-produced foods such as grass, hay, straw, etc.

This question of the kind of material an animal can utilize is, of course, practically as important as the efficiency of conversion. Grass is by far the cheapest and most plentiful feeding-stuff in Great Britain. There is one egg-producing animal which can utilize grass, namely, the goose. Would it not therefore be worth while making an effort to increase its efficiency as an egg-producer by systematic trap-nesting and selection, as has been done in the case of the hen and the duck? It did not take a very long period of systematic selection to increase the egg-production of ducks from a few dozen a year to the level of that of the most high-yielding hens, and the same thing would probably prove true of geese. At the same time, a smaller strain, producing an egg of a smaller, more convenient size, could be evolved by selection.

If, by these methods, geese could be made to replace hens largely as egg-producers in Britain, I think it would be an achievement of very great national importance.

STANDARDIZATION OF VITAMIN E

If war had not broken out, it was intended by the Health Organisation of the League of Nations to hold a third meeting of the International Conference on Vitamin Standardisation, in preparation for which the Vitamin E Sub-Committee of the Accessory Food Factors Committee (Lister Institute and Medical Research Council), at the request of the Health Organisation, set on foot a co-operative study of *dl*-α- tocopheryl acetate as a possible international standard for vitamin E. It has in the interval been decided that it would be more accurate to use the name synthetic racemic tocopheryl acetate, and this will be done in future.

A supply of the substance sufficient for extensive biological and stability tests, and to provide a standard should the substance ultimately be adopted, was very kindly provided by Messrs. Hoffmann-La Roche of Basle, through the British associated company, Messrs. Roche Products, Ltd., Welwyn Garden City.

Workers in Europe and the United States experienced in vitamin E tests were invited to participate, and solutions were prepared by Dr. P. Hartley and issued to seventeen laboratories. The workers were asked to test four solutions of the tocopheryl acetate of graded strengths, the proportion in which the series was graded being stated, but no indication being given of the identities of the numbered solutions corresponding with the different strengths.

The object of the test was to obtain the relation between dosage and response, the response used being the fertility-rate defined as the percentage of positively mated female rats which produced a litter. Vitamin E deficiency is a condition which in an individual animal is not cured in a smoothly graduated series of stages ; for statistical purposes the response is treated as of an all or none, not of a graded, type. However, the dosage response relation can, as is usual in such cases, be transferred into a linear one by plotting the normal equivalent deviation (or probit) of the percentage response against the logarithm of the dose.

Arrangements were made whereby the stability of the feeding solutions after the tests and of the original material after keeping was tested spectrophotometrically by Dr. R. A. Morton, who reported that the stability of all the materials was entirely satisfactory.

Thirteen of the seventeen laboratories invited completed the biological tests and sent in reports which were submitted to Dr. J. O. Irwin and Dr. E. J. Williams, then at Cambridge, for statistical analysis. In four of the laboratories the slope of the dosage-response curve proved not to differ significantly from zero ; in other words the responses to the graded doses were not themselves significantly graded. No determination of the median fertility dose could therefore be made, and the results did not lend themselves to further statistical analysis. For the remaining nine laboratories such a study could be made and the results are summarized in the accompanying table.

Laboratory	No. of rats used	Slope of probit/log dose line	Standard error of slope	Median fertility dose (mgm.)	Limits of error	
					95%	99%
1	83	5·17	1·09	0·56	86–117	82–122
2 (*a*)	40	5·34	1·42	0·55	82–123	77–131
(*b*)	42	7·00	1·73	0·66	85–118	80–125
3	91	3·60	0·99	0·66	72–139	65–155
4	68	2·63	0·96	0·72	58–172	49–204
5	48	9·23	3·35	0·84	85–117	81–123
6 (*a*)	79	6·83	1·32	1·13	88–114	85–118
(*b*)	50	5·07	1·30	1·14	82–123	77–131
7	78	5·52	1·03	1·36	87–116	83–121
8 (*a*)	52	5·89	1·48	1·50	85–117	81–123
(*b*)	52	11·55	3·17	1·05	90–112	86–116
9	58	6·53	1·62	1·71	84–119	80–125
Means and errors Total	689	4·989	0·383	0·986	78–128*	72–139*

2 (*a*) and (*b*). Ratio of 4 doses the same in each case, but bigger absolute dose given in 2 (*b*).

6 (*a*) and (*b*) Virgins used in 6 (*a*) ; rats which had resorbed in 6 (*b*).

8 (*a*) and (*b*) Criterion in 8 (*a*) birth of at least one living young one ; criterion in 8 (*b*) birth of at least one young one, living or dead. Rats used in 8 (*a*) same as in 8 (*b*).

* This error includes error due to inter-laboratory difference.

The table shows the number of rats used by each worker, the slope of the probit/log. dose line, the median fertility dose and the limits of error for each worker's result. The median fertility dose is that dose which enables 50 per cent of the rats used to bear a litter. The results have been arranged in the table to show the variation in size of the median fertility dose, from 0·56 mgm. synthetic racemic tocopheryl acetate in the first laboratory, to 1·71 mgm. in the last laboratory, the average value being almost exactly one milligram. The reasons for the variation will be discussed when a fuller report is made, but it is interesting to note that the size of the median fertility dose varied in laboratory 2 in two separate tests, and in laboratory 8 when the definition of a litter was varied so as to require the inclusion of at least one living young one in the litter. These observations of the great variation in the size of the median fertility dose add further evidence, if that were needed, of the necessity for establishing an international standard for vitamin E so long as biological tests are needed.

The accuracy of the biological technique, as evidenced by the limits of error, seems to be about the same as that usually found with vitamins for a biological method which has been fully elaborated and in use for some time, and the whole co-operative study affords a satisfactory basis for recommending that synthetic racemic tocopheryl acetate should be adopted as international standard for vitamin E.

The workers who took part were: A. L. Bacharach, Glaxo Laboratories, Greenford, Middlesex ; A. Z. Baker and M. D. Wright, Vitamins Ltd., Hammersmith, London, W.6 ; F. Bergel, Roche Products Ltd., Welwyn Garden City, Herts. ; A. M. Copping Lister Institute, London, S.W.1 ; K. H. Coward and B. G. E. Morgan, Pharmaceutical Society, 17

Lister Institute,
London, S.W.1.

AN INTERNATIONAL STANDARD FOR VITAMIN E

It is now announced that an international standard for vitamin E has been established and that, as in the case of the international standards for the vitamins A, B_1, C and D, the National Institute for Medical Research, Hampstead, London, N.W.3, acting on behalf of the Health Organization of the League of Nations, has undertaken its supply to laboratories, institutes and research workers, throughout the world.

Synthetic racemic α-tocopheryl acetate ($C_{31}H_{52}O_3$) has been adopted as the international standard for vitamin E. The investigation of the chemical, physical and biological properties of this substance, its suitability for adoption as the international standard, and the manner of its application in biological assay was carried out, at the request of the Health Organisation of the League of Nations, by the Vitamin E Sub-Committee of the Accessory Food Factors Committee of the Lister Institute and the Medical Research Council. The sub-Committee was able to enlist the co-operation of experts in laboratories in Europe and the United States, and, as a result, it was able to recommend the adoption of synthetic racemic α-tocopheryl acetate as the international standard for vitamin E. The Sub-Committee further recommended that the international unit for vitamin E should be defined as the specific activity of 1 mgm. of the standard preparation, this quantity being the average amount which, when administered orally, prevents resorption-gestation in rats deprived of vitamin E.

In normal circumstances the results of the co-operative investigation would have been submitted for discussion at the Third International Conference on Vitamin Standardisation, which had been arranged for the autumn of 1939. On account of the War this Conference could not be held. The report and recommendations of the Sub-Committee have, however, been placed before those members and officers of the League of Nations' Permanent Commission on Biological Standardisation and of the International Conference on Vitamin Standardisation, who were available and accessible, and these consented to accept the responsibility of taking such decisions as would normally be accepted by a properly constituted International Conference and by the Permanent Commission. They have accordingly adopted the proposed standard for vitamin E, accepted the recommendation defining the international unit, and authorized the National Institute for Medical Research, Hampstead, to proceed with the distribution of the standard.

The international standard for vitamin E is issued in the form of a solution in olive oil of which one international unit is contained in 0·1 gm. It will be supplied to directors of national control centres in those countries in which these have been established, for local distribution; also to laboratories, institutes and research workers in Great Britain, and in those countries in which national control centres have not yet been established. Application should be made to the Department of Biological Standards, National Institute for Medical Research, Hampstead, London, N.W.3.

PSYCHOLOGICAL HANDICAPS IN THE SEARCH FOR TRUTH

BY DR. J. HETTINGER

THERE are three main psychological factors which handicap the mind in its search for truth, irrespective of the nature of the subject. They are:

(1) The limitations of the field of mental vision;

(2) Our personal mental worlds; and

(3) Our lack of knowledge of the true relationships between *all* existing realities and, accordingly, lack of unity in our personal mental worlds in correspondence with the unity reigning in the universe.

(1) LIMITATIONS OF THE FIELD OF MENTAL VISION

All forms of sensory perception have their respective limits, for example, as regards space, time, clearness, intensity, etc.; purely intellectual perception, such as we experience in mental contemplation and meditation, and which may be referred to as 'mental vision', extends over a field which has its own specific limits.

The first limitation of the field of mental vision is determined by the amount of knowledge we have

individually stored mentally by personal experience, observation and learning, out of the total knowledge acquired by the human race. We can scarcely imagine anyone possessing that total knowledge; and the latter is most likely still infinitesimally small as compared with the knowledge yet capable of acquisition in the course of the future history of mankind. Let us assume that there are some erudites who have followed the precept that "Everyone ought to know everything about something and something about everything". In these, presumably ideal, instances, the limitations are implied in the precept itself. It will thus be readily conceded, that in any controversial discussion, especially when a number of inter-related subjects are concerned, the fields of mental vision of the different participants will most likely vary to a great extent as regards the knowledge they respectively possess on the subjects which come into question; and in any event be limited as compared with the sum total of the knowledge at present available to the human race plus that which is still capable of acquisition.

The second limitation is imposed by the extent to and the rapidity with which knowledge stored as memory can be summoned from the subconscious into the conscious in order that it may be contemplated and meditated upon. The failure of any knowledge pertinent to a particular subject or set of subjects of emerging into the field of mental vision results in a limitation which may lead to wrong conclusions in the search for truth. Even if none failed to appear, unless the parts of pertinent knowledge emerged simultaneously or in sufficiently quick succession to enable the mind to contemplate them in their entirety, the conclusions may again be wrong.

A third limitation is that the field of mental vision often lacks clearness and stability, mainly due to uncertainty as to the accuracy of the knowledge displayed therein. This limitation is a great handicap in the perception of new from old knowledge according to the noegenetic principles of cognition enunciated by Spearman[1].

(2) OUR PERSONAL MENTAL WORLDS

This concept stands for the whole of the contents of individual minds, including all the factors, namely, thoughts, feelings and actions, responsible for their having been absorbed or built up therein. According to how our respective minds have gradually grown, altered, been acted upon, and reacted, they attain a characteristic state of their own, and they become more or less crystallized into a pattern which determines our mental attitude and behaviour.

We need not go into details to show by way of example how our personal mental worlds are gradually built up differently from early infancy, through the imitative and destructive periods, through the years of elementary and secondary school education, and so on, often in a haphazard way. Nor need we refer to the different inherited abilities and predispositions, emphasize the importance played by environment, dwell on the question of desires and ambitions, or point to the many present-day glaring examples indicative of the petrifying effect on our personal mental worlds exerted by all kinds of vested interests and by fear. The influence of all these factors on our psychological make-up is too well known.

In fact, we are now passing through a period of history which is a striking example of how the mental worlds of individuals may be so formed and transformed, that, although we are all living in one and the same world, facing one and the same reality, the mental worlds of some of us are poles apart from, and in conflict with, one another; and between these two extremes there are endless variations of personal worlds which conflict with one another in some respect or other.

We find that not only are the personal worlds of, for example, many representatives of religion totally different from those of many men of science, of many alleged to belong to the so-called 'capitalist class' equally quite different from those of many stated to be of the 'working class', of many nationals of one country opposite to those of nationals of another country, but also that within one and the same group the personal worlds of many are in conflict with one another, even as regards the facts supposed to constitute the very foundations of the group. Most of these are firmly convinced that they are right; but obviously it is a logical impossibility for all of them to be right if the views are mutually exclusive.

The fact that these conflicts are attributable to different patterns of individual mental worlds, and the pattern differences to the ways and circumstances in which those worlds were formed, shows the theoretical and practical value of the concept we have just discussed, as regards the study of psychological factors which handicap us in the search for truth.

(3) LACK OF KNOWLEDGE OF THE TRUE RELATIONSHIPS BETWEEN ALL REALITIES

It has already been pointed out above that the human race is far from possessing all the knowledge that it can, or may possibly, acquire. This applies also to the true relationships between *all* existing realities, including intangible ones, such as the relation between body and mind, natural phenomena and reasoning, gregarious instinct and moral behaviour, etc. Whether we shall ever be able to determine all of them may be left an open question. It is clear, however, that unless we know the actual relationships between *all* realities, including the mind, we cannot perceive the unity reigning in the universe and, consequently, assemble the total knowledge of our personal world in a corresponding unitary system. This means, however, that so long as our knowledge is wanting as regards the interconnecting links of *all* realities, our personal worlds necessarily lack the assurance that what we know represents "the truth, the whole truth, and nothing but the truth".

In spite of all the progress that may be made by the specific sciences and the many partial truths that may thereby be revealed, the facts representing the 'whole truth' may continue to elude us for yet a long time, and deprive our personal mental worlds of the safest guide in our manifold searches.

I have purposely refrained from encumbering this concise analysis by details which might have tended to obscure the essence of the three concepts I ventured to put forward. They represent important handicaps in the search for truth; and to bear them in mind in controversial discussions may prove helpful.

[1] Spearman, "The Nature of Intelligence."

ROAD CONSTRUCTION IN WAR-TIME

In co-operation with the Ministry of War Transport, the Road Research Laboratory of the Department of Scientific and Industrial Research has now issued the second of a series of Wartime Road Notes*.

Road-building and road-maintenance in time of war differ in many respects and also in degree from peace-time practice. Not only are roads required for special and temporary purposes which demand different standards of design from those employed on the highways, but also speed in construction is vitally important and the use of local materials is a necessity. These war-time notes are intended to assist engineers in dealing with the special problems created by these conditions, and they present in brief form the latest findings of research and practical experience.

The recommendations in the first of these two publications refer to tar carpets (or thin surfacings) $\frac{3}{4}$–1 in. thick and surface dressings, and are based on systematic full-scale trials supported by laboratory investigations. Bituminous carpets of this description have been introduced quite recently and are capable of providing a non-skid surface having a reasonably long life and costing less than the British standard surfacings. The nature of the aggregate as well as its grading determines the quality of the carpet. Crushed rocks are preferable, but gravel may have to be used, and this has also been investigated. The recommendations, which can best be described as concise working instructions, cover the materials, the mixing procedure, and the laying of the materials on the road.

The second of the notes in this series has been prepared in collaboration with the Geological Survey and Museum, and supplies very necessary information as to the numerous sources in Great Britain of naturally coloured chippings such as might be used for surface-dressing roads and for similar purposes. It deals mainly with black or dark grey stones, and with the darker shades of red, brown and green. The colour of the rocks most widely quarried for use as roadstone are dark grey, pink, grey or buff, and whitish or pale brown or pale red as represented by such sources as Clee Hill basalt, Mountsorrel granite, dolomite and Hartshill quartzite. After describing the igneous rocks, the sedimentary rocks, metamorphic rocks and other potential materials, the note provides a valuable list of quarries arranged in three tables referring to three different groupings of colours.

Although an important consideration for the engineer, the question of strength is not discussed. It is stated, however, that the Road Research Laboratory is available at all times to answer inquiries or to amplify the contents of the notes where this is desired.

* Wartime Road Notes. No. 1: Recommendations for Tar Carpets and Surface Dressings. No. 2: Sources of Naturally Coloured Chippings in Great Britain. (London: H.M. Stationery Office, 1941.) 6*d*. each.

FOREST RESEARCH IN INDIA

The annual report on forest research in India and Burma is issued in two parts (Manager, Govt. of India Press, Delhi, 1940 and 1941). Part 1 is devoted to the Forest Research Institute at Dehra Dun; Part 2 to provincial reports for Burma and the provinces of India, all of which have special research officers in one or more of such branches of forestry as sylviculture, forest utilization, working plans and statistics, entomology and so forth. Perhaps only to those who witnessed the beginnings of research at the Forest Institute and out in the provinces of India and Burma are in a position to realize the great progress which the last three and a half decades have brought about in research problems in many branches of forestry. The reports must be consulted for a full appreciation of this statement.

That for the Institute for 1938–39 commences with the remark that although handicapped by serious financial restrictions the year in question had been for the Institute one of the busiest in its history; and the provinces, especially in sylviculture and forest utilization, appear to have been engaged upon equally important work.

The most numerous inquiries were in connexion with the manufacture of paper and ply-wood; but smaller industries such as the making of pencils, umbrella handles and cigarette-holders were equally to the fore. Other subjects had reference to suitable woods for semi-industrial purposes, such as the use of bamboo as reinforcement in concrete structures, and the chemical values of a large range of minor forest products—a branch so long neglected at the Institute owing to lack of funds. The co-ordination of the research of provincial research officers with that of the Institute involves a large amount of work—for inevitably the latter has to form a central clearing and co-ordinating centre for investigations carried out throughout India and Burma.

It has become evident that the staff sanctions for certain branches of the Institute in 1924 is no longer adequate to meet present-day demands. In connexion with minor products it is of interest to note that a permanent incumbent is to be appointed to the chemical branch of the Institute. This is apparently the result of a valuable report on the branch submitted by Dr. S. S. Bhatnagar, professor of chemistry at the University of the Punjab, after a visit to the Institute.

The War may have brought to the notice of smokers and the housewife that matches made in India are now on the English market. It was the Research Institute at Dehra Dun in the early years after the War of 1914–18 which assisted in establishing this industry in India. Umbrella handles have been mentioned above. In the days before the Institute a young Indian forest officer addressed a big umbrella merchant, stating that he had in his forests quantities of an excellent bamboo for umbrella handles. The price at length quoted by the merchant would not have paid for the cost of carriage of the bamboo from forest to the Indian coast! It required the establishment of the research institute to enable such problems to be elucidated—for research paves the way to utilization.

FORTHCOMING EVENTS

SATURDAY, OCTOBER 18

NUTRITION SOCIETY (at Cambridge).—Conference on "The Evaluation of Nutritional Status". (See page 433 of last week's issue.)

THURSDAY, OCTOBER 23

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 4 p.m.—Sir Noel Ashbridge: Inaugural Address.

FRIDAY, OCTOBER 24

INSTITUTION OF CHEMICAL ENGINEERS (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 2.30 p.m.—Sir Richard Gregory, Bart., F.R.S.: "Scientific Knowledge and Action" (Fourth Hinchley Memorial Lecture).

INSTITUTION OF MECHANICAL ENGINEERS (at Storey's Gate, St. James's Park, London, S.W.1), at 2.30 p.m.—Mr. W. A. Stanier: "The Position of the Locomotive in Mechanical Engineering" (Presidential Address).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

MAINTENANCE ENGINEER—The Borough Electrical Engineer and Manager, Halifax Electricity Department, 19–23 Northgate, Halifax (endorsed 'Maintenance Engineer') (October 21).

LECTURER IN CHARGE OF THE MARINE ENGINEERING SCHOOL, Hull Municipal Technical College—The Director of Education, Guildhall, Hull (October 27).

INSPECTOR OF SCHOOLS (WOMAN)—The Director of Education, Education Offices, Deansgate, Manchester 3 (October 31).

ENGINEER AND MANAGER of the Belfast Gas Undertaking—The Town Clerk, Belfast (November 5).

THE BEHAVIOUR OF GERMANY

"*Why and how are words so important that they can not be too often used.*" (Napoleon.)

DETACHMENT for a moment from the stress of personal circumstances and the attempt, howevêr humble, to view with cool sanity world affairs of the moment, at once bring an uncomfortable feeling of bewilderment. More than that, there is a very present sense of something evil. Things accepted as obvious truths or the plain commonsense of everyday behaviour have gone by the board : so much of mankind is acting and thinking as if the simplicities of truth and honesty, fair dealing and plain speaking, self-respect and respect for one another, all the great whole summed up in the words 'do as you would be done by', are no longer valid, are indeed no more than the outworn catchwords of a grandmotherly age.

If the ordinary man in the street ignores these primary rules of conduct we call him neurotic, criminal or insane, according to the degree of departure from the ordinary. Does the same standard apply to nations ? Here we might listen to the psychologists, who hold an insight into the springs of conduct deep in every human purpose. One of them, H. G. Baynes, a practising psychologist, with the additional advantage of an intimate acquaintance with Germany and the Germans before the War, has recently put forward this approach in his book "Germany Possessed"*. It is not at all technical but a serious study of one of the great problems of humanity, meant for the man in the street intelligent enough to see beyond his own parochial boundaries.

Civilization, General Smuts has said, is undergoing a spiritual migration ; it is on the march. Something is happening. Our own lives have been made a mess of, caught up as we are in the sweep of something quite beyond ourselves. What then can be done for the others treading so closely behind ? The hurrying years do not leave so very much time wherein to take thought for the morrow.

At the root of it all lies this German business ; could we but grasp that, perhaps the horizon might be clearer. Still holding to that detachment, still accepting as fundamental that every human being is entitled to his own opinion, to be himself, what has happened to the kindly, beer-drinking, musical, philosophic, rather fat and middle-aged German that Carlyle knew ? The Germans have changed ; it is not the old Germany of before 1870, it is not even the Germany of the War of 1914–1918 ; it is something utterly different, and what is more, something utterly worse, something utterly vicious. It is again "the great blond beast avid and rampant for plunder". It is the *furor teutonicus*

* "Germany Possessed". By H. G. Baynes. Pp. 305. (London: Jonathan Cape, Ltd., 1941.) 16s. net.

of which Heine wrote in 1834: "and should that suborning talisman the Cross, break, then would come crashing and roaring forth the wild madness of the old champions, the insane Berserker rage of which the Northern poets say and sing. That talisman is brittle and the day will come when it will pitifully break."

Discarding wishful thinking and looking at things as they really are, one or two points stand out. The first is that the Germans really do mean it. It is absurd to imagine that the great mass of a mighty nation are being in any sense led, badgered or cajoled by a system which they do not accept into conduct of which they do not approve. The Germans would be quick enough to accept the spoils of victory if Hitler won. To suggest any other than that Germany is solidly behind the Nazi regime is to be blind to the history of the last hundred years.

A second point takes in the political thesis of the totalitarian State. Again the Germans do mean it. They accept and believe in, nay, passionately uphold, the doctrines of National Socialism. The very words are a contradiction in themselves, for it is not national save in its claim for the rights of the *Herrenvolk*, and not socialism save in the complete subordination of every living person to the over-riding mastery of an irresponsible rule. Hitler himself has said: "There will be no licence, no free space, in which the individual belongs to himself. This is Socialism—not such trifles as the private possession of the means of production." We prate freely of the ideals of democracy, as if they were self-evident truths, and dismiss in so many words any possible challenge in ethic or in fact. It were surely better to think quietly what it all means, what are the arguments behind it, which is the pith of this convulsion that has swept through the German people. That it is gravely wrong, there is no doubt. But we shall have to go on living with the German people afterwards, and perhaps if we could understand their error it might be better than merely punishing them for it.

No one can be literally free, for everyone is in himself at once the duality of an individual and a social unit. But the claims of the latter aspect bear upon all, are settled jointly and equitably, are granted, not taken. There are, moreover, advantages in counterbalance. That is in essence the principle of democracy. The differences implied in theory or in practice between the English, the American, the Chinese and the Russian standards are matters of detail, not of principle, which can be comparatively easily reconciled. It is largely a question of how much to render unto Cæsar.

The totalitarian idea says something quite different. The individual here is allowed no personal existence whatsoever, he is not himself in any sense at all except as one of the subordinate items of a multiple unit, just as in the exquisite harmony of the body, a cell in the skin, the liver, or the lung, is admittedly self-contained and is yet entirely bound up in the maintenance of a whole. The philosophy of the 'total State' claims to determine the place of every man. "The state is the absolute, the will that became substance." So Hegel, and so Fichte, Schopenhauer, Nietzsche, and others, in the will to power, the superman, the good of all before the good of one, and such-like phrases. It is interesting, by the way, to notice that the great prophets of the Nazi regime, Hegel and Nietzsche, both took pains to emphasize their dislike of Germany. "It is part of my ambition to be considered as essentially a despiser of Germany", is another quotation from Hegel not so often met with.

We may find it amazing that a nation, which has contributed so greatly to the progress of humanity, should have reverted to cynically deliberate fraud, cold-blooded murder, revolting and atrocious cruelty; but we ought not to find it surprising, for these are but the logical derivatives of the principle that might is right. Further, as has been said, Germany means it, Germany in the sense of the ordinary man in the street, who has put Hitler where he is and Germany where she now stands.

It would be interesting to trace the rise of the evil in Germany, the change that has overtaken her in the last hundred years or so, and to try to give proportionate weight to the many contributory and interacting factors, but this is not the time. Even allowing that many circumstances had effect, their import would still not really explain this strange phase. One senses the presence of something not normal, something evil, something insane. It is here that the study of emotional urges, or motivation, has its place.

People are thinking and talking about the rationale of German conduct; a recent leading article in the *Daily Telegraph*, inspired by many letters sent in, asks pertinently whether the soul-state that has produced Nazism is transient or congenital.

Psychology takes in not only the individual but also the crowd. It has long been recognized that any group of people, even as big as a nation, tends to react as a unit, that there can be a synthesis of separate mind-entities when diversity is momentarily or temporarily subordinated to a homogeneous and concerted feeling, impulse or action. In mass, an aggregate of isolated minds is capable of coalescing into something distinct, something coherent, something bigger. The subject may be further pursued in such books as Trotter's "Instincts of the Herd", or le Bon's study "La Foule".

Baynes puts forward the view that the collective unconscious of the German people has been swept into a hysterical outbreak, a reaction into an irreconcilable and unacceptable attitude, emotional, not consciously realized and considered. That is to say, not rational. There are, of course, two obvious factors, the intrinsic, that is, the nature of the people concerned, and the extrinsic, that is, the circumstances in which they found themselves. That their situation was difficult and unpleasant we may at once concede. But that in no sense implied the need of irrational and indeed non-moral response. At no time in the last twenty years have the problems of Europe been incapable of solution on moderate give-and-take grounds. But the path of Germany has been a subordination at every step to wild impulses of hatred and revenge, to the irrational, emotional, aggressive, behaviour of a child, which, of course, ultimately defeats itself.

This tendency has, indeed, been noted by independent observers. Lawrence of Arabia during a visit to Germany so far back as 1923 wrote with a strange prescience: "You stiffen your backbone and you listen to the night. There is a sense of danger. It is not the people. They don't seem dangerous. Out of the very air comes a sense of danger, a queer, *bristling* feeling of uncanny danger. Something has happened. Something has happened which has not yet eventuated. The old spell of the old world has broken, and the old bristling, savage spirit has set in . . . and it is a happening of far more profound import than any actual *event*. It is the father of the next phase of events." Jung in 1936 saw clearly the cruel force pressing upon Germany. "Germany is a land of spiritual catastrophes, where certain facts of nature allow only a patched-up peace with reason." These two very apposite quotations are taken from Baynes's "Germany Possessed".

Crowd psychology holds yet another quality in the curious, again irrational, yet vivid, immediate and intense response to a certain type of individual. The type so able to influence the collective unconscious has something of the mystic about it. They are intuitives, themselves receptive of and guided by impulses without the ken of the ordinary man. Intuition is probably present to a small extent in every one, to a distinct degree in a limited number, and notably so, very rarely. Certain individuals are undoubtedly capable of undergoing states of consciousness in which they would appear to make an unusual contact with the realities of space and time. Joan of Arc provides a good example. A poor country girl, she heard voices bidding her take up the redemption of her people; she succeeded in imposing her will not only on an ignorant peasantry but also on the first soldiers of France, and swiftly transformed the whole military situation. There are other instances in history of the same sort of thing, explanation of which is not easy.

The German Fuehrer is one of these "daemonic" personalities. His strange and obscure life, his peculiarities of behaviour, his childish tempers, his prejudices, his intuitions, his inspirations ("waiting until he knows"), and his intense and vehement power over a German audience stamp him as something unusual. Note that it is not just the credulous man in the street whom he has swept along with him; it is also the hard-headed German General Staff and much of the intelligentsia. All this makes the greater pity that with such gifts he should have given his country's policy the sinister twist of these last years.

Is Germany then in the throes of an intense mass movement, a crowd hysteria, a surge of the old savage unconscious rushing down the slope of the irrational, the childish, the neurotic? Can their compulsive drive against, not some, but all their fellow-men, be so explained? Their actions are not normal. Their causeless suspicions, as of 'encirclement' and against Russia; their intense need for self-assertion, the sure stamp of inferiority, as in the '*Herrenvolk*' and the 'Aryans'; their crudity; their cruelty; their lack of every decency. To be suspicious, to break faith, to lie, to cheat, to murder—the common man knows that it does not work. There is no need of moral words, it simply does not work. How then can the Germans do these things? There can only be one outcome. Therein lies support for the conception of a nation "possessed".

Of course, there are obvious difficulties. The whole subject is new and unexplored. Patient and persistent study not only of this episode but also of many others is demanded to reinforce such a hypothesis, no matter how feasible. That Germany has stepped down from the climbing stairs of civilization into some callous, cynical, egocentric crudity cannot be altogether accepted as a new phase. Frederick the Great with all his good qualities was not conspicuous for keeping faith; Bismarck was responsible for the episode of the Ems telegram; and we all remember something about a 'scrap of paper' in the War of 1914–18. German atrocities are not a new story; they were spread, with some justification—to use restrained language—in 1870 and in the last war. German philosophy has been alone in advancing doctrines to which German conduct to-day gives but the logical expression. In short, their present state of mind cannot be altogether regarded as unexpected; it could even be legitimately argued that Germany was the only nation from which such

might have been expected. Alternatively, there may be something in the national make-up rendering them more unstable, more suggestible, more liable to some such breakdown.

"Germany Possessed" offers a sane and serious study of the why and how of all this unpleasant muddle. More than that, it dispels with a happy insistence the traitor doubts that may beset even an honest mind and a clear conscience. It submits a contribution certain to be helpful in the ultimate problems that will clutter up so heavily the final disentanglement. Without necessarily agreeing with every detail, everyone can find in Baynes's book much to approve, much that is reasonable and much that is encouraging. That it may superficially appear without immediate practical application is untrue; mankind advances not in arithmetical but in geometrical progression. The alarming hypothesis of yesterday is the happy certainty of to-day. Psychology may be a new science, it may submit surprising, perhaps revolutionary, concepts, but its admitted conquests in the individual field insist that it be at any rate heard in the collective sense. The mere appearance of such a thesis at this present moment justifiably infers that even under the vivid edge of a cruel conflict man can still hold to the high, ardent and vehement purpose of co-operation in the conduct of this life. Difficult, yes; but then ideals are made that way.

DESERT SANDS AND DUNES

The Physics of Blown Sand and Desert Dunes
By R. A. Bagnold. Pp. xx+266+16 plates. (London: Methuen and Co., Ltd., 1941.) 24*s.* net.

LIEUT.-COLONEL BAGNOLD is well kno for his scientific publications on desert sands and dunes, and for a book describing his travels in the Egyptian and Libyan Deserts. The present book combines these papers and much other original research into one comprehensive volume, which would, however, have possessed an added interest to readers if the introduction had included some reference to the author's work as a pioneer of motor travel in the desert. Descriptions of desert features in various parts of the world have been written by many travellers, but this book is unique in that the author has combined the results of experimental research in a wind tunnel with personal observations in the desert. The subject has a particularly topical value in connexion with the present war operations in the Libyan Desert, and the explanations of many desert features vitally affecting such operations will interest a wide range of readers. There is also scope for applying the researches to other kindred problems, such as the encroachment of desert sands over cultivated land, which is a serious menace in certain parts of the United States.

The contents of the book are divided into three sections dealing respectively with the physics of grain movement, small-scale effects such as surface ripples and ridges, and large-scale dunes. The first section shows in a fascinating way the mechanism of the interaction between sand grains and wind, as observed both in the desert and in the wind tunnel. Contrary to popular impression, dust storms in which fine particles are carried to a considerable height in suspension in the air are of comparatively rare occurrence in the true desert country. Sand grains can be lifted by the wind only to a height of several metres at the most, and the author shows by photographs and diagrams how the bulk of the sand movement is limited to a height of a few inches above the desert surface. These sand grains travel in a succession of leaps alternating with impacts on the surface grains, the process being given by the author the name of saltation. There is also a slow creep of the surface grains due to the impact of the grains in saltation, the whole process being considerably affected by the size and nature of the desert floor deposit.

The second section deals with an original method devised by the author to express graphically the size grading of sand deposits, and the application of this method to a study of deposits formed under varying conditions of wind velocity. Small ripples formed on the sand surface are shown to be entirely different in origin from the familiar ripples left on the ocean shore, in spite of the similarity of appearance.

The third section, on large sand dunes, is of a descriptive nature, since the scale of formation is beyond the scope of laboratory imitation. Although some of the theory advanced is admittedly tentative, the author has built up a convincing explanation of how sand dunes rising to a height as great as a hundred metres and extending for nearly a hundred kilometres, may be formed by the interplay of varying winds acting alternately from different directions. The enthusiasm of the author is shown by an account of experiments to determine the internal structure of the dunes which involved pouring precious water over the surface, the different layers being distinguished by the rate of seepage. The final chapter, which

should really have been an appendix, since it is not necessarily a large-scale effect, describes the so-called singing sands. The solution of this problem has not yet been attained, but the account of preliminary experiments shows that the author has made considerable progress in this problem and will no doubt find a successful explanation when he is able to relinquish his present duties.

Although written primarily for the geologist and civil engineer, many sections of the book will be of great help to those engaged in other branches of science. Thus the section on the grading of desert sands could be applied to many industrial powdered materials; the theory of the motion of sand grains under the influence of wind action could also be applied to the movement of dust in mine galleries, to deposits of dust in large pipe lines and indeed to pneumatic conveying of granular materials in general. Apart, however, from its specific applications to definite problems, the general reader will be rewarded with a fascinating description of a natural phenomenon which appeals strongly to the imagination.

H. HEYWOOD.

EDUCATION YESTERDAY AND TO-DAY

Education To-day

By John Dewey. Edited, and with a Foreword, by Joseph Ratner. Pp. xvi+86. (London: George Allen and Unwin, Ltd., 1941.) 5*s*. net.

SINCE the end of the nineteenth century, John Dewey has been the most effective force in the development of American education, while on this side of the Atlantic he has won for himself a large body of disciples, and the influence of his reforming zeal may be seen in British schools as well as in those of the United States. Many teachers will, therefore, welcome the publication of this volume of essays, written between 1897 and 1908, and selected from the large *corpus* of his writings to give the dominant themes of his educational work. These are summarized in "My Pedagogic Creed" (1897), which forms the first chapter of the book, and the relevant articles are then applied in a series of essays on "The Primary-Education Fetich", "The People and the Schools", "The Place of Manual Training in the Elementary Course of Study", "Democracy in Education", and "Religion and Our Schools". Some of these are inevitably dated, and the battles for which Dewey fought thirty or forty years ago have been largely won: yet the victory has nowhere been so complete or so secure that all danger of a counter-attack is removed, and though the title given to this book is rather misleading, yet its contents have a relevance to the problems of to-day which cannot be ignored, and they are shot through and through with flashes of universal truth and wisdom which make them independent of time and place.

One of Dewey's chief services to education has been to humanize it. For him, all its subjects and activities, whether considered from the teacher's or the learner's point of view, must be translated into terms of human nature, and be made relevant to human needs and human interests. We get away from the false but common view that education is an operation we perform on somebody else (and nearly always exclusively on his mind), to the truth that it is always a co-operation, and a co-operation in which the *whole* of both partners to it is concerned: it is the whole child who is being educated, the whole man who is educating him, and the process is not an action which the one carries out on the other, but a transaction between the two. In these thoughts we have "the controlling factors in the primary curriculum of the future—manual training, science, nature-study, art and history. These keep alive the child's positive and creative impulses, and direct them in such ways as to discipline them into the habits of thought and action required for effective participation in community life." Thus education becomes "a process of living, and not a preparation for future living", the school "a social institution", and the synthesizing force in a child's school subjects and activities his own social activities. The culture we teach must not be a "hand-me-down garment", an "intellectual suit which other people have worn", but the natural culture of childhood, adolescence, and manhood, a culture compounded of many elements, among which the technical and the spiritual will both have their place. Religion is to be taught not as a body of doctrine, but as a way of life—and the way of life is to be seen in the common life of the school: the schools "serve best the cause of religion in serving the cause of social unification", and the intellectual integrity which they teach is potentially much more religious than any outworn belief which it may displace.

The teacher's human needs must be considered too, and the chief of these is the "recognition of his intellectual and spiritual individuality": he must be trusted, and his judgment upon matters of educational importance (whether inside the school or outside) must be respected and effective: otherwise we have an undemocratic education for

a democratic community. It is men, not walls, that make a city, but education makes the men, and the educational system, if it is to do its work, must reflect and "simplify existing social life".

It is along these lines that Dewey fights his battles. Are the battles won? There is much to encourage us, but there is also much to make us uneasy. In Great Britain since the beginning of the century we have done much to put the child in the centre of the picture, and we remember more often than we did that it is John and Mary whom we are teaching, and not arithmetic or reading. But there are still far too many teachers 'subject-ridden' (What is a 'subject', and how does it differ from our 'object'?). From the totalitarian States there is developing a strong attack on the whole theory of education as a human activity, and there will be repercussions of this among the democracies. Culture is in danger of becoming the preserve of the educated few, and one of the chief problems of our day is that of synthesizing cultural and vocational activities. To judge from the B.B.C. material, religion and religious education are hardening in the cement of orthodoxy. While teachers are ostensibly free, they are perhaps the least trusted of all professions, and their influence on educational policy is dangerously restricted: it is an ominous sign that proposals for education after the War should have been prepared for the Board of Education by its Civil Servants as a confidential document, and should be kept from the teaching profession. Assuredly, the republication of Dewey's "essays" is not untimely.

M. L. JACKS.

THE STRENGTH AND STRUCTURE OF THE EARTH

Strength and Structure of the Earth
By Prof. Reginald Aldworth Daly. (Prentice-Hall Geology Series.) Pp. x+434. (New York: Prentice-Hall, Inc., 1940.) 3.50 dollars.

THOSE who have some acquaintance with Prof. Daly's researches and writings will expect both pleasure and profit from his latest book; nor will they be disappointed. Geophysics demands the co-operation of workers in a number of different sciences, and with the modern tendency of research to run along narrow paths there are few who have the wide knowledge required for a grand synthesis. Thus, there has from time to time been a cleavage of opinion on various vital matters between, say, geologists and mathematical physicists, although each had much to learn from the other. Happily, there has arisen in recent years a spirit of close co-operation, and some of the fruits of it are seen in the volume under review. Prof. Daly combines the wide knowledge of the geologist with a clear grasp of the modern advances in geodesy and seismology—no mean achievement. His exposition is attractive, and is illuminated by a wealth of suggestions, many of them frankly speculative, many indicating possible quantitative tests, and all of them worth recording.

The reader who is three-quarters of the way through the book will notice that so far the book had dealt exclusively with isostasy; indeed, it might be asked why the title is not simply "Isostasy". Had the last chapter been omitted and the remaining eleven chapters been left as a treatise on isostasy itself, the book would still have been worth the writing. The final chapter, however, on the strength of the earth-shells, could not have been written except in the light of a detailed description of the results of geodetic surveys. The wide acceptance of the idea of isostasy has afforded excellent illustrations of the use and misuse of inductive inference. As a working hypothesis, based on a large body of data, there has from the first been much to recommend it; the too-ready acceptance of an over-simplified model apparently gave some writers the impression that world-wide isostasy was a fundamental law, even though not more than two per cent of the earth's surface had been gravitationally surveyed.

In this book great care has been taken to put the development of the idea of isostasy in its proper historical setting. It was Pierre Bouguer who in 1749 stated in his book, "La Figure de la Terre", his belief that the measurements made between 1735 and 1745 on the meridian arc in Peru indicated a much smaller attraction of the Andes than their estimated mass would suggest. Shortly afterwards R. J. Boscovich attributed this to a thermal expansion of material in depth; he suggested that the deficiency or void ("vide") within the mountain compensates ("compense") for the overlying mass. In 1836 Sir John Herschel expressed the view that the removal of rocks by erosion to distant basins would entail horizontal flow of the plastic matter below. F. Petit, too, had proved in 1849 that the agreement of the astronomical and geodetic latitudes of Toulouse indicated a deficiency of attracting matter beneath the Pyrenees. Thus the ground was to some extent prepared for the classic work of Archdeacon J. H. Pratt, whose first paper was read in

December 1854, and of Sir George Airy, whose paper was read in January 1855. In the course of Everest's triangulation of India it was found that the difference between the geodetic latitudes of two stations, Kaliana and Kalianpur, on the same meridian, was not the same as the difference of their astronomical latitudes; the difference, in fact, was about 5″. Pratt calculated the deflecting effect of the attraction at these stations of High Asia, and on this basis predicted a difference of about 16″, almost exactly three times that actually observed. Later work by Pratt took account of the relatively weak attraction of the ocean to the south of India. Airy remarked that, surprising as Pratt's discovery was, it might have been foreseen on the current view of a fluid interior of the earth (or at any rate fluid at the time mountains were formed); he showed that on likely hypotheses the crust was not strong enough to hold up the mountains, and attributed their support to projections of the light crust downwards into the denser matter on which the crust was, in effect, floating—somewhat after the fashion of a floating iceberg. Hence the idea of the 'roots of the mountains'. Pratt, working on the idea of vertical expansion of large blocks of the crust, supposed the attenuation of density to be distributed uniformly to a certain depth, which for High Asia he estimated as about 100 miles. Between these two models one could evidently construct any number of others in which the two modes of compensation are combined. The word 'isostasy' was coined in 1889 by C. E. Dutton for the ideal state of equilibrium of a fluid or plastic heterogeneous body, and the question he proposed was: How nearly does the earth's figure approach to isostasy? Substantial extracts from the original papers of Pratt, Airy and Dutton are quoted by Daly. Measurements of the intensity of gravity tell the same story as measures of deflexion of the vertical.

Much of the book is taken up with a description of the way in which the approach of the earth to isostatic equilibrium has been tested by plumb-line and pendulum. The very fine work of J. F. Hayford and W. Bowie in the United States showed that that country approximates closely to the isostatic state; for their reductions they used a Pratt type of compensation extending to a depth of 113·7 km. Their results rather led to the expectation that isostasy would prove, to a close approximation, to be a world-wide phenomenon; they suggested, too, that compensation followed the Pratt model. A very important paper by Heiskanen in 1924 showed that the available European data indicated on the whole a close approach to isostatic balance, and that there was very little to choose between the Pratt and the Airy types of compensation, a result that was also true of gravity in the United States. Within the last ten years new observations have greatly changed the outlook. Hunter and Glennie have shown that India departs notably from the isostatic state, and the measurements of gravity by Vening Meinesz during extensive voyages in a submarine have revealed large belts of astonishingly large gravity anomalies. None the less it is still convenient to collate the observations by adopting an isostatic model and to speak in terms of deviations from complete isostasy.

A chapter on "Nature's Experiments with Ice-caps" brings us nearer to the main purpose of the book. The post-Glacial uplift of Fennoscandia, which still seems to be continuing at a measurable rate, is generally ascribed to isostatic adjustment following the removal of the ice-sheet; a similar recoil is found in north-eastern North America. Estimates of the viscosity of the underlying material have been made, but the data, and the use of the data, are decidedly precarious. The outstanding problem that geodesists and geophysicists hope to solve is whether the material below the 'crust' behaves in the long run as a fluid, or whether it has residual strength; this weak layer is termed the 'asthenosphere'. A related problem is the extent to which the crust can bear loads without fracturing, that is, the horizontal extent of the supposedly independent crust-blocks.

The researches of Jeffreys, which indicate in the asthenosphere a strength approaching that of granite, are seriously challenged by Daly, who readily admits that there are too many unknowns in the problem to permit at present of a unique solution. Daly suggests that below the asthenosphere, and probably extending down to the fluid, dense core of the earth, is a "mesospheric shell" of moderate strength and of density somewhat greater than at the asthenospheric level; this strength and density are held to arise through crystallization under pressure. The suggestion is made that the asymmetry of figure of the earth may arise from a permanent inequality in the mesospheric shell, the imperfectly healed wound left when the moon was torn away from the earth—a new variant of an old theory originally due to Osmond Fisher. An attempt is made to account for deep-focus earthquakes, but it is doubtful if the sudden freezing of a sunken mass of glass would release sufficient energy.

This stimulating treatise is illustrated by a large number of excellent clear diagrams, and the type is easy to read. The computations have evidently involved the author in much hard work, and he has done a great service in collating and rendering easily accessible the results of a number of researches scattered through a wide range of publications.

R. STONELEY.

The Aeroplane of To-morrow
By Noel Pemberton-Billing. Pp. 307. (London: Robert Hale, Ltd., 1941.) 12*s.* 6*d.* net.

THIS is a difficult book to review. One does not dare to dogmatize about anything in the aeronautical world, but the science of flight is now becoming sufficiently established to enable us to look a short way ahead with reasonable certainty. The author's conclusions as to how progress in speed or carrying capacity of heavier-than-air craft can be made, in general by an increase in wing loading, are certainly true; but the light-hearted way in which the book sweeps away, or else ignores, the attendant difficulties, rather shakes one's faith in it as a serious scientific work.

The principal part of the book is devoted to an elaboration of the author's idea of a "slip wing" aircraft, a form of assisted take-off for a highly loaded aircraft (already developed by the Short-Mayo flying-boat) evidently by his assistant, Mr. Roger Tennant, whose work he acknowledges. His figures quoted for a suggested long-range high-speed bomber are accurate aerodynamically, but in the event of a failure necessitating an emergency landing immediately after commencing a flight, the whole of the bomb and petrol loads would have to be jettisoned, and even then the author contemplates landing with a wing loading of 40 lb. per sq. foot. This is scarcely a happy procedure in the vicinity of a crowded aerodrome. This is admittedly an isolated case, but it is typical of the whole book. The best that can be said is that it puts the case of one particular avenue of possible progress in plain language such as can be read by the ordinary man, and in this sense it is useful and worth reading. One looks in vain for anything new, which the title rather leads us to expect, or anything that is not already known by serious students of aeronautics.

Intermediate Inorganic Chemistry
By Dr. J. W. Mellor. New edition, revised by Dr. H. Irving. Pp. xx+690. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1941.) 9*s.*

THE revision of this book has been carried out by Dr. Irving, who states in the preface that "he has been at pains to preserve the essential character of the book". Thus, while the numerical data have been extensively revised, only minor changes have been made to the subject-matter. The reviewer feels very strongly, however, that it would have been worth the extra cost of repagination to have omitted many of the old graphical formulæ, as well as details of, for example, hyponitrous acid, hydrazoic acid and the thionic acids, which are scarcely suitable for students at this stage. Incidentally, this would have provided space for the inclusion of one or two modern processes, such as the manufacture of nitric acid from ammonia, which ought to have been mentioned in this edition. Apart from these criticisms, and perhaps the debatable point of whether it was wise to omit the electronic theory of valency, the reviser appears to have accomplished his task successfully. A. C. C.

Honeycraft in Theory and Practice
By J. A. Lawson. Cheaper edition. Pp. xii+228+18 plates. (London: Chapman and Hall, Ltd., 1940.) 3*s.* 6*d.* net.

THIS is a reprint of one of the best-planned books on practical bee-keeping known to the reviewer. The author perhaps allows his own preferences too much scope in his exclusive recommendation of the Italian bee, and in confining attention to the 'Stoney-Archer' type of hive, although the latter, in a simplified form, is now well known and widely used under the name of 'National Standard'. The W.B.C. type —still the hive most used in Great Britain, and well suited to the climate—is dismissed in a few lines of criticism. Considerations of space would, however, probably make impossible the adequate description of more than one hive type; and the author's is a good choice.

It is to be regretted that the book has not been brought up to date in the many matters of biology and physiology, and of the physics of honey, in which knowledge has advanced since its first publication in 1931. Some of these are of practical value, and all of interest to the intelligent beekeeper. It is to be hoped that this will be remedied in a future edition.

The practical section is good, containing many useful hints and few slips. The illustrations are well chosen and produced, and really illustrate the points to which they refer. The type is large and the finish excellent, combining with the pleasing style to make the book agreeable to read. A. D. B.

Algebra
A Text-Book of Determinants, Matrices and Algebraic Forms. By W. L. Ferrar. Pp. vii+202. (Oxford: Clarendon Press; London: Oxford University Press, 1941.) 12*s.* 6*d.* net.

THIS is a text-book intended primarily for undergraduates. It is designed to give a broad basis of knowledge comprising such theories and theorems in those parts of algebra which are mentioned in the title as are of constant application in other branches of mathematics.

The book is divided into three parts: namely, determinants, matrices, and linear and quadratic forms. It will be seen at once that there are notable omissions from the usual conception of a text-book on algebra, but the author states in the preface that these omissions are deliberate.

The arrangement of the text rather resembles a geometry in its orderly array of definitions and numbered theorems, but it must be confessed that a decimal numeration of theorems to correspond with that of the paragraphs would have greatly facilitated reference. Although the treatment throughout makes pleasant and easy reading, the author is to be particularly congratulated on his exposition of matrices, which provides just what is greatly needed in many current applications.

There are numerous and well-chosen exercises, with occasional hints, and suggestions for further reading to build on the foundations so ably laid in this book.

SCIENCE AND TECHNOLOGICAL ADVANCE

TO cover effectively the wide field of technological advance, almost all of which is closely bound up with corresponding developments in science, was certainly beyond the aim of the Conference on Science and World Order held during September 26–28. As it was, the papers presented covered a wide and varied field.

Sir Harold Hartley, chairman of the Fuel Research Board, claimed that most of the scientific discoveries of the last two hundred years could not have made an effective contribution to the progress of civilization without the successive technological developments that have made energy available. The main results of this progressive utilization of energy were: (1) Power-driven machines with a continuous increase in the productivity of labour and material resources, first in industry and later in agriculture. (2) Means of rapid transport by land, sea and air, facilitating the development of new countries, making available the world resources of raw materials and food, and providing new markets for industry. (3) Development of metallurgical and chemical industries, producing secondary raw materials for industry and fertilizers for agriculture. (4) The high-voltage distribution of electricity, making possible the dispersal of industry and thus avoiding the over-crowding of urban areas.

Following on these has come another no less far-reaching revolution—the domestic—which has done so much to raise the standard of health and comfort in the home, which may be regarded as repayment by the technician of a long overdue debt for social consequences of mechanization of industry in the nineteenth century.

Fundamental research will yield continuing improvements in methods of utilizing fuel, distribution and storage of electricity, uses of power, and in production of substitutes for mineral oil from coal or vegetable products against a possible shortage. The ultimate goal is the utilization of the sun's radiation currently by some photochemical or photo-electric device or engine, to take the place of the solar energy stored in coal and oil.

The problem of energy was also comprehensively treated by Prof. A. C. G. Egerton, of the Imperial College of Science and Technology. To-day, the world makes use of 1,300 million tons of coal, 270 million tons of oil and 55 million tons of natural gas per annum. Only a very small fraction of the solar radiation (1/60,000) is currently utilized in the form of the food produced by plant life, or in the form of hydro-electric power, through the atmospheric mechanism. If ever the vast stores of energy in the make-up of the atoms can be released, controlled and used, another industrial revolution may be expected. Therefore, in preparing for a new world order, it is necessary to have more accurate knowledge of the material resources of the world and particularly the sources of energy and to plan on the basis of that knowledge.

In a paper by Dr. G. Lewi, Dr. O. Eisler and Dr. J. Cisar on "Problems of the Technology of Unutilized or Insufficiently Utilized Raw Materials and Waste Products", the authors stressed the exhaustion of some raw materials, and the war-time wastage of valuable materials. New methods are required for dealing with new raw materials, or those not sufficiently or efficiently exploited. Nitrogen has already been fixed from the air; other materials as abundant, such as clay and sea water, are waiting to be used, the former as a potential source of light metals. Large quantities of magnesium chloride, which is largely a waste product in the manufacture of potash, ought to be a rich source of magnesium.

There are also new possibilities in the use of wood. The problem involves, first, the best and most efficient methods of processing, leaving as little waste products as possible and, secondly, the further optimum utilization of unavoidable by-products hitherto regarded as waste. Of primary importance is avoidance of the wastage of utilization of coal, an improvement being, for example, the use of naphthalene for the increasingly important carbon-black. Attention was also directed to restoring harmony between the production and consumption of natural raw materials and of their synthetic artificially produced substitutes. Progress made during the War in this direction must be perpetuated.

Dr. C. H. Desch, of the Iron and Steel Institute, likewise discussed the conservation of natural resources. He pointed out that the political pledge to accord access to raw materials means international control of such sources after the War. Minerals, including coal and oil, which are the principal sources of power at present, are capital, and assets, once consumed, can never be renewed. While allowance must be made for technical improvements in working leaner ores and in mining at greater depths, it appears that certain minerals, such as oil and tin, are within calculable distance of exhaustion. Estimates vary widely, but copper, tin, gold, and phosphates, at the present rate of production, are believed to have a further life of less than a century. Coal and iron may last for thousands of years, while the estimates for oil

reserves are very conflicting. Little information is available for the sparsely occurring minerals, such as nickel, tungsten, molybdenum and vanadium, which are increasingly essential for high-class steels. In the first quarter of the twentieth century the quantity of ores taken out of the earth was greater than in the whole of previous history (say, six thousand years after copper was first mined), and at the current rate of development, the world production of many minerals doubles itself in 10–20 years.

Dr. L. E. Howlett described "Canada's Optical Industry" as an example of how the State can establish a new industry to fill a gap in its economy and to supply an urgent need. A great amount of the preliminary investigation of the possibilities, needs in materials and personnel were made by officers of the National Research Council. As a result of this extensive work the Department of Munitions and Supply established an entirely Government-owned company—Research Enterprises, Ltd.—which is charged with the responsibility of producing manifold types of optical instruments required for military, naval and air operations. Although this company is under the responsibility of a different ministry of the Crown from the National Research Council, the resources for research and development and technical counsel which the National Research Council can provide are always at its disposal.

"Science and Technological Advance Applied to Building", was the title of the paper presented by Mr. R. Fitzmaurice, of the Building Research Station He explained why building tends to lag behind other industries in the use that it makes of scientific advances. In the last twenty years, however, much has been done in establishing basic scientific principles which govern building problems. Of principal importance are: the acoustics of buildings, heating and ventilation, daylight illumination, and the exclusion of dampness. Auditoria no longer need result in unintelligible speech, and refinements in design are alone required to reveal the full tonal balance of an orchestra. Technically, local and external noises can be reduced below nuisance values. The cost entailed in these problems has been materially reduced by a proper study of conditions.

More exact control of the usage of fuel has directed attention to provision of heat and ventilation, with greater comfort to the users. The principles underlying the transfer of water in porous parts of buildings have been elucidated, and there is no longer any justification for dampness in buildings.

To apply this knowledge more rapidly, greater emphasis might be given to elementary science in the training of workers in the building industry, including architects, builders, craftsmen and surveyors.

In a paper on "Some Recent Applications of the Theory of Elastic Dislocations", Prof. Enrico Volterra, of King's College, Cambridge, described concrete structures as an example of the utilization to a maximum degree of the resistance of the material employed in building. This was achieved by a study of the conditions of elastic-plastic equilibrium, and of pre-stressing structures. The first study increases knowledge of the state of stresses and deformation of structures when the elastic limit of the material is passed, which then becomes the plastic condition. The second study enables stresses favourable to its stability to be established within the structure. The combined study is called the theory of elastic dislocations, and is the result of the blending of science and technology upon which progress in civil engineering is based.

"Technical Advances in Biology" formed the subject of a discourse by Dr. C. H. Waddington, of the Strangeways Laboratory, Cambridge. Dr. Waddington dealt mainly with agriculture, although medical advances were touched on, such as the alleviation of malnutrition, the conquest of tropical diseases, and the reversal of the falling reproductive-rate, the latter being a political rather than a technical medical matter. Great changes in the production of plant products will probably be brought about; tank culture, with or without artificial lighting, is likely to spread. The control of hormones affecting the growth of particular organs is still comparatively new. Vernalization, in the U.S.S.R., has led to adjustment of the latency, growth and flowering of plants to climatic conditions. There have been spectacular results in utilizing hybrid vigour in maize, and this technique will probably spread to other crops, such as tomatoes. The wealth of new wild forms which have recently been placed at the plant breeder's disposal will make practicable the extension of the zones in which certain flowers flourish. The importance of extending the potato to the tropics and the arctic can scarcely be over-estimated. The recently acquired control over the production of tetraploids, both pure-bred and hybrids, by means of drugs such as colchicine, can scarcely fail to produce entirely novel crop-plants of importance.

The improvement of productivity in animals has always been more difficult than with plants. Artificial insemination already allows the sperm of a tested male to be used on many more females than otherwise would be possible. A tissue method of keeping testes alive might increase the number indefinitely. Hormonal methods of inducing ovulation have already been used to get two crops of

lambs a year. Methods of producing super-ovulation are also known and, combined with the transplantation of the ova to other females, might enable us to multiply by a considerable factor the offspring of a valuable female. A first step has been taken towards the artificial production of tetraploids in mammals, and the doubling of hybrids cannot be considered technically out of the question. The hormonal control of sex-development may yet play a part in poultry and, perhaps, the dairy industries. Methods of separating female- from male-producing sperms have already had some success and may soon play a large part in the same two industries. The use of growth hormones for inducing giant forms, which might conceivably reproduce themselves true to type, is a possibility which may be realized within a few years.

The greatest technical advance which may be expected shortly is organization. The liaison between advanced institutes for practical and for theoretical biology is much less close in Great Britain than in many of the leading countries, such as Sweden, the U.S.S.R. and the United States. The return of many biologists from war-time tasks to biology will be a suitable time to introduce a well-considered re-organization of the whole scheme of biological teaching and practice, from the primary school to the university. Such a reorganization has been long over-due.

In dealing with industrial research and the universities, Dr. F. H. Boer inquired into the possibilities of promoting a beneficial exchange between science and industry. The application of new scientific discoveries and methods to industry and the consequent furtherance of research, necessitates a very close collaboration between men of science and all those concerned in the application of science, but in most countries collaboration between universities and industrial research laboratories is not close enough. The fear that industry will lose its secrets is one of the main factors, though in practice one finds that many of the so-called secrets are not secrets at all. In some large industrial research laboratories close co-operation between scientific workers and technicians exists, and the scientific workers are in touch with the universities.

Leaders of industrial research laboratories must be scientific men with highly developed technical minds and imaginations, and preferably some of them should hold a semi-official position at a university. Smaller industries should unite to establish and maintain sufficiently large research laboratories; there can be no place for small isolated research laboratories in the future, in Dr. Boer's opinion. The Government should endeavour to bring the smaller industries together, and to induce minorities to accept majority decisions. If industry realizes that its first task is to serve the community, then science will minister to industry unreservedly.

The technological advances of the last few decades, which, as Mr. Ritchie Calder pointed out, amount to a second industrial revolution, have made it incumbent upon scientific men to make certain that these advances are used to the benefit of humanity. The immediate task, in the words of Sir Harold Hartley, is to ensure that in the replanning of the world full use is made of the basic knowledge that science alone can provide, particularly in the fields of nutrition and energy, with all that they imply for the well-being of mankind.

SCIENCE AND WORLD PLANNING

Science and world planning was the subject of one of the sessions of the Conference on Science and World Order, and, in one form or another, planning was implicit in most of the papers presented at the Conference.

The need for planning was stressed by many speakers, and during the discussions on human needs and post-war relief the immediate aim of world planning was clearly stated to be the relief of human suffering and the provision of an adequate standard of life to human beings everywhere. Preparations with this immediate aim in view must be made now.

World planning is not a task to be lightly undertaken or one in which quick results can be expected. As M. Maisky, the Soviet Ambassador, reminded the audience, it took the U.S.S.R. twenty years to reach its present advanced state of planned economy. In his view, the chances of replanning the world are years ahead. He characteristically claimed that the immediate plan for all of us is to win the War. Nevertheless world planning can and must be undertaken, provided we do not lose sight of our immediate objective, that of winning the War, and thus ensuring the opportunity to plan.

Some people object to planning because they fear that it would sacrifice the energizing force of competition. But, as Mr. Maurice Dobb, lecturer in economics in the University of Cambridge,

pointed out, competition to-day is not what Adam Smith and the early economists extolled. We have now monopolistic competition, where the public interest tends to be thwarted rather than asserted, and the economically weak subordinated to the economically strong. This is the alternative with which we have to compare economic planning.

The post-war world will need larger economic units and more economic intercourse between nations. But it will need also the maintenance of full employment and the ending of exploitation of weak nations by strong. This synthesis demands a new regime of international planning. It implies the dominance of the social interest over the sectional, of the common good over individual profit.

The need for a new outlook was also stressed by Lord Hailey when dealing with colonial planning: ". . . a modern world which can combine to control the production of tea or rubber, or tin, or copper, in the interest of an investing public might well find the means of exhibiting a greater solidarity in dealing with issues vital to the welfare of Colonial peoples."

Mr. M. Wynants, of the Belgian Commission for the study of post-war problems, who spoke on town planning, was one of the few who attempted to look at the problem of world planning as a whole. He pointed out that the post-war world will be very different from the world we knew, and therefore we must face without delay the need for drastic solutions to the political, economic, social and moral problems. These are aspects of one and the same reality, and it is impossible to propose a solution in one of these fields without automatically bringing about corresponding reactions in the others.

Among the tasks mentioned by Mr. Wynants that can be satisfactorily accomplished only by international planning are: access to raw materials, development of backward areas, public works of an international character, human migration. A solution to these problems will be dependent upon a corresponding organization of political relations.

Town and country planning—according to Prof. William Holford, of the University of Liverpool—is chiefly concerned with the use of land for a variety of human purposes which may be broadly grouped as (*a*) agriculture and forestry, (*b*) development, including industry, (*c*) recreation and (*d*) transport.

The problems of agriculture were outlined by Sir John Russell, director of the Rothamsted Experimental Station. The agricultural systems of pre-scientific days, he stated, had two features in common: they aimed at providing complete subsistence for the community, and at conserving the land. The three-field or strip system common in Great Britain, round the Baltic, in northern India and elsewhere aimed further at an equitable distribution of good and bad land.

As practised in Europe, the strip system had the merit of permanence but was of low productiveness and had to be abolished. The U.S.S.R. adopted one method and Poland another, but a change was essential. In Great Britain the change to unified holdings was made before the scientific era, and technical improvements raised the output per man higher than in any country in Europe, though the output per acre was less than in the smaller western countries of small holdings. In the new economic system introduced since the War, under which specified prices will be received and specified wages must be paid, and with the help of scientific methods, the indications are that high output per acre will be attained, as well as high output per man (see also NATURE, of October 18, p. 456).

The dangers of deforestation were touched upon in a paper prepared by Lord Onslow, who made an appeal for the conservation of the wild life of the world. Within the last hundred years or so, several dozen species of animals of æsthetic, scientific and commercial value have been exterminated, and it is of the utmost importance to save others from a similar fate.

"Free play given to economic forces in the past has led to localization of a single industry in one district and has resulted in derelict areas and 'ghost towns' when that industry was depressed", stated Prof. P. Sargant Florence, of the University of Birmingham. Recent scientific progress has on the whole intensified the economic trend towards industrial concentration; if the social and socio-economic criteria are accepted and dispersion of industry is adopted as a policy, hard thinking and fighting lies ahead for planners.

Dr. Othmar Ziegler, lately of the University of Prague, dealt with the transport problems of the Danube States, and estimated that if transport can contribute to raising the standard of life in south-eastern Europe to one third or one half of that of western Europe it will furnish employment, through the expected increase in exports, to tens of thousands of workmen in western Europe.

The world's heat and power requirements was the subject of a paper by Sir Harold Hartley, who pleaded for a detailed consideration of the world's energy resources, their utilization and conservation, in the light of post-war schemes of reconstruction. If all the potential water resources were to be harnessed, the estimated energy would not exceed 30 per cent of the requirements, so that burning of fuel must continue to supply the greater part of the world's energy consumption until some other source, such as the direct utilization of the

sun's radiation, has been made practicable upon a large scale.

Carbonization of raw coal and the use of electricity in a co-ordinated scheme, designed to secure maximum advantages from both, will help to solve the problem of smokeless cities and provide cheap energy needed in homes. Wider application of energy on farms, and in conditioned transport and storage, would increase productivity and accelerate processing. With the scientific knowledge we now possess it should be possible to plan with much greater certainty than in the past.

Dr. Ove N. Arup, a civil engineer from Copenhagen, inquired into the reasons why modern buildings lack many of the desirable qualities which modern science and technique have made possible : warm, sound-proof rooms, well ventilated and provided with labour-saving devices. The difficulty appears to lie in specialization, and Dr. Arup asked whether a "composite mind" could be created in the form of an organization that would achieve a well-balanced synthesis from the wealth of material available. There exist already teams which include architects, engineers, heating specialists, etc., but so long as such groups work for profit they may try to keep their experience secret or advocate materials and processes in which they have interests. An extension of the present research stations is needed, to carry out the checking up and classification of existing technical information, and the creation of planning organizations.

The nature of modern science demands not only planning and team work, stated Mr. D. P. Riley, of the University of Oxford, but also international planning and team work. To overcome the language difficulty a co-ordinated system of abstracting would be very valuable. More frequent international conferences should be held and their scope should be enlarged so that, with a modified organization of conference procedure, they may become valuable world-planning commissions.

Prof. Jacques Metadier, formerly professor of biological physics in the University of Poitiers, advocated the setting up of an international society for scientific research, a kind of co-operative society to which everyone concerned in the exploitation of scientific discoveries would have to contribute a small percentage of their profits. Out of the resulting fund payments would be made to scientific workers whose researches had been economically exploited, and, in addition, research scholarships would be created and pensions would be made available to research workers over a given age, even though their labours may not have had practical applications.

Turning from visions of what the future might bring, to research now being carried out relating to planning and to post-war reconstruction, Prof. Alvin H. Hansen, of Harvard University, gave an outline of what is being done in the United States. For the last eight years the National Resources Planning Board has been engaged in studies relating to the natural, human, scientific and economic resources of the nation. Some of its activities in connexion with social welfare have already been noted (see p. 455). In addition, the Board is required to maintain a six-year programme of Federal Public Works.

In 1934 the Board sponsored a survey of the extent of soil erosion, which led to the establishment of the Federal Soil Conservation Service with authority to make surveys, conduct research, establish demonstrations and educate the public about soil conservation. In 1936 the new Agricultural Adjustment Act combined the dual purpose of soil conservation and agricultural production, and the Flood Control Act charged the Department of Agriculture with responsibility for watershed treatment.

One of the most significant achievements of the United States Government during the past ten years has been the redevelopment of the Tennessee Valley, with an area nearly as large as Great Britain. The large-scale planning carried out by the Tennessee Valley Authority was described by Prof. L. Gulick (see p. 388). Planning, said Prof. Gulick, is not only compatible with a democratic system of multiple parties, free elections, free criticism, free discussion, free enterprise and private capitalism, but it is essential in releasing the energies of freely co-operating individuals and governmental and private corporations in fulfilment of plans and objectives.

Mr. Hugh P. Vowles, on the other hand, who has made a study of large-scale electrification in several countries, considers that scientific planning upon a comprehensive scale is incompatible with private capitalism. There can be no co-ordinated development of power and associated resources, since one authority would plan electrification and another gas supply without pausing to consider whether they fit together, or with other associated activities. In the Soviet Union, he claimed, co-ordinated planning covers all aspects of exploitation of power and material resources, with the public welfare kept steadily in view.

This ends the series of summaries of deliberations of the Conference. In this, and in the previous five reviews, an attempt has been made to bring together pronouncements bearing upon specific subjects, so as to form a consecutive whole. Unfortunately, the contributions considered, though generally good in their particular field, frequently bore little relation to one another ; they will serve excellently, however, as material for a future conference on world planning.

SCIENCE IN THE DEFENCE OF CIVILIZATION

RADIO MEETING AT MOSCOW

WORLD-WIDE interest and sympathy has been aroused by the appeal of the meeting of men of science held in Moscow on October 12. Messages of greeting, sent in advance to the meeting, included one from Sir Henry Dale, president of the Royal Society of London, declaring solidarity with the Soviet men of science and those of the whole world who are united in the struggle against Germany's attack on freedom, including free scientific research.

The Secretaries of the Royal Society also sent messages declaring that Russian men of science are fighting for all that is essential for the development of science, and that their great achievements in science will serve as a firm support in this struggle.

In the name of forty thousand members, the secretary of the British Medical Association sent greetings to the representatives of medical science in the Soviet Union, and wishing success in the common task of freeing humanity from its sufferings in a new, better world which will be built after the War.

Other messages were sent including greetings from Sir Richard Gregory, president of the British Association, Prof. Julian Huxley and Prof. J. B. S. Haldane and Mr. and Mrs. Sydney Webb. Many messages were sent from the United States, including those from the president of Harvard University, representatives of Columbia University, the Universities of Chicago and New York and from many other American men of science.

The Association of Scientific Workers, in its message, welcomed the timely action of Soviet men of science in organizing the meeting. Its message concluded: "We British scientists deeply appreciate that our Soviet colleagues are right in the front-line of the struggle against Fascism, and we send them our warmest greetings. We feel that world-wide contact between scientific workers, in order to exchange information, ideas and technique, will be an important factor in ensuring victory. In particular, the closest collaboration must be created between Soviet, American and British scientists. We represent between us a free intellectual power which Hitler cannot emulate. Let us make certain that it is used to the full to win the war and create a better world. Our Association is organising a Conference in January to discuss in detail how we, as scientists, can increase production, protect the people's health, and train reserves of technicians. Let us hear from your scientists all over the world how you tackle these problems."

Prof. V. L. Komarov, president of the Academy of Sciences of the U.S.S.R., was prevented by indisposition from attending the meeting. He sent the following message: "Brothers in the common cause, scientists of the world, creators of culture and progress, this is a decisive and momentous hour for humanity.

"The sinister hordes of modern vandals are holding out a mortal threat to world civilization. The mightiest democracies of modern times, together with all freedom-loving peoples, are mobilizing their forces against the enemy of mankind. Part of the arsenal of the anti-Fascist coalition is the unlimited creative power of science.

"The scientists of the Soviet Union are ardently taking their share in promoting the industrial, cultural and military progress of their country. The knowledge of danger multiplies our strength and will to victory. Throughout the vast expanse of their country, Soviet scientists are seeking new sources of raw material and power, developing new technological methods and designing new plant with the purpose of expediting victory.

"Soviet scientists appeal to the science of the world to aid the greatest and most worthy cause of modern times. We appeal for the union of all forces for the utter defeat of Fascist Germany. The time is short; decisive days have come. The future of mankind, its progress and plans demand the annihilation of the reactionary Hitlerite clique."

Prof. Butyagin, who took the place of Prof. Komarov, said: "Hitler is the enemy of science, progress and enlightenment. He has destroyed culture in France, Holland and the Slavonic and other countries which he has occupied. Hitler seeks to suppress culture and science all over the world. Therefore it is our task to fight for the liberty of humanity. The scientists of the Soviet Union are taking a whole-hearted part in the industrial, cultural and military development of the country. Soviet science has been responsible for great achievements, for the translation of the scientific literature of various nationalities, for new development in many fields."

Prof. P. Kapitza, who was formerly Royal Society Messel research professor and director of the Royal Society Mond Laboratory, and is well known for his work in magnetism and low-temperature research, pointed out that in the past twenty years military technique has made great strides, and there is no doubt that, with the present level of knowledge, it may make greater strides still. Fascism employs science solely for

the purposes of war. The task to-day is to eradicate Fascism, which has already caused so much misery and destruction all over Europe. The scientific resources of the democratic countries are considerably larger than those of Nazi Germany. Under the ægis of Nazism, the level of even the exact sciences has declined frightfully in Germany, and partly for this reason German technique has already begun to lag behind in many respects.

Science has not exhausted its potentialities of combating the aggressor. Consequently, if other men of science join their efforts to those of the U.S.S.R., the enemy will be defeated all the sooner, and the menace threatening the world will be averted.

Prof. T. O. Lysenko, well known for his work on the process of vernalization of seed, said that true science directs its creative efforts to the discovery of the laws of Nature, to mastering and directing these laws for the benefit of social welfare. On the basis of the teachings of Charles Darwin, Soviet men of science have achieved advances in the planned alteration of the nature of plants important for agriculture. They have created remarkable new varieties of plants and animals.

Present-day German men of science pervert and defile biological science. The Nazi racists distort biological science in order to give a so-called 'scientific basis' for the Nazi theory of higher and lower races, for the ruthless extermination of millions of people.

Scientific discoveries can improve the living conditions on this earth. Bloodthirsty Nazism, however, does not set itself the aim of making life happier and easier by conquering the forces of Nature for the service of man, as can be done through the medium of science. Its aim is to devastate the earth by robbery and violation.

The true men of science, biologists of the United States, Great Britain, the Soviet Union, who respect humanity and its creations, do not defile the science of biology, do not use it in order to enslave humanity. With their scientific work, they help humanity to make better and better use of natural resources . Modern science is inseparable from democracy, and we must do our part in liberating humanity from Fascist tyranny.

Prof. A. E. Fersman described the Soviet Union as a country stretching from polar islands to the tropics, reaching heights of more than seven and a half kilometres, and with valleys lying hundreds of metres below the sea-level, with deserts and stretches of land of permanent frost and ice, of more than ten million square kilometres, a vast country inhabited by the greatest variety of nations, speaking a hundred and fifty different languages, with their national cultures, habits and ways.

For many years it was desolate and unexplored. More than half of it had never been investigated by geologists or geographers. Only fourteen kinds of metals out of the ninety elements of the Mendeléeff table were extracted from its earth. The plants of its tropics were growing wild.

But the country has risen to new heights during the last twenty years. Tens of thousands of scientific expeditions have carefully explored its unknown parts. During this last quarter of a century, the first geological map of the U.S.S.R. was made, and during these years about 75,000 new fields where useful ores could be extracted were found. The amount of coal resources known increased ten times, that of iron ore thirty-three times, copper and lead more than ten times. Many of these ores have never been extracted before. Mendeléeff's table has been practically covered by the variety of our extractions.

The rich soil, too, was explored. Agriculture developed all over the country, in the north, in the deserts of middle Asia. A new geography was started in the country. A network of railway lines was covering it—connecting the industrial centres with the far-away southern Urals, the heights of the Altai, the rough forest district of the Pechora. It was a grand picture of peaceful labour, transforming the earth by human reason and scientific work.

Now this work of conquering the forces of Nature has been crudely interrupted by the wild aggression of barbarism. Soviet science has switched over, and turned its powerful knowledge wider, fuller still for the protection of the Soviet country. War not only requires more raw materials. It also requires thousands of new materials for defence work. It opens up a wide field of activity to all geologists and other men of science. Then, when Fascism is smashed, science will again return to its peaceful course, and will place the fruits of its labour at the disposal of a liberated world.

Prof. A. N. Frumkin spoke in the name of all Soviet chemists. Among the weapons with which Fascist Germany is attempting to strengthen the legend of its invincibility, an important part is played by the high level of German chemistry. Without doubt, the development of chemistry and chemical industry are among the most essential factors on which modern warfare depends. At the beginning of the War of 1914–18, Germany occupied undoubtedly the first place in chemical industry, the high level of which helped her to a great extent to overcome the difficulties caused by the blockade. However, in spite of such great achievements as the development of the production of synthetic ammonia, etc., the chemical industry in Germany was unable to avert the exhaustion of its resources and the final collapse.

In the period after the War, there was a strong development of chemical industry in the United States on the basis of the oil industry. Apart from this, the achievements of German chemical industry were largely due to the high level of scientific research. This basis of scientific research was broken up by the decline of German science when Nazism came to power.

In the period between the War of 1914–18 and this War, German chemical industry, which was then on a technical level much superior to that of Tsarist Russia, was developed. In spite of this, we can be sure that if chemistry was unable to save Germany in the War of 1914–18 it is still less able to save it now. The Soviet chemists have been able to evolve a number of new and important methods of production. At the present moment, they are mobilizing all their strength to help in the struggle against Fascism. The Soviet chemists will collaborate with the men of science in Great Britain and the United States who signed the appeal to fight Fascism.

Prof. Frumkin called on men of science throughout the world to use their knowledge for the invention of new methods in the fight against Fascism. In the face of the Fascist attack there can be no place for 'science for the sake of science', for 'science which must remain neutral'.

The Soviet men of science then issued an appeal to all men of science, the substance of which was as follows: "Soviet scientists gathered at the Anti-Fascist meeting in Moscow appeal to scientists of the whole world to unite their forces against Hitlerism, the greatest enemy of culture and science. By participating in the war of our country against Fascism we are endeavouring not only to do everything within our power to expel from our territory the Fascists who have been inflicting unheard of and bestial tortures on our citizens, but also to help in establishing a democratic life for all peoples and to come to the aid of science and culture now threatened by Fascism. This menace of Fascism hanging over the whole world seeks to destroy freedom, civilization and all scientific progress.

Hitler's vandals have closed down the centres of culture in the countries which they have occupied. Universities and schools have been closed in Belgium, Norway, Holland, Latvia, Lithuania, Poland, Yugoslavia, Greece and Czechoslovakia. Fascist reaction has stifled scientific thought in France. Fascism has defiled science. In the place of the power of reason the Fascists have proclaimed the power of brute force, ignorance and base instincts. In place of biology, the majestic science of the laws of life, the Fascists invented their inhuman racial theory, with the object of justifying their domination of the whole world. For sciences which foster greater unity among peoples and better mutual understanding, such as geography, ethnography and history, Fascism has substituted so-called geo-politics, with the sole aim of justifying Germany's right to predatory invasion and the enslavement of other peoples. Fascism has replaced the humanism characteristic of the spiritual development of peoples by the creed of eternal war and progressive marasmus, by depravity, the enthronement of darkest reaction and the mass murder of the weak, the old and the infirm. Fascism is a deadly menace to culture and science which are most dear and precious to us. In their common work for the conquest of Nature, scientists throughout the world pay the greatest attention to the furtherance of culture and the welfare of the human race, whereas Fascism utilizes the achievements of modern science and its technique for destruction and extermination.

"Our scientific work has always been closely related to the requirements of the peoples of our country, which coincide with the interests of the whole of humanity. Our scientists have always put their work at the disposal of our country in making available its immense natural resources and developing its national economy. The scientific development of our national economy permitted the creation in twenty years of large-scale industry and a reorganized agriculture, which has increased the standard of living of all the peoples of the Soviet Union.

"Our country grew in strength as a result of the collaboration of all the nationalities inhabiting the Soviet Union. By the laws of our constitution all nationalities have equal rights and are equally respected as members of our large Soviet family. Our scientists study the history of all peoples of the Soviet Union, study their folk-lore and enrich Russian national culture. This work has fostered the unity of our people and their mutual respect for each other's culture.

"We Soviet scientists are convinced of the final victory over Fascism and its complete annihilation. We consider that the mutual understanding and respect of all nations, based on equality and the independent culture of each country, is the basis for their collaboration.

"We appeal to the scientists of the whole world at a time when the Soviet people have to bear the brunt of Hitler's war machine, when our towns are being destroyed and our people subjected to plunder and torture, at a time when the question of the existence and liberty of the peoples of the Soviet Union, Great Britain and the United States are being fought out on our battle-fields.

"All people interested in culture and science must unite to prevent Hitler from destroying the nations one by one."

ACTIVITY OF CARBONIC ANHYDRASE WITHIN RED BLOOD CORPUSCLES

By Prof. D. Keilin, F.R.S., and Dr. T. Mann
Molteno Institute, University of Cambridge

CARBONIC anhydrase, the enzyme which catalyses the reversible reaction $H_2CO_3 \rightleftharpoons CO_2 + H_2O$, is present in a large concentration in the red blood corpuscles[1], the gastric mucosa[2,3,4] and the pancreas[5] of vertebrates, especially mammals. The enzyme plays a very important part in the carbon dioxide transport by the blood, and its activity is directly or indirectly linked with the reactions involved in the acid-base equilibrium in the body.

It was shown recently that carbonic anhydrase is a zinc-protein compound where zinc forms the active part of the enzyme molecule[6,7]. Although carbonic anhydrase is present in mammalian erythrocytes in a very large concentration (namely, 0·21 gm. of pure enzyme per 100 c.c. of erythrocytes) the activity of this enzyme cannot be detected on intact blood cells by applying to them the standard manometric or colorimetric methods. In fact, the entire study of this enzyme, including that of the kinetics of the reactions it catalyses, has so far been carried out either on laked blood or on hæmoglobin-free enzyme preparations[1,7,16]. On the other hand, the small activity exhibited by the corpuscles in manometric experiments carried out under certain conditions[8] cannot definitely be ascribed to this enzyme as no control experiments were done under precisely the same conditions on corpuscles treated with one of the inhibitors of carbonic anhydrase.

In the present article we propose to describe a simple spectroscopic method by means of which the catalytic activity of carbonic anhydrase within the corpuscles can be easily demonstrated and studied quantitatively. This method is based upon the following facts:

(1) Hæmoglobin within the red blood corpuscles can easily be oxidized to methæmoglobin without affecting the integrity of the cell walls.

(2) Methæmoglobin can act as an indicator[9,10] changing its colour and the pattern of its absorption spectrum with the change of pH from 6·5 to 9·5.

(3) The change from acid to alkaline methæmoglobin within the corpuscles can easily be observed[11] by treating them with alkaline phosphate or carbonate solutions. The reverse reaction can be seen by treating the alkaline cells with carbon dioxide or acid phosphate solution.

(4) The velocity of these changes can be determined spectroscopically with great precision.

(5) Carbonic anhydrase is strongly and reversibly inhibited by sulphanilamide[12] which rapidly penetrates within the corpuscles and which, unlike other inhibitors of carbonic anhydrase (such as potassium cyanide, hydrogen sulphide and sodium azide) does not react with methæmoglobin.

The catalytic activity of carbonic anhydrase within the corpuscles can, therefore, be determined by comparing the velocity of the changes from acid to alkaline methæmoglobin and *vice versa* in presence and in absence of sulphanilamide.

Preparation of Methæmoglobin Corpuscles

The red blood corpuscles of 100 c.c. of defibrinated horse blood separated from serum are washed with 0·9 per cent sodium chloride. 50 c.c. of washed corpuscles are mixed with an equal volume of isotonic solution of sodium nitrite (1·06 per cent), left standing five minutes, washed four times in 200 c.c. of 0·9 per cent sodium chloride and suspended in 100 c.c. 0·9 per cent sodium chloride. The suspension A thus obtained is composed of brown cells showing a distinct absorption spectrum of acid methæmoglobin.

On addition of alkaline phosphate or of carbonate solution to this suspension its colour turns from brown to red and the absorption spectrum of acid methæmoglobin is gradually replaced by that of alkaline methæmoglobin.

Spectroscopic Study of Methæmoglobin Corpuscles.

The changes in the absorption spectra of these corpuscles were followed at 17° by a method devised previously for the study of methæmoglobin[13], the observations being carried out by means of a microspectroscope ocular attached to a microscope (Fig. 1). 2·5 c.c. of suspension A are mixed with 150 c.c. 0·9 per cent sodium chloride forming a dilute suspension B. 3 c.c. of B are put in the flat-bottom vessel g 16 mm. in diameter immersed in a small glass water-bath h placed on the microscope stage. The depth of suspension in g is therefore $\frac{3}{3 \cdot 14 \times 0 \cdot 8^2} = 1 \cdot 5$ cm. The standard suspensions of acid and alkaline methæmoglobin corpuscles are introduced into compartments e_1 and e_2 of a double-wedge trough 15 cm. long and 2·3 cm. wide (inside measurements). These suspensions

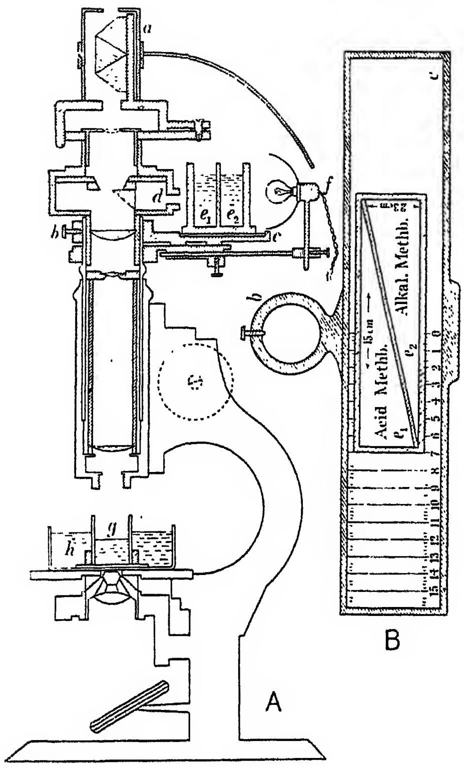

Fig. 1.

are prepared in such a way that in a depth of 2·3 cm. they match completely the 1·5 cm.-deep suspension of vessel g. For this purpose 1·63 c.c. of stock A is suspended in 120 c.c. 0·9 per cent sodium chloride forming stock C; to 60 c.c. of this suspension is added 15 c.c. of $M/5$ phosphate solution of pH 6·4 forming the suspension for the side e_1 of the trough, to the remaining 60 c.c. of stock C is added 15 c.c. of $M/5$ sodium bicarbonate in $M/10$ sodium hydroxide solution forming the suspension for the side e_2 of the trough. The trough is placed in front of the side aperture d of the micro-spectroscope on a brass platform c attached by means of a ring b to the microscope tube. The position of the trough is read on a scale fixed to the platform and covered by a sheet of glass along which the trough can be easily moved. The vessel g is illuminated in the usual way, while the trough is illuminated by a 4-volt filament lamp f. The intensities of both lamps can be regulated by means of independent rheostats. While keeping the illumination of the two spectra equal by adjusting the rheostats, the trough is moved along the platform until the position is found where the intensities of the absorption bands of the spectra obtained from the suspension in g and from that in the trough are equal. At the beginning of the experiment the suspension in vessel g received 0·1 c.c. of $M/5$ phosphate solution pH 6·4 and the position of the trough is adjusted and read on the scale. The vessel g then received 0·1 c.c. $M/5$ sodium carbonate which is rapidly and thoroughly mixed with the suspension of corpuscles. The trough is moved along the platform towards the left and its positions at which both spectra match are read from the scale at intervals of 10, 15, 20 seconds or longer if necessary. The percentage of alkaline methæmoglobin formed is obtained by multiplying the reading (in centimetres) of the scale by 100/15. Thus if the reading is 6·5 cm. the alkaline methæmoglobin formed will be 43·2 per cent.

Concentration of sulphanilamide	Time for 50% change (sec.)
0	34
$5 \times 10^{-6} M$	52
$5 \times 10^{-5} M$	75
$5 \times 10^{-4} M$	210

The experiments described above were followed by others in which a small amount of sulphanilamide ($5 \times 10^{-4} M$ final concentration) was added to suspension g one or two minutes before the addition of carbonate. The results of a typical experiment in presence and in absence of sulphanilamide, which are shown in Fig. 2, clearly demonstrate the catalytic activity of carbonic anhydrase within the red blood corpulscles. The effect of other concentrations of sulphanilamide which was determined by the time (in seconds), required for 50 per cent change is shown in the accompanying table.

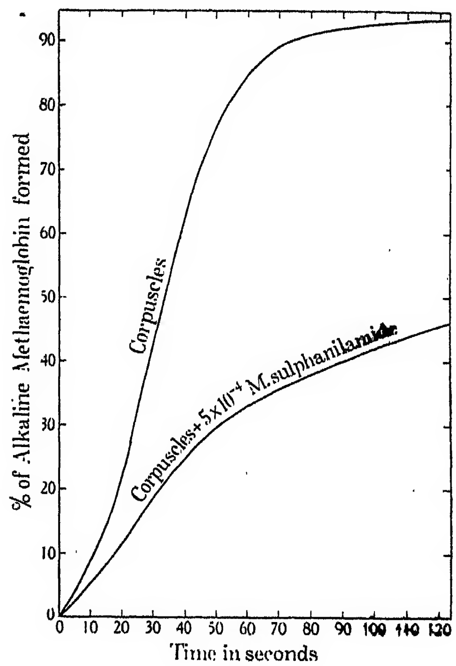

Fig. 2.

That no laking takes place during all the experiments described in this article is clearly demonstrated by the colourless supernatant fluid left after centrifuging off the corpuscles in suspensions *g*.

Chloride Shift

The method described above affords also an easy approach to the study of Hamburger's chloride shift. It is well known that the red blood corpuscle is impermeable to metallic cations, so that when, for example, bicarbonate ions move into or out of the corpuscle, the ionic equilibrium on both sides of the membrane is re-established by the movement of chloride ions in the opposite direction, which is in accordance with Donnan's membrane equilibrium theory[14,15,16,8]. The available chloride ions in the corpuscle may therefore become the limiting factor in determining the amount of another anion which can pass through the membrane[16]. On the other hand the concentration of the chloride ions in the corpuscles can be greatly reduced by washing them in an isotonic phosphate solution[8]. It is, however, important to note that washing the corpuscles in acid phosphate makes them impermeable also to anions. Thus, acid methæmoglobin in such corpuscles does not turn alkaline even after prolonged incubation in an isotonic mixture of sodium chloride and sodium carbonate and yet on plasmolysis methæmoglobin becomes completely alkaline. The simplest way for removing chloride ion from corpuscles without affecting their permeability is to wash them in an isotonic alkaline phosphate solution or in a solution of $M/5$ sodium bicarbonate in $M/10$ sodium hydroxide. The corpuscles washed in this way and suspended in 12 per cent sucrose solution show about 85 per cent alkaline methæmoglobin. Such corpuscles were used for spectroscopic experiments carried out as above, except that acid phosphate is now added to alkaline corpuscles and the velocity of the formation of acid methæmoglobin is recorded. The results of these experiments summarized in Fig. 3 clearly show that the addition of acid phosphate alone produces only a slow and incomplete change from alkaline to acid methæmoglobin. A rapid and complete formation of acid methæmoglobin takes place, however, if together with the same amount of acid phosphate a small amount of sodium chloride is added to these corpuscles. The fact that this rapid reaction is also inhibited by sulphanilamide shows that also the chloride shift depends on the activity of carbonic anhydrase. Cl′ in this reaction can be replaced by Br′ and I′.

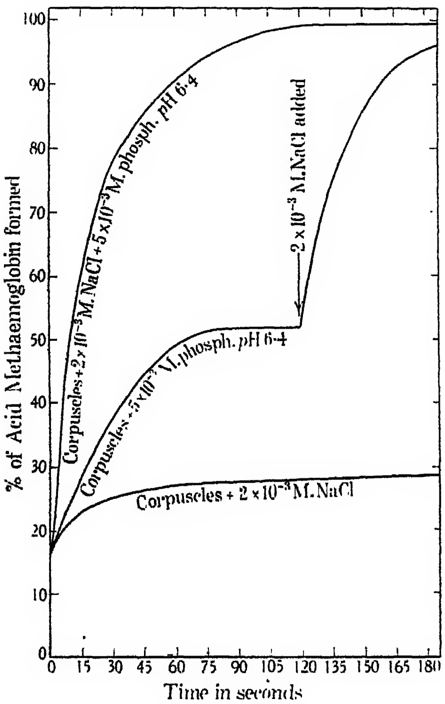

Fig. 3.

The results obtained spectroscopically, which are moreover in agreement with previous views on the subject[8,16], are corroborated by direct estimations of chloride diffusing from the corpuscles into the surrounding medium. For this purpose methæmoglobin corpuscles or untreated red blood corpuscles are washed in 6 per cent glucose solution. 2 c.c. of these corpuscles are suspended in 11 c.c. of isotonic glucose solution, kept for thirty minutes at room temperature and cooled to 0° C. The cold suspension is treated then with 1 c.c. of $M/5$ sodium bicarbonate in $M/10$ sodium hydroxide and the corpuscles are rapidly centrifuged within two minutes, leaving 10 c.c. of supernatant fluid *D*. The second sample of 2 c.c. of corpuscles is suspended in 11 c.c. of 6 per cent glucose solution containing 70 mgm. sulphanilamide and then treated in the same way as the previous sample, giving finally 10 c.c. of supernatant fluid *E*. The third 2 c.c. sample of corpuscles is also suspended in 11 c.c. of 6 per cent glucose and, without previous treatment with carbonate, the corpuscles are centrifuged off, leaving 10 c.c. of supernatant fluid *F*. The estimation of chloride in these three fluids, carried out in the usual way[17,18], gave the following results: sample *D* obtained in absence of sulphanilamide contained 2·5 mgm. chloride, sample *E* obtained in presence of sulphanilamide contained only 1·63 mgm. chloride, and the untreated sample *F* contained 0·3 mgm., chloride. While a delay in centrifuging up to fifteen minutes has no effect on samples obtained in the absence of inhibitor, those in presence of sulphanilamide after four and fifteen minutes delay in centrifuging contained respectively 1·9 mgm. and 2·5 mgm. chloride.

All this clearly shows that sulphanilamide, as would be expected, delays the reactions which induce the 'chloride shift'.

The main results of our investigation consist, therefore, in the direct spectroscopic demonstration: (a) of the activity of carbonic anhydrase within red blood corpuscles, and (b) of the link between this activity and the chloride shift which forms part of the mechanism controlling the acid-base equilibrium in blood.

OBITUARIES

Mr. A. H. Smith, C.B., F.B.A.

MR. ARTHUR HAMILTON SMITH, who died on September 27, was best known among classical scholars and archæologists by his Catalogues of Classical Sculptures and of Engraved Gems in the British Museum, but in unobtrusive ways he rendered valuable service to ancient art and archæology.

He was born near Glasgow on October 2, 1860, the son of Mr. Archibald Smith. He was a scholar of Winchester College and of Trinity College, Cambridge. In the Classical Tripos Part II he was placed in the first class in 1883. In 1886 he entered the British Museum as an assistant in the Department of Greek and Roman Antiquities, at a time when the great reorganization initiated by Sir Charles Newton had reached the stage at which the antiquities could be catalogued and described. To Arthur Smith were assigned the "Catalogue of Engraved Gems" (1888), a modest but very useful book, and the "Catalogue of Sculpture" in three volumes and on a more extensive scale, which occupied the greater part of his years of museum service. He also wrote the popular "Guide to the Department of Greek and Roman Antiquities" to which many owe their first introduction to ancient art in general. Unofficial but closely related to his departmental work was his editing of the first two fascicules of the "Corpus Vasorum" for Great Britain, an early contribution to a vast project, of French origin, which needed judgment and industry such as his in its first rather experimental stages. He had already contributed in an unusual and interesting way by devising a 'cyclograph' in which a cylindrical or conical object was carried forward along the circumference of a circle, and at the same time rotated in front of a photographic camera at the centre, so that a record of its curved surface was made on a flat print. The procedure was that of the rotary printing press; though unless the surface was approximately cylindrical there was distortion, and if it was convex in a second direction there was loss of focus also. To demonstrate his invention Smith published a series of "White Athenian Vases in the British Museum" with collotype plates; but the device has not been much used, though it was awarded a gold medal at the Berlin Photographic Exhibition in 1896.

Smith's learning and sound judgment were well employed on the catalogues of the Lansdowne, Yarborough, and Woburn Abbey Collections, where there was a good deal to add to the pioneer descriptions of Michaelis. He wrote a historical account of "Lord Elgin and his Collection", and a critical study of the "Sculptures of the Parthenon".

Most of Smith's work was naturally in London, but when the Turner Bequest enabled the British Museum to make excavations in Cyprus, Smith was for a while in charge at Amathus in 1893–94, and at Enkomi near Salamis in 1896, and he took his share in the publication of the finds (1899). But these lay outside his special interests, and for Enkomi there was the further drawback of the preposterous chronology favoured by his chief.

In 1909 Smith became keeper of his Department, and on retirement in 1925 received the C.B. He was a fellow of the British Academy, and of the Society of Antiquaries, president of the Hellenic Society, 1924–29, and for long the editor of its *Journal*. For many years he was treasurer of the British School of Archæology in Rome, and chairman of its Faculty of Archæology, History, and Letters. In 1928–30 he went to Rome as its director, and returned in an emergency in 1932. His administrative experience and sound knowledge of his own subject were invaluable here, but he had little experience of students or academic life. Another external interest was in Byzantine art, and he was one of the founders and managers of the Byzantine Research Fund, later administered by the British School at Athens.

His unassuming manner and hesitancy of utterance did not conceal his kindly and humorous outlook on men and things, and his knowledge and judgment were always at the disposal of others.

JOHN L. MYRES.

WE regret to announce the death of Prof. R. B. Wild, emeritus professor of materia medica and therapeutics in the University of Manchester, aged seventy-nine.

NEWS AND VIEWS

The Prospect Before Us

On p. 477 of this issue appears an argument which attempts to explain the behaviour of present-day Germany. On p. 490 are published extensive abstracts from the messages sent by Russian men of science to others in democratic countries. These messages constitute first a direct appeal to all decent men; but they go farther than that. They tell of the progress of science in post-revolutionary Russia. As shown in an article on "The Rise of Science in Russia" (Nature, September 27, p. 357), science in that country was initiated chiefly by men invited for the purpose from other more progressive countries. Science of the past quarter of a century in the U.S.S.R. has been developed by her own sons, as shown in the two articles "Present-Day Science and Technology in the U.S.S.R." and "Biological Science in the U.S.S.R." (Nature, September 27, pp. 360 and 362). But one of the faults of modern science in the U.S.S.R. has been its intense nationalism, though that great country has certainly shown signs of veering away from this drawback during the past ten years. The tendency to keep her scientific discoveries to herself has been too evident in the U.S.S.R., so it is no cause for surprise that many other men of science have questioned, even suspected, Russian scientific claims in the recent past. That cause for complaint is, we are glad to see, fast disappearing. For example, glancing through the correspondence columns of Nature over a period of the past ten years, we see an increase in Russian contributions which runs concurrently with a corresponding decrease in contributions from Germany. These naturally inspire the questions: Where is it all leading: what is the prospect before us? Looking back, we must realize that the U.S.S.R. had the despotic Tsarist regime behind it; small wonder that to-day they are 'realists'. On the other hand, present-day Germany with her science in chains has a past of great scientific achievement based on the best traditions.

We might say there are at least three sources of inspiration for a man of science as such—fear, gain, service. Who can doubt that present-day Russian men of science are inspired by service—service to their own country? Nevertheless, we feel that in the past they have kept themselves too much to themselves. Their science has been directed solely to their own needs: as M. Maiski recently stated, Russian science is planned; "there is no place in the U.S.S.R. for pure science"—a rather unfortunate statement, since we do not believe that pure science has been altogether taboo in the U.S.S.R. Nazi German so-called science is, on the other hand, inspired solely by fear or gain—by fear of political or military overlords or by the desire for Nazi favours or personal profit. From the designing of murderous weapons of war to the postulation of absurd racial theories, it is clear that little true science exists in that unhappy country. And all this went on before war broke out—it has been going on since 1933. There has been such complete subjugation of science that what there is left must remain suspect, if not, indeed, the subject of ridicule, such as the Nazi-inspired philosophy of Stark, one of the world's greatest physicists (see Nature, 141, 770; 1938). All this makes the prospect of those concerned for the future of science one of enormous difficulty, fraught with many tough problems, but none of them insurmountable. The vexed question of pure as opposed to applied science will be one which will have to be considered with cool judgment.

Of course there are, and there will be, extremes and extremists. Even now it is often difficult to decide what is pure and what is applied. The period between a scientific discovery and its application to human society must vary within very wide limits. If planning aims at reducing that period to the minimum, then planning is good; but where the period cannot be envisaged at all, as in the more theoretical sciences and philosophies, we must not allow the extreme materialists to eject such branches of science from the programmes of the future. The ultimate prospect must be a thorough study of the impact of science on society. That cannot be undertaken under any form of duress; there must be complete freedom. But the extremes must be brought to book. Those who will look only at such sciences which can show immediate application must broaden their views. On the other hand, there are those who deliberately hold themselves aloof from any effect their science may have on human society; they are, to say the least of it, selfish, though how often has one heard them claim that they are the only champions of scientific freedom. Science, planned but free, must be the ultimate aim. But the immediate aim is more urgent. This is no time for half-measures and compromise; neither is it the time for ideals. The truth is, Russian men of science have appealed for scientific collaboration with the immediate aim of crushing Nazi barbarism. Men of science in all free countries must respond to that call. That aim demands an immediate unity of purpose and action in smashing aggression; the complete unification of world science must be left to times less terrible and urgent, though not necessarily until the end of the War.

Arrest of French Men of Science

On October 19, the Vichy Government confirmed the arrest in Paris by the German authorities of five prominent professors of the University of Paris, namely: Prof. E. Borel, professor of mathematical physics; Prof. P. Langevin, professor of experimental physics in the Collège de France; Prof. L. Lapicque, professor of physiology; Prof. C. Mauguin, professor of mineralogy; Prof. A. Cotton, professor of physics. According to some sources they are

charged with spreading de Gaullist propaganda, according to others with pro-British sentiments, while some newspapers lay emphasis on the fact that the political activity of Profs. Langevin and Borel has been well known since the time of the Front Populaire. Prof. Langevin was imprisoned earlier this year and released later for health reasons.

According to *The Times*, these arrests are causing bewilderment in Haute Savoie, as even the former political opponents of these men of science cannot believe that they have been arrested on account of their personal views. Some light may be thrown on the affair by a recent article published by M. Laval in his newspaper the *Moniteur du Puy-de-Dôme*. In this he says that now that Germany has conquered her enemies, who are those of France, the latter must conquer her disorder and errors and hold out her hand to Germany. Laval then declares that all French persons who are still imbued with anti-German prejudice should be at once dismissed from public offices. He adds that this prejudice now exists, mainly among the intellectuals, where it may be regarded as a remnant of anti-Fascism. In Haute Savoie the view is expressed that the above 'ultimatum' by Laval inspired the Vichy Government to act accordingly, as the French authorities certainly lent a hand in the arrest of the Paris professors.

German Persecutions in Poland

WE have received from the Association of Polish Professors and Lecturers in Great Britain (Polish Research Centre, 32 Chesham Place, London, S.W.1) a letter protesting against the second series of persecutions by the Germans of Polish men of science and others since the War began. The fury of the first German attack on Polish science and culture was raging in November 1939, when 180 professors and assistants of the oldest Polish university, that of Cracow, were deported "as criminals" to the concentration camp at Oranienburg. Now we are witnessing the second German attack on Polish science, carried out in the newly occupied territories and aiming at completing the destruction. On occupying Lwow the Germans executed Prof. C. Bartel, professor of mathematics in the Lwow Technical College (see NATURE of October 4, p. 402); they also arrested sixty other professors, among them a number of elderly men. The German persecutions are an integral part of the methodical campaign aiming at the total destruction of Polish culture. All the Polish universities, technical and agricultural colleges, commercial academies, all research institutes, all scientific societies, including the Polish Academy of Sciences, have been closed by the Germans. The same fate has befallen all secondary schools. The scientific apparatus and the equipment of laboratories have been transported to the Reich. The Polish museums were and still are being looted. Publication of books and periodicals as well as of independent newspapers has been suspended. Monuments which showed the artistic culture of the nation have been pulled down and destroyed.

All the professors of the University of Poznan have been expelled, deprived of all their personal possessions and left starving. Some of them, headed by Prof. Bronislaw Dembinski, honorary professor of history, have died as a result of the dreadful conditions of life to which they were exposed. Eighteen professors of the University of Cracow, among them the most prominent representatives of Polish science, have died as a result of tortures suffered in the concentration camp of Oranienburg. The professors of the Catholic University of Lublin were kept in prison for some months and some of them are still in concentration camps. Recently a number of Warsaw professors perished as victims of undeserved persecution. "To this black record of German persecutions a new page has been added—the persecutions of Lwow. Executions and concentration camps for Polish men of science—that is what the German 'crusade in the defence of civilisation' has brought with it." In view of these new German crimes which bear full witness to a total degeneration of Hitlerite Germany, we feel sure that men of science in all free countries will wish to join in this solemn protest by Polish savants in Great Britain.

Developments in Agricultural Research

THE extended field of activity and additional financial resources which have recently been granted by the Government to the Agricultural Research Council have opened the door to new developments in this branch of applied science. A large part of the Council's activities will still be devoted to co-ordinating, and advising on, the work of the various research institutes to which the Ministry of Agriculture and Fisheries and the Department of Agriculture for Scotland are making maintenance grants, and to furthering the interests of these institutes in every possible way; but it is the Council's intention to devote some part of the funds to be expended at its own discretion, for which it is answerable to the Lord President of the Council, to the furtherance of agricultural research in university departments, and to the enlargement of its own scientific staff. It is, in particular, the Council's desire to encourage both senior and junior research workers in the biological sciences to enter the agricultural field. In pursuance of this policy, the Council has established two new research units under its direct control, a Unit of Animal Physiology, and a Unit of Soil Enzyme Chemistry.

The Unit of Animal Physiology will be under the direction of Sir Joseph Barcroft, with the assistance of Mr. A. T. Phillipson and Dr. R. A. McAnally. This Unit will, by agreement with Prof. E. D. Adrian, be housed in the Department of Physiology at Cambridge, and will work in close liaison with the Institute of Animal Pathology and the Institute of Animal Nutrition. In the first instance, the staff of this Unit will devote a large part of their time to the study of ruminant digestion. The Unit of Soil Enzyme Chemistry will be under the direction of Dr. J. H. Quastel, assisted by Dr. P. J. G. Mann and Mr. D. M. Webley. By agreement with Sir John

Russell, this unit will be housed in the Rothamsted Experimental Station. Dr. Quastel and his staff will, in the first instance, be engaged mainly in the study of the influence on soil fertility of enzyme systems derived from soil bacteria, or from other micro-organisms.

Scientific Films

THE possibilities of scientific films are immense. They appeal directly to the eye, and their appeal can be reinforced by spoken or printed text. Their capabilities in representing motion enable them to illustrate processes which cannot otherwise be adequately conveyed to the mind. By the control of speed they can be used to demonstrate actions taking place too quickly or too slowly for the unaided eye to grasp; and the wide possibilities which they offer in magnification and reduction bring processes of nearly all dimensions within the compass of the screen. The mechanism of motion pictures also enables full use to be made of reversal, superimposition and stroboscopic effects in the production of scientific films. Recognition of the value of these films is leading slowly to their use in general scientific education. Another direction in which their future seems bright, although at present almost unexplored, lies in the popularization of science and in conveying in an acceptable manner some understanding of the relation of science to other forms of human work and culture. A further use of scientific films lies in various fields of research in which permanent records are required of processes in action.

Yet in the sphere of their production, scientific films have many difficulties with which to contend. Their production is scarcely a commercial proposition. They cannot effectively compete with the ordinary popular entertainment films. Also, the technique of their production calls for highly specialized and gifted talent, not likely to be attracted to the business unless the prospects are good. As a consequence, the number of institutions and organizations showing scientific films is small, and it will not expand rapidly until there is a wider selection of better films to draw upon. To promote the use of such films, the Scientific Films Committee of the Association of Scientific Workers, 30 Bedford Row, London, W.C.1, has recently issued a leaflet on "The Scientific Film", in which a summary is given of the possibilities available in the production and use of films for scientific purposes. This Committee offers its services in the selection of films and in drawing up programmes for different types of audience. Having adopted the practice of viewing scientific films as they become available, the Committee is in possession of information of considerable value to prospective users, and incidentally also to film producers. A small grant from public funds for scientific films would be of great educational worth. In its absence, the field is occupied to a considerable extent by films prepared for commercial and industrial firms, many of which are excellent in themselves, but not entirely free from bias of some kind or other. In spite of this, if full use were made of such films as are available, a great step forward would have been made.

Conditions of the Peking Man Bones

IT must always come as somewhat of a relief to the ordinary anthropologist that quite ordinary explanations are adequate to account for conditions to which more romantic solutions have been attached. It is, therefore, with some sense of thankfulness that we learn that Prof. F. Weidenreich has decided ("The Extremity Bones of Sinanthropus Pekinensis." *Paleontologia Sinica*. New Series D. No. 5. Peking: Geol. Survey of China) that the breaking of certain limb bones of Sinanthropus in the caves of Choukoutien has been due to the activities of the hyæna rather than, as he formerly postulated, to a series of cannibal feasts on the part of Peking man. He still believes it necessary, however, to invoke the assumption "that Carnivores and man competed in the breaking of bones both human and animal". May it not be possible that Carnivores have also produced the broken condition of the skulls? In another way this latest publication on Sinanthropus is pleasing, for it makes it quite evident that the Peking man's femur "is identical with the human femur in size, form, proportions, and character of the muscular markings, differing in all these features from the anthropoid thigh bone in much the same way as any human femur". It is also certain that his humerus is exactly as it is in modern man: and the same applies to the only two other limb bones so far discovered—the clavicle and the os lunatum. For some, it may be rather a descent to earth, but for the science of physical anthropology it is surely a gain that we are at length permitted to know that Sinanthropus possessed the most ordinary and typically human limb bones, and that he walked as upright as the best of us.

Scottish Rock Carvings

THE September issue of *Antiquity* contains a note by Prof. V. G. Childe on some finds of rock carvings in Scotland. Two of these are in Argyll and one in Midlothian. The first photograph shows a hind engraved in outline from Gleann Domhain, Argyll. The figure is in profile, two long ears appearing side by side and only two legs. There is a blunt and intriguing tail and an eye is shown. The style of this engraving reminds one forcibly of the Arctic culture rock drawings of Norway and Sweden (Scandinavian Art Group I). Prof. Childe's second photograph is of a fish which has been found near Roslin, Midlothian. This carving is not merely an outline but rather appears to be done in low relief and it, too, might have links with Scandinavia. Not so the third find, of a stylized, rather shapeless, animal figure from Dunadd, Argyll, which is very different in style from either of the other two and might easily belong to a different and later culture group.

The influence of the Scandinavian Arctic Culture—itself probably an offspring of the northern Mesolithic civilization—on eastern Britain has long been suspected, suggested by certain finds of stone implements as well as by the engraving on a piece of flint crust which was found in the earliest levels at Grimes Graves. The new Scottish discoveries, especially the Gleann Domhain hind, powerfully reinforce this

notion, and even go farther with the inference that the Arctic Culture not only reached our eastern coasts, but indeed, penetrated considerably inland—at least in the northern areas of Britain.

Corrosion in Steel Chimneys

In the last twenty years, developments in the size and efficiency of boiler plants have led to the abandonment of huge masonry chimneys serving a number of boilers in favour of a separate chimney for each boiler. In *Engineering* of September 12, Mr. A. V. Staniforth shows that this has been brought about not only for the sake of the advantages accruing during overhaul and repair from such sectionalizing, but also because the very large units, now common, call for much larger chimney areas. The normal chimney was built of lapped riveted plates, but corrosion was found to be very rapid. At one large power station, five steel stacks, each 7 ft. 6 in. in diameter by 80 ft. high, constructed of $\frac{3}{8}$-in. mild steel plates riveted together, had corroded away in parts to paper thickness in five years in spite of annual internal and external cleaning and painting. In all cases the corrosion had become most serious at, and had undoubtedly started from, the joint laps and rivet heads, and was most marked in the upper parts of the chimney. The temperature of the gas entering the chimneys was about 250° F., at which the steel temperature, particularly near the top of the chimney, often fell below dew point, especially during the colder periods of the year. This caused the deposition of moisture, sometimes increased by rainfall. Combining with the sulphurous gases, it formed sulphurous acid which attacked the steel. The moisture running down the chimney collected along the joint laps and rivet heads, and thus was responsible for the especially severe corrosion at these points.

In solving the problem it was considered desirable first to eliminate the points of corrosion, namely, the lapped joints and rivets, and secondly to find some type of lining which would afford adequate protection to the steel plates. Modern developments in electric welding suggested the use of welded butt joint chimneys, which are easy to construct and give a smooth parallel barrel free from all foci for corrosion. In protecting the interior of the chimney plates from corrosion, asbestos sheeting of certain types was found reasonably suitable. The five steel stacks mentioned above were replaced by lined stacks in 1935, and five years later a section of the lining was removed from one of the stacks. It was then found that no corrosion of any kind had taken place and that the mill scale was still on the steel. Another advantage is that the heat-insulating effect of the lining cuts down the heat loss, and so the period during which the temperature of the steel falls below the dew-point is very much reduced. Tests showed that with a gas temperature of 290° F., the outside temperature of an unlined stack was 210° F., while the lined stack had an outside temperature of 150° F. The lower outside temperature of the stack reduces considerably the cost of maintenance of the outside of the chimney by increasing the life of painting.

Health of Hawaii

ACCORDING to the report of the Board of Health of Hawaii for the fiscal year, the lowest death-rate ever recorded for these islands, namely, 7·18 per 1,000 inhabitants, occurred in 1940. There were 3,025 deaths in a population of 423,332, the chief causes being heart disease, cancer, congenital malformation and disease, tuberculosis and nephritis. Pneumonia dropped from the second to the eighth leading cause of death, a fact which was attributed to the use of serum and sulphapyridine, which were distributed free to practitioners for the medically indigent. The birth-rate was 22·62, as compared with 21·79 in 1939. An outbreak of 101 cases of infantile paralysis with 10 deaths occurred during the year. The death-rate from tuberculosis was 63·2 per 100,000, the lowest on record. There were 56 cases of typhoid fever, which were attributed principally to carriers; no cases were traced to milk or to the potable water. There were 77 cases of typhus with 1 death. There were 1 case of human plague which ended fatally and 47 cases in rodents as compared with 129 the previous year.

Announcements

THE Lister Medal for 1942, which is given in recognition of distinguished contributions to surgical science, has been awarded to Prof. Evarts A. Graham, professor of surgery in Washington University, and he will deliver the Lister Memorial Lecture in 1942, or later, under the auspices of the Royal College of Surgeons of England. This is the seventh occasion of the award, which is made by a committee representative of the Royal Society, the Royal College of Surgeons of England, the Royal College of Surgeons in Ireland, the University of Edinburgh, and the University of Glasgow.

IT has been decided not to award any Nobel Prizes this year.

THE Tenth International Ornithological Congress, which was to have been held in the United States in 1942, has been indefinitely postponed.

A MALARIA survey of Trinidad was recently begun under the supervision of Dr. Mark F. Boyd and Dr. W. G. Davis of the Rockefeller Foundation.

MESSRS. ROWNTREES, of York, have made a grant to Dr. F. C. Happold, reader in biochemistry in the University of Leeds, of £150 a year for two years for research work on nutritional problems.

ERRATUM.—It was stated in NATURE of October 18, p. 457, that Dr. E. Kodicek, who contributed a paper on post-war relief at the recent British Association meeting, was formerly lecturer in psychology in the University of Prague; this is incorrect. He held the position of head of the Department for Vitamins and Hormones at the University Clinic, Charles University, Prague.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

Chromosome Breakage and Sterility in the Mouse

SNELL[2] has shown that the offspring of X-rayed male mice produced before the onset of complete X-ray sterility contain a certain proportion—depending on the dosage—of semi-sterile individuals, which when outcrossed to unrelated animals throw litters of reduced size. This semi-sterility could be shown to be inherited and was assumed to be due to an interchange of segments between non-homologous chromosomes induced by irradiation. The genetical behaviour of semi-sterility was extensively studied in breeding experiments[2,3,1]. A great

a b

PHOTOMICROGRAPHS SHOWING THE ASSOCIATION OF FOUR CHROMOSOMES DURING THE MEIOTIC DIVISION IN MALES OF LINE A (a) AND OF LINE T (b).

number of valuable data on zygotic lethality during the early embryonic development was also collected by various investigators[4,5,6,10], yet so far no cytological analysis of chromosome behaviour in interchange heterozygotes has been attempted. With this programme in view, three semi-sterile lines, A, B and T, each from a differently treated male, were produced by us using the X-ray technique of Snell.

The presence of the interchange was usually determined by the breeding test. Interchange B, however, was first identified cytologically in a number of mice and later verified by the breeding test. The breeding results so far obtained show that the average litter size produced by outcrosses of the semi-sterile individuals in line A is 2·6 (11 litters), in B 4·2 (15 litters), and in T 3·6 (44 litters). In the related but untreated control lines it is 7·7. Spermatogenesis in the interchange hybrid has shown that an association of four chromosomes is regularly present during meiosis (Figs. a and b). In lines B and T it is represented as a chain of four chromosomes, and in A it usually forms a ring. The association of four in an interchange hybrid, if metaphase orientation is at random, will lead to the production of six kinds of sperms in equal numbers; four out of the six will have one chromosome segment in duplicate, another segment not represented at all. Fertilization of eggs with unbalanced sperms will result in the production of 66·7 per cent defective zygotes. These expectations have been confirmed experimentally in plants and Drosophila. We can confirm it for line T of our mice, the only line in which a sufficiently high number of individuals has been tested as yet. Out of twenty-six animals tested eleven proved to be fertile and fifteen semi-sterile, which is a good agreement with expectation, namely, 8·7 fertile and 17·3 semi-sterile.

The cytological analysis of interchange hybrids of lines A, B and T has shown clearly that the different degree of sterility is determined by the frequency of multivalent association and by the type of orientation of the quadrivalent. The behaviour of multivalents during the first meiotic metaphase and the data of the breeding test suggest that in lines B and T a long and short segment of two non-homologous chromosomes are interchanged and that the breakage points are located far away from the centromere. In line A, on the other hand, the interchange involves larger segments with breakage points adjacent to the centromere. The high incidence of sterility in line A is due to the high frequency of non-disjunction which follows.

In line T there was a sudden increase in fertility between the first and following generations. The average litter size in F_2 (6 litters produced by one semi-sterile son of the original X-rayed male outcrossed to various fertile females) was 2·0. In F_3 22 litters produced by outcrossing 3 semi-sterile F_2 males and 4 semi-sterile F_2 females had an average size of 3·7, and in F_4 this average remained materially unaltered at 3·8 (17 litters produced by outcrosses of 4 F_3 males and 2 F_3 females). The 3 F_2 males, however, had not only a very small litter size but also failed to produce litters with several females known to be fertile, although vaginal plugs were observed in two instances showing that mating had taken place but remained unsuccessful. No offspring for breeding could be secured from these males except one daughter which did not carry the interchange. Thus the F_3 consisted only of descendants from the less sterile F_2 individuals. No exceptionally sterile individuals were observed among the F_3, the average litter sizes for each tested individual all ranging near the average for the semi-sterile group of this generation as a whole. These data indicate that, beside the segmental interchange present in all semi-sterile individuals, minor structural changes or mutations with a deleterious influence on fertility were also brought about in the chromosomes by irradiation and handed on by chance segregation to some individuals of the next generation. These additional changes are eliminated rapidly on account of the high degree of sterility they cause when superimposed on the major chromosome rearrangement.

Further experiments are in progress with the view of establishing lines homozygous for the interchanges,

and of combining the different interchanges in order to test whether there is a position effect, and to find out if some of the interchange chromosomes of the various lines are common or not. Meanwhile we may point out that there can no longer be any doubt that X-raying germinal cells in man involves the serious risk of inducing heritable sterility in the descendants owing to embryonic mortality of zygotes with an unbalanced chromosome complement.

Natural Occurrence of Polythionic Acids

IN 1937 I assisted Dr. A. L. Day in a survey of the thermal region of the North Island of New Zealand, and part of the work carried out for him was the collection of samples of the waters of the most vigorously boiling pools in the various hot spring areas. During the analyses at the Dominion Laboratory, Wellington, advantage was taken of the opportunity to examine the samples for the presence of polythionates. The method used was titration with sodium hydroxide solution after addition of mercuric chloride to the neutralized sample. The examination of seventeen acid waters from seven areas showed the presence of polythionates in only two waters, but these were from the most active springs. One was the "Black Pool" at Ruahine, near Rotorua, the largest and most vigorously boiling pool in the thermal region, and the other, the "Black Geyser", a perpetual spouter at Ketetahi Hot Springs on the slopes of Mt. Tongariro. On the authority of Mitchell and Ward, from whose book the method was taken[1], it was assumed that as the waters contained hydrogen sulphide, the only polythionate present was the trithionate. However, it has since been pointed out to me by Dr. A. Kurtenacker (private communication) that this is not correct.

The occurrence of a polythionic acid in Nature was first reported by J. S. Maclaurin, late director of the Dominion Laboratory, who in 1911 discovered pentathionic acid in the water of the lake in the crater of White Island[2]. This lake, of an area of about fifteen acres, containing 5 per cent free hydrochloric acid, was a feature probably unique in the world. Unfortunately, it no longer exists. It was drained in 1912 to facilitate the working of the sulphur deposits. It is probable that the drainage helped to bring about the landslip and steam outburst that completely changed the character of the crater. Apart from the loss of twelve lives, the cost of the work in this, and later efforts, far exceeded the value of the few thousand tons of sulphur extracted. A little scientific investigation would have indicated the exaggeration in the estimates of the amount and purity of the sulphur deposits. It is doubtful whether the present features offer the same interest to the scientific worker or tourist as those destroyed. The island is still threatened with exploitation, for it has been allowed to pass into private hands, and proposals are occasionally mooted to use the natural steam for the production of salt from sea-water. This is but one example of the regrettable lack of appreciation in New Zealand of the varied, and often unique, features of the thermal region, and there is still no move to safeguard and conserve for posterity all the hot spring areas under one control, for example as a national park.

In 1939 I spent a week on White Island, carrying out chemical and physical investigations on an expedition organized by Dr. P. Marshall. Fumaroles and steam vents are now the main type of activity, and hot springs are rare. However, at the bottom of a depression about 50 ft. deep, named "Middle Crater", there was found a vigorously boiling pool, and a sample of this was taken.

Since the previous work, methods for the complete analysis of solutions containing polythionates had become available in the book by Kurtenacker[3]. These depend on titration, with iodine solution, of the varying amount of thiosulphate formed by the reaction of the polythionates with sulphide, sulphite and cyanide. Only one litre of the water was available for analysis, and from this it was necessary to remove a large amount of ferrous iron. The analysis indicated that the water contained 170 mgm. per litre of tetrathionate ion (S_4O_6''). This amount is not much less than that found by J. S. Maclaurin[2] in the water of the lake, 240 mgm. per litre, although the polythionate found by him was the pentathionate.

A sample sufficiently large to permit a thorough investigation of the polythionates present was obtainable only from a more accessible area, and early this year it was possible to obtain a four-litre sample of the "Black Geyser" at Ketetahi Hot Springs. This sulphate water of pH 5·4 was found to contain 99 mgm. per litre of tetrathionate ion (S_4O_6'') and 66 mgm. per litre of pentathionate ion (S_5O_6''). Further work appears desirable on the particular polythionates which can occur in Nature.

The presence of polythionates in hot springs is not merely of academic interest. The origin of these sulphur acids might be ascribed either to the oxidation of hydrogen sulphide by the oxygen of the air as a step in the formation of sulphuric acid, or to the interaction of hydrogen sulphide and sulphur dioxide, present as constituents of the ascending volcanic steam. The first explanation does not seem probable. Some confirmation of the second explanation is given by the fact that small amounts of sulphur dioxide were actually found in the fumarole gases of White Island. Besides the discovery of J. S. Maclaurin, the only instance of the natural occurrence of polythionates is that recorded by Day and Allen[4], who found pentathionate in incrustations in the crater of Lassen Peak. In this case also, sulphur dioxide was found in fumarole gases.

I have pointed out[5] that if the passage upward of magmatic steam is slow enough to enable equilibrium in gas reactions to be maintained until the steam has cooled to 400°–500° C., there would be no appreciable amount of sulphur dioxide unconverted to hydrogen sulphide. The presence of sulphur dioxide in fumarole gases, and possibly also the presence of polythionates in the hot springs, would indicate rapid

cooling from a magma near the surface. It would be much simpler to estimate polythionates in waters than to determine sulphur dioxide in fumarole gases, and this estimation might be a useful way of judging the activity of an area, or following changes in activity with time.

Flow of Air through Rocks at Low Rates

DURING routine measurements of the permeability of rocks carried out in 1939–40, certain anomalies were observed when the rate of flow was extremely low. It was seen that when the rock was highly impervious and the velocity of the flowing air was consequently low due to limitations in the pressure, a plot of the pressure loss *v.* rate of flow did not yield a straight line passing through the origin. Darcy's law having been established with such rigour by many workers before, however, necessitated the rejection of the anomalous results as due to "experimental errors". The same type of anomalies, however, were again observed recently in measuring the permeability of other samples. Thus, it was decided that the phenomenon be investigated, after having first refined and adapted the apparatus for measurements at extremely low rates of flow.

Fig. 1 shows the results on one sample which was subjected to the test. The ordinate is the product of $\bar{Q}$, the rate of flow at mean pressure, $(P_1 + P_2)/2$, where P_1 and P_2 are inlet and outlet pressures in atmospheres, and μ the viscosity of the air at the temperature of observation, divided by the cross-sectional area of the sample, A. The abscissa is the differential pressure across the sample $(P_1 - P_2)$ divided by the length of the sample, L. It is seen that at low rates of flow, or low differential pressures, the graph is a curve and not a straight line.

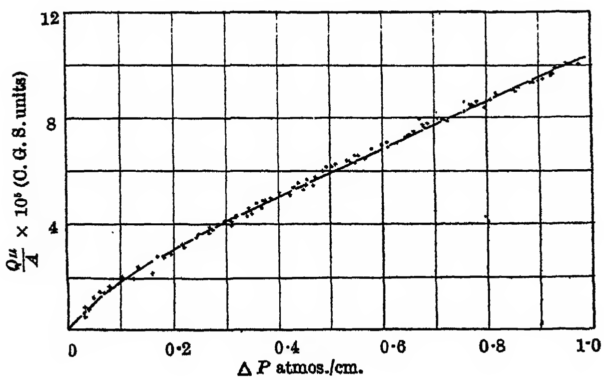

Fig. 1.

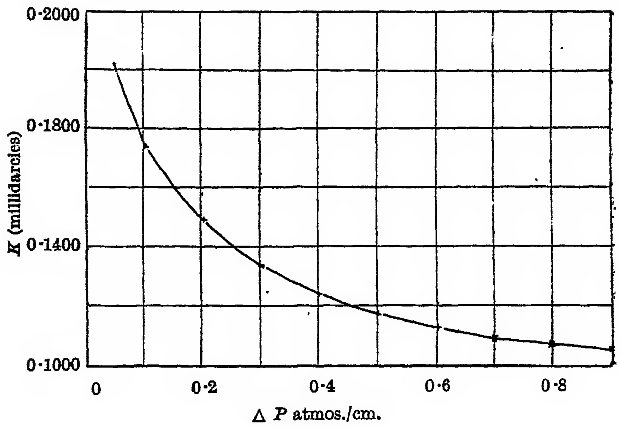

Fig. 2.

Fig. 2 shows the results in another form. The permeability, which is the tangent at each point of graph on Fig. 1, is plotted against the pressure differential. It is seen that instead of the constant value for permeability demanded by Darcy's law, a variable permeability is obtained, falling to an assymptotic value at higher rates of flow. The assymptotic value is what is usually obtained in permeability measurements using fairly high rates but necessarily limited to the viscous regime.

The possibility of turbulence is completely excluded by the nature of the tests, by the fact that at higher rates of flow in Fig. 1 the curve straightens out into the normal viscous regime curve, except for the anomaly that it does not pass through the origin exactly, and further by the fact that the region where the graph curves does not follow the equation

$$\Delta p = av + bv^2.$$

Other tests reveal the fact that the permeability value first increases to a maximum, after which it descends in value until it reaches the assymptotic value indicated.

Full description of the experiments will be published later in another place.

The Philosophy of Physical Science

SIR ARTHUR EDDINGTON has not met my point (NATURE, Sept. 20, p. 341). Assuming, in accordance with his claim, that criteria could exist which would determine that a law was applicable to certain experiences, I asked what he would do if such experiences were found to violate an "inviolable" law. He has related what Adams and Leverrier did when experience afforded an opportunity of testing a law not held to be inviolable. My question still remains.

I agree that if a law appears to be broken, the physicist asks whether a factor has been overlooked. He also reviews his calculations to look for errors, repeats his observations to make sure he was not

mistaken, and even suspends judgment for a while, in daily expectation, like Mr. Micawber, that something will turn up. I assumed in my former letter that all that had been done. The alternatives I mentioned are then the only ones left open. If a historical reference is necessary (which I do not admit) let it be to Mercury rather than Uranus. Here an unknown planet was looked for and not found. What happened was that the law was abandoned. (I have discussed the problems of both Uranus and Mercury elsewhere[1], taking into account also the difficulty mentioned by Eddington arising from "the congruence of gravitational and radiative sources". The facts are perfectly consistent with the view of scientific law as an expression of relations found in experience, though not with the view that science is a description of an external world of physical objects.)

Some interesting points are raised by Eddington's further elucidation of his position, but I refrain from following them up since it is already difficult enough to concentrate the discussion on the main issue. It is no digression, however, to suggest that when he says he is trying to make sense of modern physics but not of experience, he contradicts himself, for modern physics expresses relations found in experience. I find it difficult to believe him serious when he writes: "I cannot find that modern physics imposes any such condition of relevance [that is, a 'condition implying some special relevance to experience'] on the laws which it accepts as fundamental." Suppose the facts now available concerning the orbit of Mercury, gravitational deflexion of light, etc., had accorded with Newton's law and not with Einstein's. I am ready to believe that Eddington's trust in human reason would lead him to accept Einstein and reject Newton, in the sure and certain hope that some perhaps never to be discovered sources of gravitation existed which would justify him. But does he seriously assert that "modern physics" would do the same? If so, twenty thousand physicists will know the reason why.

In reply to the question implied in Sir Arthur's last paragraph, I would say that at the top of things is experience. I was, of course, adopting his metaphor, which is ill-adapted to my view. I do not picture science as digging beneath a surface layer of experience to reach some metaphysical necessity, but if I do express myself in that way I must say that unless the bottom layer can itself support experience (other experiences, of course, than those through which the spade went), then science is digging in the wrong field. But the picture is very unsatisfactory. I prefer to think of the experiences so far obtained as arranged by us in a pattern. By inspection we can infer the plan of the pattern and continue it beyond the area covered by existing experiences; and if future experience falls into place in the extended pattern, we have some confidence that the plan is the one we are seeking. If it does not, then we rearrange existing experience into another pattern into which the new experience will fit. The essential point is that experience is the beginning and end of the business: it suggests the pattern and controls its development.

I await an answer to the question: If the scheme of inviolable law is violated by an experience to which the criterion shows it to be applicable, what about it?

HERBERT DINGLE.

Imperial College,
S.W.7.

[1] "Through Science to Philosophy", pp. 93–95 (Oxf. Univ. Press, 1937).

I FIND it very helpful in all discussions on the philosophy of science to make two distinctions. The first is to restrict the word 'science' to those studies involving experiment with something other than symbols. This rules out mathematics as a science and prevents, for example, the confusion that arises when it is held up as an example of the perfect science. The second distinction, which is of the greatest importance, is to distinguish between science and exact science. Exact science is that part of science which deals with the numbers produced by the reading of pointers—Eddington's "pointer readings". This is very far from being the whole of science, although it is often held up as being the ideal aim of all sciences. (It is sufficient to recall that the theory of evolution, perhaps the most convincing of all scientific theories, does not rest on measurement or even on simple counting.) Science deals with the experiences of ordinary life, tables, octopi, schizophrenic persons and so on, but exact science deals only with numbers obtained by conventional methods of measurement. Thus it may well happen that the philosophy of science is different from the philosophy of exact science.

To account for the structure or relationships of symbols we naturally start with symbols and use methods of dealing with symbols, namely, mathematical methods. But to account for the structure of tables, we clearly cannot start with symbols, but must follow Newton's rules of reasoning in philosophy, namely, "We are certainly not to relinquish the evidence of experiments for the sake of dreams and vain fictions of our own devising; nor are we to recede from the analogy of Nature. . . . The extension, hardness, impenetrability, mobility, and vis inertiæ of the whole result from the hardness, impenetrability, mobility, and vis inertiæ of the parts; and thence we conclude the least particles of all bodies to be also extended, and hard, and impenetrable, and movable, and endowed with their proper vires inertiæ. And this is the foundation of all philosophy."

Newton's philosophy is the philosophy of science; Eddington's is the philosophy of exact science. Newton attempts to account for the experienced properties of bodies; Eddington attempts to account for the relationship between the numbers produced by acts of measurement on the bodies, and admits that he is not trying "to make sense of experience". Thus Eddington has only to account for symbolic relations and so he starts with symbols—relata and relations—"the relata are the meeting points of the relations"[1]. Their structure "has some significance in regard to the ultimate structure of the world—it does not matter much what significance"[2]. His suggested method is to start with a symbolic structure of great generality and build up other symbols having various relationships. He then expects the scheme of relationships arrived at by the analysis of ***metrical*** observational knowledge to be identifiable among the plethora of schemes arrived at *a priori*. Once this is done, the rest of the metrical properties of the universe could be predicted.

Some further light may be thrown on the numbers resulting from acts of measurement by some considerations which I have put forward recently[3]. Stated briefly, these considerations start with the fact that numbers are put into Nature by the physicist, and it is suggested that, by studying the conventional measuring operations by which numbers

are put in, we may be able to predict something about the numbers which come out. It appears that only two direct methods of introducing numbers are available, the measurement of length and the measurement of time. If we take L and T to represent a length and a time measurement respectively, it follows that the measurement of all physical quantities can be represented by L and T raised to various powers, the powers representing the subsequent treatment of the numbers, that is, whether they are multiplied or divided, etc. But L and T are not independent, for a measurement of length involves an interval of time, so that it is a space-time interval that is measured and a "pure" length measurement is not possible. This is a result of the finite velocity of light which is taken as a brute fact of Nature. This space-time interval can be symbolized by a number in two ways, either by measuring its length or by measuring the corresponding time interval and multiplying by c the velocity of light. Consequently we have a relation connecting length and time measurements, namely, $L=cT$: thus we could say that c is the rate of exchange between a length measurement and its corresponding time interval.

Now if we have a case where numbers have been introduced in two different ways—and this has arisen in electromagnetism where we have the electromagnetic and electrostatic systems—then if we take the ratio of measurements of the same physical quantity on the two systems, we can only get the rate of exchange between the two systems of introducing numbers or some power of it. But the measurements on the two systems can only be L and T raised to different powers, and if these are equivalent, they must be interchangeable by means of the equivalent relation $L=cT$. Thus c, or some power of it, must be the ratio of numbers expressing the value of a quantity on the E.M. or E.S. systems.

Sir Arthur has suggested a case where this might not be so, but from the above point of view, the ratio cannot be anything else but a power of the velocity of light. This conclusion involved the experimental result that the velocity of light can be *measured* to be a finite number: this could not have been inferred *a priori*, although, as Sir Arthur says, it could not have been measured to be infinite. There is a tertium quid: it might not have been measurable at all.

An analogy with two other systems of introducing numbers as symbols for aspects of experience, namely, the dollar and pound monetary systems, may help to make this clearer. The measuring of the magnitude of a physical quantity on the E.M. and E.S. systems, and showing surprise that the ratio of the numbers turns out to be a power of the velocity of light, and then concluding that light is electromagnetic in nature, is, on this view, as absurd as measuring the value of a piano in dollars and pounds, showing surprise that the ratio of the numbers is the same as the dollar exchange given in the financial columns of the newspaper, and then declaring that a piano is financial in its nature.

Sir Arthur says that the important question is whether the physicist will recognize "the bottom of things" when he reaches it; but cannot we say that we have *a priori* knowledge that at the bottom of symbolic relationships will be the relation of symbols ? And cannot we say with Newton, that we know *a priori* that at the bottom of things, in the case of tables, octopi and schizophrenic persons, lies something which is not a symbol—not a "vain fiction of our own devising" ?

G. BURNISTON BROWN.

University College, London;
at University College,
Bangor.

[1] "The Nature of the Physical World", p. 230 (Camb. Univ. Press).
[2] "The Mathematical Theory of Relativity", p. 213 (Camb. Univ. Press).
[3] *Proc. Phys. Soc.*, 53, 418 (1941).

I AM glad to have had the opportunity in three earlier letters of debating the difficulty which some physicists find in my scientific epistemology; but I think the time has now come to conclude my share in a discussion which might continue interminably. It only remains to comment briefly on the letters printed above.

Prof. Dingle begins and ends his letter with a question which cannot arise. If the fundamental ("inviolable") laws are not assertions about experience, they cannot in any circumstances be violated by experience. In regard to the rest of his letter, the imagined misbehaviour of Mercury does not differ materially from the imagined misbehaviour of the Michelson-Morley experiment which has already been discussed. In his third paragraph Dingle contradicts me, but I see no justification for his assertion that *I* contradict myself.

Dr. G. B. Brown's letter, with which I am in general agreement, provides a text for some concluding remarks. He emphasizes that the characteristic features of "the philosophy of exact science" come from the fact that exact science is concerned with *numbers* resulting from acts of measurement. Thus we shall get to the root of the matter more directly if we focus attention on numbers—if on the experimental side we consider physical quantities rather than physical objects, and on the theoretical side we consider the numbers which appear in the fundamental laws (namely the fundamental constants) rather than the laws themselves.

Our laboratories and observatories are occupied in amassing numbers most of which could certainly not be foreseen without measurement. But theoretical physicists have sublimated out of this numerical material a set of fundamental laws which (after removing the inconsistencies between current wave mechanics and relativity theory) are found to contain no unforeseen numbers. The co-efficients in the fundamental equations are all of the same type as the co-efficient $\frac{3}{2}$ in the specific heat of a monatomic gas, or as the ubiquitous 2π, the mode of entry of which into the formulæ can be traced without ambiguity. This gulf between the system of the theoretical physicists, which involves no numbers except such as are clearly of their own devising, and the everyday occupation of physicists and astronomers with numbers which are clearly not of their own devising, gives a jolt to one's philosophy. When it became quite clear that the gulf was complete, leaving experience on one side and the theoretical system on the other side, without a single bridge so far as *numbers* are concerned, a radical change of outlook became necessary It is not likely that a first constructive effort to find a scientific philosophy adapted to this new situation has achieved finality; but, whatever defects may be found in it, there can, I think, be no going back to the type of outlook which Sir James Jeans and Prof. Dingle support.

A. S. EDDINGTON.

NATURE AND MEASUREMENT OF WHITENESS

THE mechanism by which a 'white' substance reflects light is fairly simple and is fundamentally the same for crystalline and vitreous powders such as snow and borax, for suspensions such as milk, paint and opal glass, and for fabrics and paper. In all these cases, a multiplicity of transparent particles or fibres is suspended in a transparent medium of different refractive index, and a beam of light incident on the substance is specularly reflected and refracted at a large number of random interfaces, without any transformation and with very little absorption, resulting in a diffused reflexion. A coloured substance has the same mechanism, except for interference colours, but the minute particles also exert selective absorption on the light passing through them. If the difference of the refractive indexes between the particles and the surrounding medium is reduced, a white substance will have a reduced reflexion factor owing to reduction of the interfacial reflexion, and for the same reason a coloured substance will have an increased coloration, as may be simply shown by wetting a white or a coloured fabric. No reflecting substance has colour of its own, but only introduces colour by virtue of the selective absorption which it exerts on light falling upon it, and a white substance is uniquely characterized by its absence of selective absorption of light.

A 'white' light has no such unique character, and the range of lights which are called white can only be defined subjectively from the white-hot metal in a furnace at a temperature of about 1,700° K. to north sky daylight the colour temperature of which may be 10,000° K. It is, however, essential that standard white illuminants should be employed for measurement of white and of coloured substances, and ten years experience of Illuminants *A*, *B* and *C* specified by the Commission Internationale d'Éclairage in 1931 has proved them adequate for most purposes.

The Colour Group of the Physical Society held a discussion on whiteness on September 24, and three papers were read on different aspects of the problem of measuring near-whites. The introductory paper by J. G. Holmes, of Messrs. Chance Brothers and Co., Ltd., gave the theoretical background and indicated some of the visual and colorimetric problems peculiar to near-whites. It was pointed out that a white substance can be picked out quite critically either in daylight or in artificial light, whereas a particular yellow or blue calls for an effort of memory and for uniformity of lighting, and this sensitivity to small departures from whiteness is stimulated by the frequency with which white and near-white substances are employed in everyday life. The exact measurement of their colour is more exacting than that of coloured substances, and instrumental methods may be hard taxed to detect and to measure differences which are quite obvious to the unaided eye. The amount of departure from whiteness is usually expressed as the difference between the colour of the light reflected from a substance and the colour of the light incident upon it; a truly white substance making no change in the colour of the light.

A brief review was given of the instruments available and of their usefulness in industry. The usual type of trichromatic colorimeter is not satisfactory, as the method of building up a white light by adding together three strongly coloured primary lights produces a very uneven spectral energy distribution and, when this is compared with the light reflected from the specimen, the difference in energy distribution in the two halves of the colorimeter field renders the match liable to appreciable variation from one observer to another. This disadvantage may be reduced by employing a subtractive colorimeter, in which the selective absorption of the specimen is approximately reproduced by that of the subtractive filters, but all visual colorimeters have a small field size, leading to poor sensitivity. Spectrophotometric measurements are free from these disadvantages and good results can be obtained by visual or photoelectric 'abridged spectrophotometers', which measure reflexion factor in eight or more comparatively narrow spectral bands selected by filters, and by complete spectrophotometers which measure re-reflexion factor in monochromatic light at a series of wave-lengths.

Dr. V. G. W. Harrison, of the Printing and Allied Trades Research Association, dealt with colour tolerances and methods of control in the paper industry. The natural colour of paper is yellowish, its hue being about 5800 A. and its saturation about 12 per cent with C.I.E. Illuminant *B*; the paper trade tends to call this 'white', and to call a true neutral pulp 'blue-white'. There is a marked preference for the latter colour which is not due to any tradition in the trade, and Dr. Harrison described experiments in which twenty observers were asked to compare the brightness of eight different papers. Analysis of their results showed that the physical reflexion factor of a paper is no measure of its brightness by subjective estimation, and that a blue-white paper actually appears brighter than a natural white paper the reflexion factor of which is about 6 per cent higher than the blue-white.

It seems that the eye is more sensitive to changes in saturation, or depth of colour, than in reflexion factor, and a paper is judged brighter if it has less selective absorption, which explains the common practice of a beaterman in a paper mill, who adds a dash of blue or black to his pulp to 'brighten' the paper. The accepted commercial tolerances are very close when papers have to be bound together in a book, and Dr. Harrison referred to a single run of paper from one mill which had to be graded visually into six 'colours' in order to ensure consistency. Colorimeter measurements failed to show any significant difference between the six grades, and in order to get sufficiently accurate data it was necessary to send the specimens to the United States for measurement on a recording photo-electric spectrophotometer. Subsequent tests on a photo-electric 'abridged spectrophotometer' gave very similar results, although these were not suitable for direct calculation of the trichromatic coefficients, and the tolerance for good commercial quality appeared to be closer than $\pm 0{\cdot}0005$ in the C.I.E. trichromatic coefficients and $\pm$ 0·5 per cent in the reflexion factor.

A manufacturer has to work to a standard pattern, and it is very difficult to check gradual change due to dirt and ageing without accurate measurement. An appeal was made for the provision of a rapid and accurate spectrophotometer available for frequent and inexpensive industrial testing of patterns,

preferably under the auspices of a testing centre or research association.

C. G. Heys-Hallett, of the Morgan Crucible Co., Ltd., discussed the apparent whiteness of cinema screens. Coloration of the screen itself and the colour of the light from the arc are found to vary widely in many cinemas and to lead to serious distortion in the excellent colour films of the present day. This distortion can be overcome by standardization, but it is first necessary to measure the apparent colour and brightness of the combination of arc, optical projection system and screen in order to demonstrate to cinema proprietors the necessity for uniformity. Such measurements need not be on a standard system and do not need the high accuracy required in the paper industry, and Mr. Heys-Hallett described a photo-electric brightness meter which indicates screen brightness with no film in the projector and the relative brightness with each of three colour filters interposed in the beam.

The variation from cinema to cinema is large, being more than 50 : 1 in screen brightness and about 30 per cent in colorimetric saturation, with the result that many films are shown at a disadvantage. The variation in brightness is attributable to the use of the most powerful arc lamps in some of the smaller modern cinemas and unsuitable projectors in some of the older cinemas, rather than to the reflecting properties of the screen; whereas the variation in colour is due to the use of low-intensity and high-intensity arcs, the variety of mirror and lens collecting systems and the rapid ageing of the screen. It is interesting that the use of a blue filter in the projector to correct a yellowish colour is a definite disadvantage, contrary to experience in the paper industry, as the loss of screen brightness causes more subjective colour distortion than the partial correction given by the blue filter.

Demonstrations were given by lantern slide, and it was suggested that if the projected colour and brightness could be standardized at any practical value, colour films could be made to suit. Such a standardization could fairly easily be applied also in the United States and on the Continent, but it would restrict the development of huge super-cinemas until more powerful light sources are available.

THE 'G.E.C. HEAVY ALLOY'

IN an article on the new 'G.E.C. Heavy Alloy' published in the *G.E.C. Journal* of August, G. H. S. Price and S. V. Williams, of the G.E.C. Research Laboratories, in conjunction with C. J. O. Garrard of the Witton Engineering Works, describe the preparation, properties and industrial uses of a tungsten alloy which is fifty per cent heavier than lead and has the tensile strength of a good-quality steel.

Of the common metals, lead is the only one which is substantially heavier than the general engineering materials. Lead, with its excellent corrosion-resisting properties, is a very useful metal, but it is weak mechanically, and for this reason its use is limited to those applications where the stresses are low. The precious metals such as gold or platinum are heavy metals, being two to three times as heavy as iron or copper, but their high price prohibits their use for general engineering purposes. Tungsten, however, has a density equal to that of gold and is also relatively cheap. A considerable tonnage of tungsten is used annually as an alloying element in the production of special steels, and for this purpose the metal is added in the form of powder or as a ferro-tungsten alloy. Tungsten is characterized by a very high melting point (3,400° C.) and this precludes the production of the pure metal by ordinary metallurgical processes. Pure tungsten in the form of ductile wire or sheet such as is used in the manufacture of electric lamps or radio valves, is produced by a powder metallurgical process. The successful development of the process about thirty years ago was one of the first and most important examples of this method of producing metals and alloys, a method which has been extended in many directions, particularly during the last few years.

So far as tungsten is concerned, a bar of pressed powder is sintered to a high temperature and afterwards worked by swaging, drawing or rolling to produce the metal in wire or sheet form. The sintering temperature required is in the region of 3,000° C. and this is obtained by passing an electric current (about 2,000 A. per 1/16 sq. in.) through the bar. The method of sintering, however, limits the size of the bar that can be conveniently handled, and having regard to the fact that it is only after a considerable amount of work has been done on the sintered bar that the metal approaches its theoretical density, it is evident that fully dense tungsten cannot be produced in massive form.

In the first instance, attempts were made to produce an alloy of tungsten and lead. Tungsten powder was mixed and pressed with a sufficient quantity of lead powder to fill the interstices between the tungsten particles, when the mixture was heated. It was found, however, that tungsten and lead do not wet each other, and homogeneous masses could not be produced. It was known that nickel and tungsten alloy very readily, and experiments were made using mixtures of tungsten powder with 5–10 per cent nickel. On pressing and sintering to a moderate temperature, alloys were obtained with densities of the order of 16·5–17 gm./c.c., which is more than twice that of steel (7·8) and about 50 per cent greater than lead. It was then found that the addition of a certain amount of copper assisted production, and although the quantities of nickel and of copper can be varied, the material which is known as 'Heavy Alloy' usually contains 90 per cent tungsten, 7·5 per cent nickel and 2·5 per cent copper. In addition to its high density, 'Heavy Alloy' has a tensile strength comparable with that of a good quality steel.

It is an interesting fact that although the light alloys of aluminium and magnesium are playing such a leading part in modern aircraft construction, it is in this field that ever-increasing use is being made of 'Heavy Alloy'. It is well known that tungsten is practically unmachinable, but 'Heavy Alloy', although it contains about 90 per cent tungsten, has excellent machining properties. The development of 'Heavy Alloy' with a tensile strength of 40 tons/sq. in. and a density more than twice that of steel opens up new possibilities for the designer.

CINEMA ACOUSTICS AND TELEVISION RECEIVERS

As was mentioned in the issue of NATURE of February 15, the Institution of Electrical Engineers now publishes extended abstracts only of papers in Part I of its *Journal*, the full papers being issued later in either Part II or Part III, according as the subject-matter of the paper is appropriately classified as power or communication engineering. Part III includes the Proceedings of the Wireless Section of the Institution, and the September issue of this part contains three related papers in full.

The first of these is by Messrs. C. A. Mason and J. Moir, and is entitled "Acoustics of Cinema Auditoria", and the paper describes the results of investigations made to discover the reasons for the difference in performance of sound reproduced by identical equipment in apparently similar cinemas. It was apparent from the preliminary investigations in four different theatres that overall frequency characteristics and reverberation times were not the controlling factors for good sound quality, which is defined in terms of both intelligibility and intimacy, the latter term being used for the impression conveyed to the audience that the sound actually proceeds from the picture on the screen. Experiments were then conducted with an impulse source comprising a short train of waves of a fixed audio-frequency emitted through the loud-speakers. By means of a microphone and cathode-ray tube equipment, measurements were then made of the paths taken by the reflected sound in the auditorium.

The results showed first that there was little distortion in the amplifiers and loud-speakers, but that the sound received in the auditorium comprised a direct pulse and some reflected pulses, the number and magnitudes of which depended upon the design and shape of the auditorium. The authors conclude from their investigation that while the reverberation-time of a cinema should approach the optimum value for good intelligibility, it is also necessary that the shape of the auditorium should be such as to avoid reflected-sound paths differing greatly in length from the direct path. The paper concludes with a detailed discussion of the practical design of an auditorium with good intimacy, as well as intelligibility, properties.

The second paper is by B. J. Edwards, and is entitled "The Design of Television Receiving Apparatus". This paper comprises a detailed description of the design of a particular form of receiving equipment for television reception to the standards provided for by the B.B.C. transmitter at Alexandra Palace prior to the outbreak of war in 1939. In portraying the detailed electrical and mechanical features of the design, the author shows the fundamental reasons for the adoption and evolution of the particular methods employed. For example, the advantages and disadvantages of electric and magnetic deflexion in cathode ray tubes are demonstrated, and in justification of the adoption of the fully magnetic tube, it is claimed that it gives reproduction of a television picture of superior definition and brightness, and that it lends itself to a slightly more economical design of circuit.

In the concluding portion of the paper, some speculation is given to the trend of design for television reception. The possibility of a general increase in the carrier frequency up to the order of 100 Mc./sec. is envisaged, and this will bring with it certain problems in the attainment of selectivity for reception; also the general demand for a larger picture is likely to result in the development of the small projection type of cathode-ray tube, giving a picture of high intensity of illumination, in association with a suitable projection lens constructed possibly of a suitable plastic material at a favourable price.

The third paper under consideration is of a theoretical nature. It is on "Electromagnetic Waves in Metal Tubes of Rectangular Cross-Section" and is contributed by J. Kemp. The attenuation of electric waves propagated through the interior of metal tubes of rectangular cross-section is calculated by the familiar telephone transmission formulæ, instead of by the usual classical method first used for this problem by Lord Rayleigh. The present author states that the characteristic advantages of the former method are its simplicity and the directness with which the final results emerge. The method reveals the existence of a link between two seemingly disjointed branches of telecommunication, first the classical circuit comprising a 'go' and 'return' path, and second, the transmission of waves through a hollow metal tube without a return path in the conventional sense.

DRUGS FROM THE EMPIRE

The Imperial Institute has reprinted as a booklet an article from the *Bulletin* of the Institute by Dr. M. Ashby*, surveying the possibilities of producing in the Empire drugs hitherto obtained from Central Europe. Dr. Ashby has done his work well and the publication is timely. There has been much unco-ordinated and misdirected activity in the field of drug supplies and this paper helps to set the problem in perspective. Two basic considerations have tended to be forgotten by enthusiasts who have sought to encourage new cultivation. One is that energies should be directed to essential drugs only; the other that to the commercial grower, the problem is a business problem as well as a patriotic one. By reason of lack of early official guidance, many enthusiastic amateurs in Great Britain are wasting both energy and ground in the collection and cultivation of plants having the weakest of claims to being essential in therapeutics. Dandelion, coltsfoot, camomile and the leaves of the lime are a few examples. They command good prices, but those who grow or harvest them would do better to concentrate on potatoes or onions. Belladonna, hyoscyamus, stramonium, digitalis and perhaps colchicum

* War-Time Drug Supplies and Empire Production. By Dr. M. Ashby. Pp. 39. (Imperial Institute, London, S.W.7.) 1s. net.

are probably the only drugs upon which ground or energy should be expended in Great Britain, and the cultivation of the first three is a task for the expert grower. One lesson of the War of 1914–18 which has been forgotten is that the cultivation or collection and the drying of medicinal herbs cannot be undertaken by amateurs efficiently. Inevitably there is great wastage and disappointment. Dr. Ashby emphasizes this in his sections on cultivation, harvesting, preparation and drying.

The problem for the commercial grower is, at bottom, whether he can get a price for his harvest sufficient to pay him to put extra land under cultivation. So far the Ministry of Health has fought shy of guaranteeing prices and the growers have consequently hung back. The yield per acre of ground under medicinal herbs compares at best unfavourably with the yield under foodstuffs, and the grower has in mind always the possibility of an ending of hostilities before his crop is disposed of. This is to-day the obstacle for the home grower: how much more is it likely to prove an obstacle for the Dominion or American grower. Dr. Ashby wisely emphasizes the need for some form of Government protection if Empire cultivation is to flourish.

The Ministry of Health has an advisory committee upon the cultivation of medicinal drugs, but there is still much confusion and unco-ordinated effort. What is needed is (1) active discouragement of the amateur or professional growing or collecting of herbs which have no important therapeutic value; (2) the allocation among home and overseas growers of future requirements of valuable herbs, with guaranteed prices; (3) the co-ordination of research into the conditions of cultivation that will produce the optimum yield of the needed constituents of the herbs.

There is little indication that the present committee has seriously settled down to this triple task, which is indeed less one for the Ministry, however able its advisory committee, than for a body such as the Agricultural Research Council in daily contact with the practical details of modifying plant stocks in required directions and with the relative value to the country of putting land under medicinal herbs or food.

THE MACKAY RADIO AND TELEGRAPH COMPANY COMMUNICATION SYSTEM

COMMANDER M. H. ANDERSON has contributed a paper to *Electrical Communication* (No. 4, 19, 1941) giving a historical account of the growth of the Mackay Radio and Telegraph Co., the successor of the radio communication business of the Federal Telegraph Company.

The Federal Telegraph Company commenced activities in California in 1909; it was organized by a group of Stanford University men who had secured the American rights to the patents of Poulsen and Pedersen of Copenhagen, Denmark. Up to that time the only practical method of radio communication had been by the use of damped waves generated by spark-type equipment. Operation was confined largely to radio communication with ships at sea; the use of radio for point to point communications was very limited, largely because of the inability to cover in a trustworthy way long distances, particularly in the day-time. The arc type of high-frequency generator developed by the Danish inventors made possible the use of sustained or undamped waves. This gave the Federal Company a definite advantage, and it established radio telegraph services interconnecting San Francisco, Los Angeles, San Diego and Portland (Oregon) in 1911, and San Francisco and Honolulu in 1912, and competed for business with the existing cable and land line companies.

The immediate success of the long-distance circuit between San Francisco and Honolulu encouraged the United States Navy Department and the Federal Telegraph Company to install in 1912 a Federal arc transmitter at the naval radio station at Arlington, Virginia, as a result of which this station was able to communicate with the San Francisco and Honolulu stations, during daylight hours, a feat never before accomplished. Eventually the Navy Department adopted the Federal arc system as standard for its services. In 1913, an extensive construction programme was started, including a chain of high-power naval radio stations for connecting Washington, D.C., with the Canal Zone, California, Hawaii and the Philippines. These ranged in power from 100 to 350 kw. and were supplemented by a system of medium-power equipments located at all important naval establishments on United States territory and on ships of the American Fleet. The climax of this development was reached when the Navy Department built the large radio station near Bordeaux, France, during the War of 1914–18, for which the Federal Telegraph Co. supplied two transmitters of 1,000 kw. each.

In 1914, the Federal Telegraph Co. entered the marine radio field at San Francisco, enabling ships plying the Pacific to secure daylight communication over great distances. Activity in this field developed rapidly.

When the United States declared war in 1917, Federal Telegraph's radio stations were taken over by the U.S. Navy, but the company continued its domestic telegraph business by utilizing leased wire circuits. In 1921, it constructed a new communication system along the Pacific coast with three complete duplex channels between San Francisco and Portland and three between San Francisco and Los Angeles. Other cities were connected by local lines to this main radio trunk system, so that by 1923 the Federal network included offices in Seattle, Tacoma, Portland, San Francisco, Oakland, Los Angeles and San Diego, besides marine radio stations.

In 1928 the Federal Telegraph Company's system was acquired, along with other properties, by the International Telephone and Telegraph Corporation, the name having been changed to the Mackay Radio and Telegraph Company (California) during the year 1927. The change in ownership occurred at the time when high-frequency vacuum tube transmitters were coming into use, resulting in reduction in the cost

of establishing radio circuits. The Atlantic and Pacific groups of offices are interconnected by radio trunk circuits between New York and San Francisco, New York and Los Angeles and Chicago and San Francisco. This closely knit domestic system serves main business and population centres and the contiguous districts, totalling more than eight hundred communities. Messages may be filed with Mackay Radio to thirty-one countries and by means of its associated companies it can accept messages to any country in the world.

The third division of Mackay Radio Service—communication with ships at sea—is carried out by six powerful coastal stations. A Marine Division is maintained through which ship owners and operators may secure modern ship radio equipment, properly installed and adjusted to obtain the maximum range of communication.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

TUESDAY, OCTOBER 28

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Mr. E. H. Hunt: "High Places of Sacrifice in Palestine and Petra".

CHADWICK PUBLIC LECTURE (at the Royal Sanitary Institute, 90 Buckingham Palace Road, London, S.W.1), at 2.30 p.m.—Mr. J. C. Dawes: "The Cleansing of Towns and Cities".*

THURSDAY, OCTOBER 30

CHEMICAL SOCIETY (Joint Meeting with the Plastics Group of the Society of Chemical Industry) (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. C. Redfarn: "The Constitution of Plastics".

FRIDAY, OCTOBER 31

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at the Mining Institute, Newcastle-upon-Tyne), at 6 p.m.—Sir Westcott S. Abell: "Merchant Sea-Power, 1919–1939" (Tenth Andrew Laing Lecture).

SATURDAY, NOVEMBER 1

GEOLOGISTS' ASSOCIATION (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. E. B. Bailey, F.R.S.: "How Scottish Recumbent Folds were Discovered".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

GRADUATE (MAN) TO TEACH CHEMISTRY AND MATHEMATICS—The Principal, Dudley and Staffordshire Technical College, The Broadway, Dudley, Staffs. (October 30).

INSPECTOR OF SCHOOLS (WOMAN)—The Director of Education, Education Offices, Deansgate, Manchester 3 (October 31).

ASSISTANT SPEECH THERAPIST—The Director of Education, Education Department, Newarke Street, Leicester (November 1).

INSTRUCTOR IN WORKSHOP PRACTICE AND PROCESSES in the Oxford Schools of Technology, Art and Commerce—The Chief Education Officer, City Education Office, 77 George Street, Oxford (November 3).

LECTURER IN CHARGE OF THE MARINE ENGINEERING SCHOOL of the Hull Municipal Technical College—The Director of Education, Guildhall, Hull (November 3).

EDUCATIONAL PSYCHOLOGIST to work in the Child Guidance Clinic—The Director of Education, Education Office, Town Hall, Bradford (November 7).

SECRETARY to the Research Association of British Rubber Manufacturers—The Acting Director of Research, 103 Lansdowne Road, Croydon (November 8).

REGIUS PROFESSOR OF NATURAL HISTORY in the University of Aberdeen—The Private Secretary, Scottish Office, Fielden House, 10 Great College Street, London, S.W.1 (November 22).

SENIOR LECTURER IN ENGINEERING SUBJECTS in the Halesowen County Technical School—The Secretary, Halesowen Higher Education Committee, 21 Gt. Cornbow, Halesowen, Worcestershire.

PSYCHOLOGIST (WOMAN)—The Medical Superintendent, Incorporation of National Institutions for Persons requiring Care and Control, Stoke Park Colony, Stapleton, Bristol.

ASSISTANT EDITOR to assist in the publication of "Monthly Science News"—The British Council, 3 Hanover Street, London, W.1.

NATURE

SATURDAY Nov. 1, 1941

YOUTH IN SCIENCE

On October 11, five thousand young men and women, representing twenty nations, met at an International Youth Rally for Victory in London. On October 13, Lord Croft, Joint Parliamentary Under-Secretary of State for War, spoke of the necessity of giving youth a bigger place in defence plans. *The Times* of October 13, commenting on the Rally, pointed out that "at the same time [the Rally was] a particular reminder to the young people in this country of the urgency of the present situation and the weight of their responsibility".

These pronouncements are a sign of the times, and all have been inspired by the seriousness of the War in which all of us are involved to a greater or less degree. We agree with *The Times* that youth has a tremendous responsibility to-day, and with Lord Croft that youth deserves a bigger part in our defence plans. But this touches only the fringe of a problem of major importance, touching it as it does in a time of emergency and therefore necessity ; but the problem itself dates back far into history and is as deeply rooted as any other human problem. It is the problem of fitting youth, not in spite of its youthfulness but because of it, into all schemes concerned with human welfare and progress.

The very remark of *The Times* that the Rally served as a "particular reminder to young people in this country" indicates an attitude towards youth which for generations has been all too prevalent—that of giving the younger generation a kind of inferior distinctiveness. The majority of the younger people in this, or any other country, need no more reminding of the gravity of the world situation than the majority of the older generation. It is because of their intelligent awareness that the Rally was held, through their own initiative ; it was not organized by their older colleagues because the latter thought youth needed telling. Youth spoke for itself.

This was clearly realized by Mr. Bevin, who opened the meeting and who emphasized that the Rally pointed the way for a *more imaginative understanding of the capabilities and aspirations of youth* both by leaders of youth organizations and by the political parties. This might well be extended to cover all organizations, including those of the sciences.

The fact that the problems of youth are almost as old as the hills is beside the point. They have always complained of a sense of frustration, of being domineered by those of more mature years, sometimes of being ignored and even of being used as rungs in the ladder to fame by those in authority over them. Their complaints have often proved well founded, but seldom have they been dealt with effectively. The reasons for it are legion, and are sometimes due to thoughtlessness, but sometimes to regrettable arrogance, self-seeking or even selfishness on the part of their older colleagues. Gone are the days when any clear-thinking layman or

more important still, psychologist would subscribe to the view that youth is synonymous with irresponsibility, and that the main characteristic of any man of responsibility must be experience. Experience is, of course, of the utmost importance provided that the person who has had it also has the intelligence and imagination to profit by it. But so often this is not the case. Furthermore, with long-drawn-out experience too often goes susceptibility to hide-bound tradition, loss of initiative and imagination, self-aggrandizement on the basis of *past* achievements and sometimes antipathy to growing youth, who still have those qualities coupled with an emotion peculiar to themselves.

To the older in years may be said "This was, this is, your world"; to youth "This is, this will be, your world". Whose is the greatest responsibility? We see little difference; but too often a distinction is made, to the detriment of youth. More collaboration is needed, thus giving greater encouragement to them. This can best be done by giving them a greater share of responsibility in all walks of life, including that of science, giving them greater representation on organizing, executive, administrative and even advisory bodies.

These questions were raised by several speakers at the recent Conference on Science and World Order, and it is to be hoped that the points made will receive the serious consideration they deserve. Dr. J. E. D. Swann pleaded for a greater utilization of youthful men of science in the war effort and incisively criticized the inefficient utilization of scientific workers in the war effort.

Mr. D. P. Riley pleaded eloquently for the younger generation of scientific workers. "There should be more democracy in science. There should be a place for younger scientists in the councils of scientific planning, in the laboratories and factories themselves, and on national and international committees or commissions. Young scientists, by virtue of their very youth, are endowed with energy, initiative and enthusiasm. They bring a new point of view, that of the younger generation, to bear. Their scientific training has been based, not on the conceptions of nineteenth-century mechanistic physics but on twentieth-century dialectical theories, in which the inter-relation of the various sciences is continually emphasized. Nowadays a chemist must also be a physicist, and a physicist an engineer, and the younger scientists have been trained from the outset in full knowledge of the diverse and powerful modes of attack on any scientific problem. The need for startling ingenuity, for completely new methods, and above all for quick thinking, is very necessary in war-time. More important than all these considerations is the fact that the humbler scientific workers can put forward the point of view of the man actually on the job—actually at the laboratory bench; actually at the production point of scientific discovery.

"The wisdom and conservatism of age and experience could thus be tempered with the effervescence and radicalism of youth. Any tendency on the part of youth to sublime over-confidence would soon be gently and firmly dealt with by their more experienced colleagues. But give youth its chance to help, and not only always at the bottom, but sometimes, dare I say it, almost at the top?

"Let youth as an essential supplement to present official plans put into direct contact with each other rank-and-file scientists in similar fields of science but working in different countries. Let personal contact be established as widely as possible. It would also serve as a valuable basis for international understanding on the cultural level after the War.

"Concerning the peace-time planning of research, it cannot be too often stressed that international co-operation is its very life-blood. In peace-time a greatly increased exchange of younger scientists between the nations is desirable. It is not sufficient to rely on private philanthropy to achieve this, as is largely the case at present, but State funds should be made generously available. These men and women would give to the foreign laboratories in which they would work the different outlook of their home training. They would bring with them different aspects of technique and approach. They would, conversely, learn and take back home with them an understanding of the methods used abroad. All this should occur during the formative years of their lives. Parochialism in science *does* exist and must be combated; this is one way of doing so."

Mrs. S. Neville-Rolfe forcibly pressed before the Conference the same argument, especially from the biological and psychological points of view.

"It is recognized already in military circles (though not always practised) that those trained and experienced in the War of 1914–18 are not the best improvisors of strategy and tactics for a war of dive-bombers and tanks. This principle applies even more strongly to questions which affect the development of man himself.

"The emotionally immature, belonging to a previous generation, with a background of traditional dogma as religion, of *laissez-faire* as social economics, of philanthropic charity as good citizenship, and an idea of the 'equality of man' which ignores biological evidence, are not qualified to govern, or to lead youth in the present world crisis; yet it is they who are in control to-day.

The old in experience and young in mind have ever been outstanding leaders, but the old in mind and years are unable to grasp the new problems or to relate new knowledge to spiritual values. They fear youth and from a mistaken sense of duty they continue to bear burdens beyond their years, and are barring advance.

"It is vital to reach the younger generation, the parents of the future in service and civil life, and gain their intellectual interest and emotional drive behind the idea that man may control and direct to the service of man the forces that he has set in motion. Experience is needed, but so are drive, a new outlook, and faith in man's destiny."

To this must be added the all-important quality of leadership—a character which is not based on experience but is the outcome chiefly of initiative, imagination, determination and faith, and therefore a character no more the prerogative of the older generations than of any others. When a youth shows ability to lead, let him lead. Those of mature age might well offer him the benefit of their longer experience and guide and advise him; but often they ignore him, and sometimes also they usurp his leadership once he has shown the way.

The President of the British Association, intervening after Mr. Riley's remarks at the Conference, expressed his sympathy with the younger scientific investigators; but there are some in authority who do not attempt to exercise such sympathy, at any rate in a practical form. Furthermore, many young men of science ask for more than sympathy; they justly demand more practical recognition as men of science in their own right and not merely as scientific assistants. By keeping them as subordinates until middle age they often lose their capacity and desire for responsibility and initiative; they are sapped of their self-confidence. The President also pointed out that so far as the Division for the Social and Industrial Relations of Science is concerned, youth has played an important part in its development. This is as it should be, especially since the Division itself is a youth. So now let the older institutions and societies and other research organizations follow this example and admit youth to their council chambers. A certain amount of balanced and controlled rejuvenation would not come amiss.

In his message to the International Youth Rally, the Prime Minister, referring to present-day needs, told youth that their place is still in the forefront of battle. H.M. the King, on the other hand, looking to the future, emphasized the gravity of the tasks which the years of reconstruction will lay upon the shoulders of youth. The two go together; they are inseparable. So also should youthful and older men of science march together, their individual status being acknowledged on grounds of scientific achievement and of intellectual, not chronological, age. Youth has a case; at present much of youth is being penalized. Until that unfair imputation is removed (and now is the time to do it), unity of purpose and team work can never be fully developed.

As pointed out in NATURE of October 11, p. 427:

"It seems well worth while investigating how to bring about the necessary unity of feeling, and to arouse sufficient enthusiasm among people agreed intellectually upon the work to be done in order to enable them to pull together as a team. Co-opting more of the younger men in the counsels of science will undoubtedly help much towards this badly needed unity. At present some of the more progressive men of science feel keenly the neglect of their services, especially when older authorities are complaining of having too much to do, too many committees to attend, etc. Once this feeling almost of frustration is eliminated, and younger men are given their rightful place in the advancement of science, a closer unity of feeling will be established."

THE NUTRITION SOCIETY

A NEW scientific society devoted to the study of nutrition, the Nutrition Society, has just come into existence (see NATURE of October 11, p. 433), and an account of its first meeting appears on p. 519 of this issue. Nutritional thought in Great Britain has so far centred around the Biochemical and Physiological Societies, and in recent years the Nutrition Panel of the Society of Chemical Industry has done much to foster interest in food problems. Admirable as these facilities were, they could not keep pace with the increasing scope of nutritional science which now also embraces agriculture, clinical study, practical dietetics and sociological problems. The new Society, while in no sense competing with existing ones, will provide a common meeting-ground

where all aspects of nutrition can be discussed by workers previously separated by the barriers of specialization.

The formation of this body is thus in a measure the expression of the recent rapid development of a science and of the strong position it has always held in Great Britain. In addition, although the atmosphere of war is seldom propitious for the development of learning, it has contributed to the creation of this new academic fellowship. A new spirit is abroad among men of science, who realize that scientific detachment is no longer possible under conditions of total war or after it, and that they have the right and the duty to ensure that the results of their labours are properly used in the cause of humanity. At this time, when the problem of feeding the people is of vital importance to the country, the desire to do something immediately useful is probably foremost in the minds of the members of the new Society. In fact, this spirit had already manifested itself during the year preceding the formation of the Society, in informal exchanges between various workers of views on matters of nutritional importance.

The determination to put to practical use the accumulated nutritional knowledge is evident from the wish of the Society to limit the discussion at its meetings to certain specific topics, rather than to open it to the free presentation of isolated academic papers. Very appropriately the first meeting dealt with the evaluation of nutritional status. Every student of nutrition observes with a sense of shame and frustration the prevalence of malnutrition in this world of plenty. It is staggering to read a pronouncement by the President of the United States of America, that in that country, the richest in the world, undernourishment is widespread and serious. For this unhappy situation the man of science is not wholly blameless, and his attitude of aloofness shares censure with the shortcomings of the politician. In this connexion it is good to hear Mr. Eden express the hope which reflects the spirit of the British Association, that science and statecraft will henceforth march together. Thus might men of science and statesmen inspire and stimulate each other.

A similar desire for the scientific guidance of human affairs has also animated the virile and fruitful National Nutritional Conference for Defense which has recently met in the United States. It has acknowledged frankly that the State machinery in the United States has not given sufficient attention to the nutritive qualities of human foods, that "interest in general has been more in protecting pocket books than health" and that in fact livestock has been given the best parts of many foods.

It cannot be said that matters are any better in Great Britain. While agriculture in this country displays very rightly a keen interest in the forage and fodder value of its products, it is little, if at all, concerned with their value in human nutrition. The value of agricultural produce as human food is rarely considered much before the stage of actual consumption; previous to that, in the stage of production and distribution, it is just a marketable commodity. Much has been heard about the marriage of health and agriculture, but it is only with scientific planning that this union will bear fruits of high nutritive value.

With the formation of the new Society a hope for the future is raised in that workers in nutrition from all spheres will get together and pool their knowledge, plan their work on a practical basis, and combine to see that the greatest possible benefit to mankind is derived from the results. It takes little imagination to foresee that the proper nutrition of the people will form the foundation of future health programmes, and here the Nutrition Society will doubtless supply much creative planning. Many data are already to hand and it will be for the Society to see that such information is better utilized in the future.

In the meantime nutrition workers in Great Britain, going about their immediate war-time tasks, will derive inspiration and support from its meetings. When the time comes some and probably many of them will take an active part in the relief of the widespread misery and starvation which Nazi rule has brought on the subjugated peoples. Ample opportunities for humanitarian service will present themselves to the Nutrition Society which, we are informed, has had the happy thought of making early contact with its American counterpart —the American Institute of Nutrition—and with leading students of nutrition in that country. It is to be hoped that they will join hands in this work of reconstruction.

It is auspicious and fitting that Sir John Orr should have been called to be the first chairman of the Society. One of the few to realize the seriousness of the nutritional problems of Great Britain, he has now for many years, with pertinacity and courage, called for a constructive policy for the scientific feeding of the people. His voice has for too long been unheeded, but things have changed and his guidance in matters of nutritional planning is now frankly acknowledged on both sides of the Atlantic. Further, the Society may be proud that it has been ushered into being by Sir Frederick Gowland Hopkins, the doyen of nutritional science, whose great work will always be, in the future, as in the past, an inspiration to all who labour in this field.

FOUNDATIONS OF WORLD UNITY

The Bases of a World Commonwealth
By C. B. Fawcett. Pp. xi+167. (London: Watts and Co., Ltd., 1941.) 7*s*. 6*d*. net.

LESS ambitious than some of the volumes and pamphlets which in the last year or two have discussed the problem of world order after the War, Prof. C. B. Fawcett's book is likely to commend itself particularly to scientific workers. It contains no constitution for a world State or even a plan for the establishment of world unity. It is concerned with the foundations on which a world order can be based rather than with the manner in which the building is to be erected. The approach has the same scientific character as that which distinguished Prof. J. T. Shotwell's "The Renunciation of War as an Instrument of National Policy" a decade and a half ago.

Prof. Fawcett's main thesis is that the developments of applied science have now made it impossible for any part of the civilized world to remain isolated from the rest, or to be self-sufficient in all the natural resources needed by a modern civilized community. These developments and those in the means of communication have linked the world into a single economic area. The dominant trend of Western civilization is towards ever larger political groupings, and the ultimate goal must be the union of the world into some form of State. The choice is between a commonwealth of free peoples or an empire dominated by the finally successful conquerors.

The major part of Prof. Fawcett's book is devoted to a critical analysis of the possible bases of world unity. These are necessarily twofold—material and moral. His second chapter, in which he discusses the geographical basis, is the most distinctive in the book and its close analysis of the distribution of the chief natural resources and of the routes by which they may be brought together indicates that there are only a few limited and definable areas which can be the bases of world power. Of these the European and American major human regions are the chief. Together they can determine the form and the establishment of world unity, but a division of the world into three or four super-States, each based on one of the major human regions, would be as likely to postpone as to advance the establishment of a world commonwealth.

This geographical analysis stresses the importance of attempting to overstep from the start the limits of any one of these major regions and to include at least parts of all or most of them, although the chief focal area must form the starting-point. While, however, in spite of its extreme political fragmentation, the physical geography of Europe no longer offers any serious obstacle to its effective economic and political unification, the moral bases are equally important. A voluntary union can be made only on the basis of agreed principles. No union can endure unless a majority of the active citizens in each participating State are agreed upon the fundamental principles on which the union is to be based. Prof. Fawcett argues that the only conceivable voluntary union of European States and peoples would be one based on the democracies, but the ten democratic States of Europe form an insufficient basis for a European union until the German people have become free men and women through a process of re-education. There is no hope, even for Europe itself, in a United States of Europe limited to Europe.

From this analysis and a further closer examination of the United States and the British Commonwealth, including the problems presented by the dependencies and by the coloured peoples, Prof. Fawcett concludes first, that while the peoples of the British Commonwealth may move towards closer co-operation with other free peoples, particularly with the United States of America, it is not practical politics to propose that Great Britain should become a member of any merely European union or of any union which does not include the other dominions. The power to initiate a new world in which the democratic ideals can be realized lies, he concludes, finally with Anglo-American co-operation. The British and the American Commonwealths alone are in a position to strike effectively for freedom, and on whether they accept that responsibility and seize their opportunity depends whether their ideals and way of life shall prevail or perish. The world can no longer endure half slave and half free, and only the British and American Commonwealths can provide the power to enforce the law or initiate the framework of law and order essential for freedom and peace.

In his main argument Prof. Fawcett makes many significant observations. He is inclined to stress the importance of a common language and looks to Esperanto as an essential second language if the peoples of the world are to become united as free peoples. He notes the backwardness of American citizens in realizing their existing imperial responsibilities and the tardiness with which the essential unity of the civilized world is

yet realized in any country. He comments on the greater ease of real community of thought across the Atlantic than between north and south on either side of it, and he recognizes the urgency of removing the linked evils of poverty, malnutrition and ignorance in the dependencies, as well as the impossibility of achieving world unity if co-operation is limited to any exclusive groupings of race, religion or colour.

What is significant at the present time is that Prof. Fawcett's analysis leads him to much the same conclusion that Streit has reached in his "Union Now With Britain", Lionel Curtius in his "Decision" or Julian Huxley in his "Democracy Marches". This concensus of opinion regarding the closest co-operation between the United States and the British Commonwealth is far more important at the moment than the exact form which that co-operation takes. Unless the foundations are sound the structure may fail once more at the first real test.

The immediate task in the establishment of world order is that of securing the widest possible active support for this conception of the essential unity of the civilized world and for the first measures required for the formation of a union based not on force but on community of ideals and interests. The significance of the Churchill–Roosevelt declaration lies more in its contribution to that task of education than in the expression of any intrinsic advance in thought. It indicates rather the extent to which action on a common policy and common principles by the United States and Great Britain has become practical politics. Similarly, Prof. Fawcett's admirable study is chiefly of value for its contribution to this task of education and for the evidence it affords that Anglo-American co-operation is already taking shape in forms which hold out the best hope of establishing for all nations a world order embodying the ideals of freedom and justice and respect for human rights and personality which are the common heritage of the English-speaking race.

R. BRIGHTMAN.

PATHOLOGY OF GRASSLAND

Diseases of British Grasses and Herbage Legumes

By Kathleen Sampson and Dr. J. H. Western. (Issued for the Authors by the British Mycological Society.) Pp. vii + 85 + 8 plates. (Cambridge: At the University Press, 1941.) 5*s*. net.

GRASS is one of the few crops which is still grown under semi-natural conditions; even the best-managed grassland still remains an association of plants, as opposed to the pure culture of most other crops. It is no idle coincidence that the pathology of grassland has been for so long neglected. The spread of diseases and pests among a mixed population is neither so rapid nor so extensive as in populations of a single species; the importance of grass diseases first came to be recognized when grasses were grown in pure culture for seed production. The practice of re-seeding pastures, and the wider use of temporary leys, strenuously advocated of recent years by the Welsh Plant Breeding Station, implies the improvement of grass strains for pasture and for hay production by selection and plant breeding. Among the difficulties of this work, the incidence of disease is by no means the least. The appearance of a bulletin on "Diseases of British Grasses and Herbage Legumes", by Miss Sampson and Dr. J. H. Western, is a welcome reminder that this aspect of the drive for grassland improvement at the Welsh Plant Breeding Station has not been neglected. The senior author, Miss Sampson, is well known for her researches on diseases of grasses and herbage plants, and this bulletin is the outcome of some twenty years investigation at the Welsh Plant Breeding Station.

The bulletin, to which a foreword is contributed by Sir George Stapledon, deals both with the individual diseases of grass species and of herbage legumes, respectively, and with the collective diseases of turf, such as snow mould, red thread, etc. It is intended, by its technical character, more for the professional plant pathologist and the agricultural adviser than for the actual grower. No exception can be taken to the mycological treatment of the different diseases, and the excellent plates are a welcome supplement to the text-figures for purposes of diagnosis.

The recommendations for control make it clear that much research work still remains to be done before the position can be regarded as satisfactory by the seed grower. It is surprising to find, for example, that the life-cycle of so well-known a parasite as *Epichloe typhina*, the cause of choke, is still partially obscure. Again, the section on individual diseases of grasses contains no reference to any root disease, though at least one root-infecting fungus, *Ophiobolus graminis*, is known to be widely distributed on the roots of grass. Whilst this fungus has so far chiefly attracted

attention on cereals, grassland is the source of the disease, and it seems possible that variation in susceptibility of individual grass species to attack by *O. graminis* may at times modify herbage composition. Again, there is no mention of any virus disease of grasses, and only half a page is devoted to virus diseases of herbage legumes. These discrepancies may be reduced by further research; in the meantime, the authors are to be congratulated on the production of a most timely and useful publication.

S. D. Garrett.

ECONOMIC GEOGRAPHY

Economic Geography
A Regional Survey. By Prof. R. H. Whitbeck and Prof. V. C. Finch. (McGraw-Hill Series in Geography.) Fourth edition. Pp. xii+647. (New York and London: McGraw-Hill Book Co., Inc., 1941.) 24*s*. 6*d*.

This is the fourth edition of a well-known text-book, produced under the limitations of war-time. These have compelled the author to omit many details of which up-to-date statistical information is not available, and thereby given more prominence to the permanent factors of geography in comparison with the now obviously less stable political limits.

The short introduction on the nature of economic geography states the author's views. It should be read in conjunction with the companion text-book "Elements of Geography" by Finch and Trewartha, in the same series. The approaches are defined as (1) regional, in which one attempts to synthesize the factors of the geography of a part of the earth, and (2) topical, in which the aim is to study some one aspect over the whole earth. In this book the method is that of topical studies within very broad divisions. Because of the importance of political limits in economic geography, particularly in a time of economic nationalism, these divisions are mainly determined by political rather than natural boundaries, and the subtitle of "A Regional Survey" is scarcely justified.

The book is in two parts: (1) the United States and Canada, which the author sometimes calls Anglo-America, and (2) the rest of the world. Part 1 is slightly the longer. Less than a quarter of the space, 140 out of 647 pages, is given to Europe, including all the Mediterranean lands and the U.S.S.R.; and only nineteen pages are given directly to the British Isles. These proportions reflect the world as seen from the Middle West of the United States.

The book is essentially a sound text for college students. Present conditions have made it difficult to get up-to-date statistics; hence there are few in the text, which makes the book more readable. A few statistical tables are given in appendixes; nearly all these can be got in such reference books as the "Statesman's Yearbook"; and it is difficult to see why they should be reprinted here, since many of them are soon out of date and students likely to use the book should have access to, and be trained to use, reference books.

In two items the book could be made more useful. The many references to the diagrams should be by page as well as by number of the figure, since it is much easier to find a page; and there should be a list of the 315 illustrations. For example, there is a diagram-map of world wheat-growing on p. 47; it is frequently referred to afterwards as Fig. 17; but it does not appear in the index or in any list. The present reader has found it worthwhile to insert many cross references, especially to the figures.

Errors are few, as may be expected in a fourth edition. There is the common Middlesborough for Middlesbrough, and also Sidney for Sydney (p. 607). The discovery of gold in Australia was made in 1851, not 1857 (p. 608). There are similarly few omissions; but it may be noted that there is no reference to wind among the sources of power, nor to the obtaining of oil from coal, both of which have some importance in parts of Europe. Hair is not included among textile materials; though there is reference to mohair in the sections on Turkey and South Africa. At the end of each chapter is a short list of selected references for further reading; these are wholly in English, and are mainly Government publications and text-books. Only eight of the many distribution diagram-maps are world maps; more would be useful to show the distribution, and illustrate the transport routes, of such commodities as mineral oil, coal, etc. Many of the map-diagrams are from the excellent series produced by the U.S. Departments of Agriculture and Commerce. But far too many of the statistical diagrams are undated.

For the study of the economic geography of North America this is likely to maintain its position as a standard text. For the rest of the world students must still look elsewhere. Here and there are sentences referring to problems of the economic utilization of natural resources, which is one of the main themes of economic geography; but this is not a study of the philosophy of the subject. The authors set out to produce a good text-book, and have succeeded.

C. B. Fawcett.

TERCENTENARY OF COMENIUS

ON October 24, the tercentenary of the visit to England in 1641 of Jan Amos Komensky (Comenius), the famous writer on education, was observed in the Senate House of the University of Cambridge.

The official representatives were as follows: Government of Czechoslovakia, Dr. E. Benes, president; Government of the U.S.S.R., M. Maisky, ambassador; Government of the Netherlands, M. Bolkestein, minister of education; Government of Poland, Count Racyński, foreign minister and ambassador; Government of Yugoslavia, M. Milanović, under-secretary of state for foreign affairs; Government of Sweden; the Board of Education, Dr. R. Fitzgibbon Young; the Royal Society, Sir Henry Dale, Sir William Bragg, Sir Frederick Gowland Hopkins, Sir Charles Sherrington; the Moravian Church, The Right Rev. C. H. Shaine; the British Council, Prof. B. Ifor Evans.

In his opening discourse Dr. Benes, President of Czechoslovakia, described Comenius's plans for peace leagues and his place in history as a great European. This pastor, later bishop of the Moravian Brethren, a brilliant pioneer in educational methods, stood in his breadth of views as a veritable giant above his contemporaries. President Benes pointed out that the position of the Czech people, surrounded as they have been for a thousand years by other peoples in the heart of Europe, has disposed them to a natural pan-Europeanism. The necessity of being on good terms with Germans to the north, Latins to the west, Slavs to the east, and the Balkans to the south, early implanted in their minds ideals of internationalism. President Benes emphasized the happy nature of the stimulus between English and Czech culture which occurred when in 1641 Comenius was invited by Parliament to visit Great Britain and prepare plans for the remodelling of education and the establishment of a "Pansophic College".

Comenius's place as an educator was next dealt with in a brilliant and moving speech by Mr. J. L. Paton, formerly high master of Manchester Grammar School and later president of University College, Newfoundland. Comenius represented all the ideas which have successfully triumphed in modern education; he was against class distinctions in the school, he was in favour of the education of women, he wanted to introduce science, music and handwork at the expense of the Latin grammar which at that time was universally learnt by heart, he desired schools to be happy workshops of humanity (in his own words) rather than the torture-chambers of youth that they were. In the "Didactica Magna", he summarized his basic belief, that man is a rational creature situated by God among visible creatures, the natures and properties of which he must of necessity know. Hence Comenius's interest in science—"the new or experimental philosophy"—arose out of his interest in education, and that in turn sprang from his theoretical position as one of the great Christian humanists.

Comenius never felt that science would clash with revelation: "Christ", he said, "called himself not Tradition, but Truth itself." Though he himself was, like most of his contemporaries, a great believer in the literal truth of the Scriptures, he nevertheless, like Sir Thomas Browne, insisted that Christians ought to pay at least equal attention to that other bible, Nature, "that open and publick manuscript which lies expans'd unto the eyes of all".

Prof. J. D. Bernal, continuing Mr. Paton's theme in the direction of the sciences, pointed out that though Comenius made no scientific discoveries himself, he brought it about by his new ideas on education that men should arise who could make scientific discoveries. Comenius was a man very comparable with Boyle, who also combined a passionate belief in the growth of natural science with a universalism which desired the propagation of the Gospel in those far parts of the world with which the voyages of exploration had made Europeans familiar.

Like Boyle, Comenius was associated with New England, and was even invited to Harvard College. This Christian universalism was the mainspring of the interest of such men as Comenius and Wilkins in a universal language as well as in universally applicable methods of education, which should deal with things and actions, not words and ideas. From the *Unitas Fratrum* (the Moravian Brethren) came the ideas of *unitas* and *communitas* which dissolved the secrecy of the alchemists and astrologers into the liquid homogeneity of a higher level of international collaboration in science, in religion and in education. We rightly commemorate Comenius, the spiritual father of the "Invisible College", and the patron saint of those who are conscious of the social relations and function of science.

The proceedings were concluded by Prof. Ernest Barker, who in a charming discourse referred to many other points of Anglo-Czech cultural contact, and expounded the great debt which all Europe owes to Bohemia, Moravia and Slovakia.

EVALUATION OF NUTRITIONAL STATES

THE newly formed Nutrition Society began its active life at Cambridge on Saturday, October 18, with a symposium on "The Evaluation of Nutritional States". The audience included the president of the Royal College of Physicians, Lord Dawson, Prof. E. J. Bigwood, professor of biological chemistry in the University of Brussels, Prof. J. Preston Maxwell and the heads of a large number of biochemical and other laboratories. Messages of good-will had been received from various British scientific societies and from research workers in Britain and America.

In the morning, the chair was taken by Sir Charles Martin, who gave a brief history of the formation of the Society and, before calling on Sir Frederick Hopkins for his introductory address, paid a tribute to his success in ending the complacent attitude of the first years of the nineteenth century. Sir Frederick outlined the changes in the outlook of the science of nutrition during the fifty years that have passed since he gave his first lectures on nutrition.

The first session dealt with the assessment of the level of nutrition in man. Dr. Leslie Harris claimed that the nutritional state cannot be assessed satisfactorily without laboratory methods. Clinical methods suffer from lack of definite standards, and food deficiencies may be present without clinical evidence. He gave examples of tests for deficiency of several vitamins and dealt more fully with the saturation test for vitamin C. Examples were given of the response to the test by well-fed and slum children, and of the effects of the War. He discussed the causes of food deficiencies in Great Britain, and stressed the frequency with which sick persons are given inadequate diets.

Dr. H. M. Sinclair, who followed, questioned the validity of the assumptions on which the saturation tests are based. He preferred to base conclusions on evidence of failure of function; for example, the corneal changes, visible with the slit-lamp, due to deficiency of vitamin A or riboflavin. These functional changes may be due to deficiency of more than one nutrient. He discussed some surveys now being made in which the results of tests are being correlated with the diet.

Drs. J. Yudkin and G. W. Robertson discussed the incidence of lowered dark adaptation and the effects of treatment with vitamin A or carotene. They have found that in some factories in the Midlands, less than 50 per cent of workers between 15 and 20 years of age have good dark adaptation.

In the afternoon, with Sir Joseph Barcroft in the chair, the subject was clinical signs of dietary deficiency. Dr. B. S. Platt showed a remarkable series of photographs to illustrate the effects of deficiencies in China and Africa. He stressed the incidence of mild wet beriberi; in some factories in Shanghai, half the workers had œdema of the ankles. He pointed out the relation of infection of the skin and mouth to vitamin deficiency and concluded by showing photographs of two groups of African workers, one ill-fed, listless and silent, the other well-fed, vigorous and noisy: the aim of the science of nutrition should be the cheerful vigour of the second group.

Dr. R. H. Dobbs enumerated various methods used in the assessment of the nutrition of children, particularly those of von Pirquet.

Mr. W. C. Nixon argued that pregnancy imposes a special strain that brings out latent deficiencies of nutrition. For example, among a poor Chinese population, vitamin B_1 deficiency was endemic. Frank beriberi appeared late in pregnancy, although during the earlier months the women suffered from cramps and vomiting. Œdema of the ankles might be present for several weeks before the onset of severe beriberi. Much of the illness associated with pregnancy may be due to deficient food.

The discussion of the nutrition of farm animals was opened by Dr. C. Crowther. He pointed out the differences in the aims and methods of the study of the nutrition of human beings and animals. The estimation of the nutritive value of the food of farm animals is much complicated by the fact that cellulose cannot be neglected. The calculation of the energy value of food has done more than anything else to improve the scientific control of feeding. Farm animals are not liable to suffer from vitamin deficiency unless they are confined and fed on concentrates. Dr. Crowther insisted on the interaction between the various constituents of a diet; it is not possible to regard the effects of constituents as merely additive.

Dr. H. H. Green gave examples of deficiency diseases in farm animals, including deficiency of trace elements. Dr. John Hammond showed a series of diagrams illustrating the effect of underfeeding mother and offspring on the growth and physical conformation of the offspring. The physique is permanently affected by a low level of feeding during the early months of growth.

Unfortunately, more than one of the speakers appeared not to have prepared his address and wasted the time of the meeting while he sought for his thoughts, or words in which to express them, and/or repeated himself. Open discussion had to be left until after tea. Although many members had left, there was a valuable exchange of views.

THE MECHANICAL PROPERTIES OF SOLIDS*

By PROF. E. N. DA C. ANDRADE, F.R.S.

STRENGTH OF SOLIDS: GENERAL

WHILE the specific heat, melting point and many other physical constants of a crystal are definite for any defined chemical composition, the mechanical strength may vary widely from specimen to specimen and depends markedly upon previous history. The existence of structure-sensitive properties in crystals shows that actual crystals cannot consist of atoms or molecules arranged in the perfect pattern contemplated by the mathematician nor can they be structures in thermodynamic equilibrium. If crystals were perfect they would all have the same properties if of the same material; similarly, if they were in thermodynamic equilibrium, they would eventually, from whatever arrangement they started, reach a final arrangement corresponding to the least free energy, and this arrangement, and consequently the mechanical properties, would always be the same. All crystals as usually dealt with must, then, be imperfect, although the possibility of preparing a perfect crystal must not be definitely excluded.

Under tension a theoretically perfect crystal should show perfect elasticity up to a high strain and have a sharp breaking point. Under shear stress it should likewise have a wide range of perfect elasticity, and if the stress exceed a certain value unlimited glide should take place. In neither case is plastic yield and work hardening, such as is actually observed with metals, to be anticipated. We can, from quite general considerations based upon the energy required to form a new surface, make a rough estimate of the tensile strength to be expected in the case of a perfect crystal, and find that for the strongest metals this hould be about 360 kilobars (=2,300 tons weight per sq. in.), which is about forty times the tensile strength of the toughest metal. If we take the yield-point, instead of the tensile strength for comparison with the theoretical value, the discrepancy is even greater. Similar calculations can be carried out for the theoretical shear strength, and give a value of about 130 kilobars, some forty times that observed for steel. Thus even the toughest metals show much less than the theoretical strength.

Ordinary metals, however, are polycrystalline; it may be suggested that for comparison with theory it would be fairer, perhaps, to consider a single crystal. Let us take rock salt as an example, for it is a simple face-centred cubic crystal composed of alternate positive and negative ions, for which the mathematicians can carry out exact calculations, of, for example, the theoretical strength. For rock salt this works out to be 20 kilobars and rupture should theoretically be preceded by an elastic extension of 14 per cent. The actual breaking strength of rock salt under tension is, however, about 20 bars, that is, about one thousandth of what it should be. Rock salt does give brittle fracture, with very small extension at ordinary temperatures, although at higher temperatures, about 600° C., it shows plastic behaviour.

A perfect ionic crystal of a type which is for most purposes well understood theoretically is, then, in practice much too weak and has much too small an elastic region. Let us look at its behaviour in a little more detail. To examine a transparent crystal we have an agent which we cannot use for metals—polarized light. A cubic crystal such as rock salt has, in an unstrained condition, no effect on such light; any strain that makes the crystal depart from its precise cubic structure causes it, however, to become doubly refracting. Obreimow and Schubnikow[1] loaded a crystal of rock salt in a beam of polarized light; at a low stress, of about 8 bars, bright streaks appeared along two directions at right angles, which were the traces of (110) planes. These lines did not appear as soon as the stress was applied, but arose spontaneously some 20 seconds later. As the stress was increased the bright lines increased in number, but appeared always in the same crystallographic directions. Surface marks also appear in the same direction if the crystal undergoes plastic extension at high temperature. The crystal shows permanent slip on certain crystallographic planes, but polarized light shows that its crystalline perfection has been destroyed along these planes. The glide-planes were established much earlier in metals, but I quote rock salt first because of the ease with which this latter point can be established. The same thing has been shown with other transparent crystals, for example, potassium halides.

Let us see if we fare any better as regards strength if we take a non-crystalline substance, say glass. The surface tensions of molten glasses are round about 150 dynes per centimetre, which gives theoretical strength of the order 100 kilobars. The actual strength of ordinary glass fibres, which give brittle fracture at room temperatures, is from

*Abridged from the Forty-seventh James Forrest Lecture of the Institution of Civil Engineers, delivered on April 29.

300 to 900 bars—less than one hundredth of what it should be. Here, however, we meet a curious fact of great importance for our subject: freshly drawn glass fibres, of hard glass, are very much stronger than old fibres, of the same glass, but gradually lose their strength as time goes on and come down to a steady value. Touching or handling the fresh fibres weakens them. A. A. Griffith[2], who has carried out fundamental work on this subject, assumes that the cause of the weakening is the formation of invisible surface cracks, which are absent in a fresh fire-drawn material. The breaking strength will depend upon the depth of the crack and the radius of curvature at the end: the greater the former and the smaller the latter, the higher the local stress and the weaker the material. There is a limit to the radius of curvature: it cannot be less than something of the order of the inter-atomic distance. If we assume a reasonable value we can work out the depth of the crack needed to give the observed strength, and it comes out about 1 or 2μ, say twice the wave-length of visible light. Of course if we have threads of this order of diameter we cannot have cracks of this depth, and very fine threads are, in fact, much stronger per unit cross-section than large threads. The variations of stress, due to cooling, necessary for the formation of the cracks, probably cannot be established in such fine threads.

These cracks are no longer a mere hypothesis. Mr. Tsien and I[3] found that attack by sodium vapour (but not by hydrofluoric acid) would develop the cracks and make them visible. On freshly drawn hard glass tube, no, or very few, cracks could be detected; on the same tube, when a day or two old, many cracks were made visible. They ran transverse to the direction of drawing of the glass rod or tube, as they should. Various controls established that we were not dealing with a spurious phenomenon. Dr. Martindale and I[4] also found that when very thin films of gold and silver were heated to about 300° C. on glass surfaces minute crystallites formed up in lines, which were in general parallel. These lines are not caused by visible scratches but are attributable to minute surface cracks. I may add that just before the War, I succeeded in showing the minute surface cracks in hard glass by a special type of illumination[5].

An experiment of Orowan's[6] is instructive in this connexion. If a strip of mica be loaded by means of parallel metal clamps, extended across the whole strip, so that the edges are stressed, we find a maximum strength of about 3 kilobars, approximately that of wrought iron and very much in excess of that of glass and of rock salt. The flat faces of mica are very perfect, and show no lines of minute crystallites when metal films are heated on them. The cut edges have, of course, no such perfection. By using special clamps, gripping the sheet near the middle only, stresses at these edges can be avoided. For a mica sheet loaded in this way the strength goes up to 32 kilobars, more than ten times that with the other method of loading, and much in excess of that of the best constructional steel. The prejudicial effect of trivial and invisible cracks at the cut edge is clear.

There are many industrial examples of the importance of the avoidance of surface cracks. Toughened glass is prepared by rapidly cooling the surface of the slabs while the interior is still molten. When the internal part solidifies and cools, the shrinkage pulls the surface into a state of compression, which prevents the formation of cracks. The glazing of industrial porcelain, for insulators and such like, is also instructive in this connexion. If the object is to be strong the glaze must have a coefficient of thermal expansion lower than that of the porcelain body. When the cooling takes place after glazing, the greater shrinkage of the body pulls the surface glaze into a state of compression. If a glaze with a higher coefficient of expansion be used, the strength of the porcelain is less than that of the unglazed body. The swelling of the metal surface by the process of nitriding may also act as a talisman against fatigue cracks, which usually start at the surface.

Glide in Metal Single Crystals

At first it might seem possible that the failure of a piece of ordinary polycrystalline metal to show the properties of a perfect crystal could be attributed to the fact that it is not a single crystal, but an aggregate of small crystals with their axes in all directions. The crystal boundaries might play an important part in determining the metallic properties. We shall see that they do, but scarcely in the way to be anticipated. In any event, it is clear that if we desire to understand metallic behaviour we must first understand the behaviour of a single crystal of metal.

Metal single crystals in the form of wires and rods can be prepared in a variety of ways and exhibit many peculiar properties. In the first place they are not, as might be expected, very strong but they are very soft. They also show very remarkable strain hardening. A copper crystal rod half an inch in diameter behaves like lead at first manipulation; it can be very easily bent in the hands, but becomes progressively harder to deform. It takes a very strong man to bend back to its original form such a rod that has once been deformed into a semicircle. Brittle behaviour is not unknown in single crystal specimens (bismuth

Fig. 2.

SLIP PLANE OF MOLYBDENUM AT 2,000° C. FROM ANDRADE AND CHOW, *Proc. Roy. Soc.*, A, **175**, 290 (1940).

crystals, for example, show brittle fracture at low temperature), but it is not typical.

Remarkable properties of single crystal wires can be exhibited by simply subjecting them to tension. On slight extension a number of parallel markings appear on the surface and as elongation proceeds these become, in general, more and more marked: in some cases the number increases. The wire retains practically its full diameter in one direction and thins in a direction more or less normal to this, so that in the case of wires that can be pulled to several times their original length, such as, for example, cadmium wires, the original cylinder becomes a thin ribbon. As the result of the work of Polanyi, Schmidt, G. I. Taylor, and others this behaviour has been expressed in terms of the geometry of the crystal[7]. The slip takes place preferentially on certain types of crystal planes and in certain definite crystallographic directions—the glide planes and glide directions.

If slip took place equally readily on all parallel atomic planes the crystal surface would, of course, be as smooth after extension as it is before extension. What takes place, however, is a preferential glide in the neighbourhood of certain planes, the so-called slip planes, spaced at more or less regular intervals, so that the crystal appears to slip in parallel slices or slabs. This produces the remarkable stepped appearance characteristic of crystal wires that have been much extended. In general the spacing of the slip planes becomes wider and wider as the temperature is raised. With molybdenum at 1,500° C., for example, the coarse appearance of the slip packets is very striking, as seen in Fig. 1; with molybdenum at 2,000° C. the slip may take place all at one plane as shown in Fig. 2. This may be compared with the appearance of cadmium at room temperature (Fig. 3). It has been suggested that the choice of the particular region where marked glide takes place may be due to local impurities, but experiments carried out in my laboratory with wires of exceedingly pure solid mercury (the impurity was probably about 1 in a hundred million), show that this cannot be so. The slip bands are very fine and close, as shown in Fig. 4. The whole question of the formation of these bands, which represent a kind of local avalanches, is a complicated one.

STRENGTH OF METAL SINGLE CRYSTALS

When we turn to the question of strength, we enter a very difficult field. The simplest case is that of brittle fracture. The determining factor here is the tension normal to the plane of rupture.

Fig. 3.

SLIP PLANES OF CADMIUM AT ROOM TEMPERATURE. FROM ANDRADE AND ROSCOE, *Proc. Phys. Soc.*, **49**, 152 (1937)

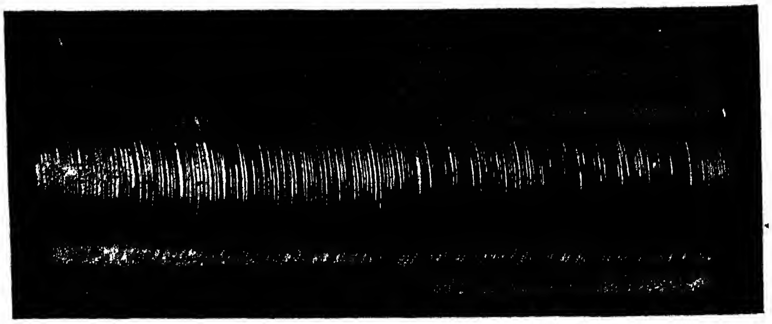

Fig. 4.

SLIP BANDS OF PURE MERCURY. FROM GREENLAND, *Proc. Roy. Soc.*, A, **163**, 28 (1937).

If the critical tension N which leads to fracture, the critical shear stress S, and the crystal structure are such that a crystal can be so disposed that the stress resolved normal to the plane of rupture is N while the stress resolved along the glide direction is less than S, fracture without glide can take place. With crystals of hexagonal structure it is possible to realize these conditions, and we find that the recorded critical tensions run from 120 to 18 bars with different metals and different temperatures; for example, 20 bars for the basal plane of zinc at $-185°$ C. This compares with 1·3 kilobar for polycrystalline zinc and a theoretical value of some 100 kilobars.

Brittle fracture is, however, rather the exception than the rule. For metals of cubic structure, where there are many alternative equivalent glide planes, the values of N and S and the geometry of the crystal apparently prohibit it. Even with hexagonal metals, glide is the normal occurrence.

The inception of glide, which takes place by sudden avalanche-like slipping in the neighbourhood of isolated planes, occurs at very low stresses, of the order of 20 bars, much less than one thousandth of the theoretical strength. If we wish to consider rupture, we are confronted with a variety of processes that can take place before actual fracture. We have in general a progressive hardening as movement proceeds, but quite often, especially with hexagonal metals, we ultimately get twinning, leading to glide on a fresh set of planes, at a new inclination, which is followed by fracture. In the case of hexagonal metals, where brittle fracture can be brought about by suitable geometrical conditions, the glide which takes place before rupture can either raise or lower the breaking strength, according to temperature. For these metals the breaking strength is, however, of the same order as that in the case of brittle fracture. In the case of certain metals, glide can lead to very great hardening, so that stresses of nearly a hundred times the critical shear stress can be supported, but here, as will be pointed out, the result of glide is that the specimen has lost much of its monocrystalline character. It remains true that a single crystal is very soft.

Before we look at any further facts, it may be well to consider the attempts that have been made to explain theoretically the outstanding difficulties offered by the softness of the crystals—their proneness to glide under very small shear stresses. The atoms are bound in their places by interatomic forces, the potential of the field of force having a minimum at the position where the atom is in equilibrium. If an atom is moved from this position the force tends to restore it; the case is similar to that of a table covered with a regular network of depressions, with a ball lying in each depression. Now consider the force required to move all the balls at once in a given direction, so that each rises out of its hole and falls into the next hole in that direction. It will clearly be the force required to move a single ball multiplied by the number of balls, and this is equally true when a ball lies in every hole and when a few vacant holes are included in the array. The low value of the critical shear stress cannot be accounted for on the basis of the simultaneous movement of all atoms in a glide plane.

The position may perhaps be clarified by considering simply a row of cylinders touching one another, with a second row of cylinders resting on them, as in a model which I have constructed. The force required to move one whole row over the other is considerable. Suppose, however, that the number of cylinders in the upper row is one or two fewer than that in the lower row. A place of non-fit, or dislocation, is arranged at one end of the row, towards the right, there being four in the upper row to five in the lower row here. To make the model resemble the atomic case all the upper cylinders in the model are connected by a long strip of elastic band. If we now run our hand over the upper row, from right to left, which is equivalent to imposing a force from left to right on the lower row, it is easy to make this dislocation travel along: at any given moment we are only moving a few cylinders through the periodic field of gravitational potential. After the dislocation has travelled, however, every cylinder has moved one place and the whole row has been displaced relatively to that below, although at any given moment we were only moving a few cylinders.

The fact that glide takes place at shear stresses so far below the theoretical value shows that a whole sheet of atoms cannot travel at once over a neighbouring sheet. The conception of the glide mechanism, which we owe to Polanyi, G. I. Taylor and Orowan, postulates that in the metal crystal there are small localities in which the crystal is out of joint, places of misfit something like that represented very crudely in our model. Under shear the whole crystal plane does not move by one atomic spacing simultaneously: rather the misfit runs easily through the crystal, leaving in its wake atoms properly spaced. In a sense, then, the weakness of the crystal is due to imperfections which are somehow inherent in the structure. A perfect crystal might have theoretical strength, but probably no such thing exists.

There is considerable doubt and diversity of opinion as to the origin and end of the dislocations. G. I. Taylor[8], for example, when proposing a very suggestive but rather formal two-dimensional model, considers that the stress produces in the metal crystal a multitude of regularly spaced

dislocations, which run a certain distance and then end their course in flaws which he postulates. It is difficult to see on this picture anything to prevent the effect being reversible, which it certainly is not. Orowan considers that the dislocations are created at microscopic 'Griffiths cracks', sharp notches where the stress has values considerably above the average, and that they run right across the specimen. W. G. Burgers and Kochendörfer believe that the crystal is built up of small blocks in which the orientation of the crystal structure differs slightly from block to block, for which there is X-ray evidence with rock salt and some other crystals. The dislocations are then supposed to start from the boundary of the blocks. There is no space to discuss details: the general conception of a travelling misfit seems, however, to be the proper basis for any theory of glide.

Another fruitful conception is that of cracks, notches, or other regions of local peculiarity leading to increased local stress. If these regions of stress concentration are small, the stress will depend upon the irregularities of atomic motion in the neighbourhood—the so-called temperature fluctuations, which are the more violent the higher the temperature. Every now and then the atoms so will dispose themselves that, speaking loosely, the crack is sharper: the longer one waits the greater the chance that the local stress reaches some high critical value. This conception is due to Becker[9]: it has been elaborated by Orowan. The rate of flow of a crystal under stress will be proportional to the frequency with which the critical stress is reached. This leads to the following formula for the rate of glide, u:

$$u = Ce^{-V(R-qS)^2/2GkT},$$

where R is the true critical shear stress, S the average externally applied stress, q a factor to represent the increase at a "notch", G the shear modulus, k Boltzmann's constant, T the absolute temperature, and V a certain small volume.

This formula has certain interesting consequences. It shows the rate as depending very strongly on the stress: according to it, flow should take place at any stress, but if the stress is below a certain value the flow is unobservably small. This is the kind of thing we must expect to find in theories based upon probabilities.

If this view is correct, we cannot define a critical shear stress for a single crystal by saying it is the resolved shear stress at which glide begins to take place, for this will depend upon what rate we are prepared to consider noticeable. I have suggested that we define it as that at which an extension of 1 per cent per hour takes place. This seems a convenient arbitrary figure, but it is nothing more. The exact rate does not make much difference: in the case of very pure cadmium, considered by Roscoe and myself[10], stresses of 1·5, 1·3 and 1·0 bar gave rates of 1 per cent per 13 minutes, per hour, and per 7 hours respectively.

This way of regarding critical shear stress as the stress at which a determined slow rate of glide begins also explains a remarkable fact, as pointed out by Orowan, who has emphasized the importance of concentrating on the rate of flow as a property of the single crystal. While the rate of flow at a given stress increases very rapidly with the temperature, at a given stage of the flow, and the strain hardening is also very susceptible to temperature, the critical shear stress is not very much influenced by temperature: even at $-235°$C. it is, for cadmium, only four times as big as it is a few degrees below the melting-point of the metal. If we take the critical shear stress to correspond to a fixed value of u at all temperatures, this means that $(R - qS)^2/T$ is approximately constant, which gives $S = A - B\sqrt{T}$, a relation which agrees quite well with experiment.

The difficulty of interpreting curves showing the shear stress plotted against extension ('hardening' curves) will now be clear. If flow is taking place all the time, these curves will depend upon the rate at which stress is increased. By working within a region where the rate of flow is very small, and applying the stress fairly rapidly, hardening curves with some meaning can be obtained, but sufficient attention has not always been given to this point. The whole question is a troublesome one, complicated by the effect of recovery, that is, a crystal that has been hardened by strain becomes soft again if left to itself at a sufficiently high temperature: for 'soft' metals, like cadmium, room temperature is sufficient. Actually, true flow in the absence of recovery undoubtedly exists, as can be demonstrated by working at low temperatures, where the rate of recovery must be so exceedingly slow as to be quite negligible: but recovery undoubtedly plays a part in flow at higher temperatures.

The time element being eliminated as best one can, curves showing the variation of stress with glide at temperatures suitably chosen can be obtained. Some very striking results are available on metals of comparatively high melting-point. Measurements made by Sachs and Weerts[11] and by Osswald[12] show that with a single crystal of nickel a shear strain of 30 per cent produces an increase of shear strength of fourteen times; with copper a shear strain of 67 per cent produces an increase of strength of sixty-eight times; while with silver a shear strain of 95 per cent produces an increase of strength of ninety-two times, all at atmospheric temperature. In many cases the hardening at low temperatures varies as the square

root of the glide: at high temperatures it tends to show a linear variation.

We have now to consider how this hardening under strain comes about, and here X-rays furnish a valuable method of attack.

If we take a Laue photograph with an unstrained single crystal, we obtain a pattern of single spots, of the familiar type, but if we strain the crystal the spots are drawn out into smears, called 'asterisms', just as would be observed in the case of a large number of crystals, oriented in slightly different ways, so as to give a train of overlapping spots. The heavy strain has produced a change in the crystal structure; in fact it looks as if the single crystal is strong because it is no longer a single crystal.

With Miss Chow I carried out some experiments[13] on sodium single crystals, extending them by an equal amount at various temperatures and measuring (1) the stress required to produce this extension, (2) the spread of the asterism. It is easy to measure this with sodium, since the asterism takes the form of discrete spots, due, as we showed, to recrystallization; the separation of the extreme spots represents the range of rotation of crystalline fragments produced by stress. These experiments show that at low temperatures, where the crystal is strong, the spread is much greater than at higher temperatures, where it is weak, for the same overall strain. We have also been able to establish some numerical regularities. I think, then, that there is now definite evidence that the strengthening is largely due, at any rate, to the break-up of the crystal, to a loss of its single crystal character. Much more experiment is, however, needed to clear up the situation.

Polycrystalline Metals

This brings us half-way to real metals and the problem which interests the engineer—Why are polycrystalline metals strong? There are very few experiments available on the dependence of strength on grain-size. In its simplest aspect this problem demands an absence of plastic deformation, which at once complicates the question, but on the whole it looks as if small grain size is favourable for strength. During plastic deformation slip takes place in the individual crystallites, the axes of which are differently oriented. In some way the boundaries between the crystallites must confer strength, but they cannot do it because they are inherently strong—the number of atoms involved is too small. Expressed in another way, the crystal boundaries cannot be regarded as playing the part of the steel rods or expanded metal in reinforced concrete: they are too thin, whatever reasonable strength be attributed to them.

Supposing that, to account for their weakness (low yield-point) as compared with ideal crystals, we accept the hypothesis that the crystallites contain submicroscopic flaws, similar to Griffiths cracks in glass, where the stress-concentration is abnormally high. If a dislocation runs from such a crack it will travel as far as a crystal boundary and will then find, for a region a few atoms thick, in any event, a place where the regularity necessary for it to propagate itself is lacking—it loses itself, but not because the boundary is hard, rather because it is soft. An experiment which I carried out some time ago may illustrate the point.

To show the effect of crevasses in weakening a solid, I cut transverse slots in celluloid strips, and compared the strength of these strips with that of other unpierced strips, of equal carrying breadth. The weakening effect of the cuts which was to be anticipated did not, however, show itself. Examination shows that at the ends of the crevasse, where the curvature was greatest and tearing should have taken place, the celluloid had yielded plastically, with slight local deformation made evident by a turbid appearance. The theoretical weakening effect of a crevasse is based upon a postulated rigid behaviour of the solid: if the solid yields plastically the local stress is dissipated and the tearing does not take place. The analogy is not a perfect one, but it does show how strengthening can take place by weakness.

There is no doubt that the intercrystalline boundaries play a very important part in the strength of metals. However, the experimental study of the properties of these boundaries is only just beginning, and, although Chalmers[14] has carried out interesting experiments on the subject, much work with different metals and at different temperatures is required before we have enough material to found a comprehensive theory. The properties of single crystals of metals may seem curious and curiously remote from anything that the engineer experiences, but it is in terms of their behaviour, and of the behaviour of the less regularly ordered atoms in the boundaries between crystals, that we must seek an explanation of the secrets of the ironmaster and of the worker in non-ferrous metals.

OBITUARIES

Dr. John Ball

BY the death of Dr. John Ball, science has lost a man of outstanding character and calibre, whose experience and contributions ranged over a wide field. His career was marked by hard work, enthusiasm, an inquiring and penetrating mind, a perception of essentials, with bold ideas and restless vigour. John Ball loved a problem and was relentless in pursuing it. New evidence and new methods usually intrigued him, though at times he seemed obdurate before accepting them. Many who read this obituary will remember with affection the breathless discussions in Egypt, London, and elsewhere, in which his partial deafness was overcome by cheerful enthusiasm, his electric device, and the seemingly endless supply of new batteries. He loved a meeting of those who shared common interests, such as the Zerzura Club of desert travellers, and the conversation on these occasions remained practical, technical, constructive; there was always something worth learning. He served in Egypt for forty-four years, and remained there during the present War; to this fact possibly his recent death in his seventieth year may be attributed.

The following is a brief sketch of Ball's career. He was educated at the Royal College of Science and Royal School of Mines, Freiberg, and the University of Zurich, and apprenticed to the Phœnix Foundry Co., Derby, where he was engaged on some important engineering works, including the Battersea Bridge, and the Liverpool Overhead Railway. The Royal School of Mines recognized his merit: then his career took him into mining, and he spent a year or so in Germany and Spain. From this period of his life four sciences already seemed to stand out, namely, mathematics, engineering, surveying, and geology. He was a marked man for the type of reconstruction and development which was afoot in Egypt at the end of the last century, and joined the Survey of Egypt in 1897. The second period of his career, which had a logical development over nearly half a century, showed the same basic interests. He was responsible for under-pinning the Temples at Philae during 1901–2 when the Assuan Dam was constructed. There was a primary demand for his geology and surveying, which bore fruit not only in his classical work on the geology of the First Cataract, but also in the early surveys of the Libyan oases of Kharga, Baharia, Kurkur, and of the south-eastern deserts of Egypt.

Geology and topographical survey developed Ball's interest in wider exploration, and the War of 1914–18 provided unexpected opportunities. John Ball and other officials and officers ranged far beyond the Egyptian oases of the Libyan Desert with the military motor patrols, and over Sinai; useful series of maps were produced for military purposes. He conducted surveys for the British Government in Somaliland and Arabia, and collaborated with the R.A.F. in the surveying of the Cairo-Baghdad air route in 1921.

Among all these efforts, the Libyan Desert seems to have intrigued Ball more than any, and it is in a sense true to say that much of his interest in the period from 1919 was devoted to that empty quarter. Thus he accompanied Prince Kemal ed Din on three of his expeditions, including the momentous journey to Merga and 'Uweinat. Many problems set his logical brain at work; for example, the nature and origin of the artesian water supplies in the oases, the growth and movement of the great sand dunes, and later the Qattara Depression near the Mediterranean coast, considered as a potential source of hydro-electric power. The examination of these problems of the Libyan Desert, which could not be the work of one man, was shared first by the small band of Survey officers past and present, secondly by a growing number of travellers who were not officials of the Egyptian Service. Discoveries and routine work of all of them were grist to the mill. Cars replaced camels, the sun compass, of which Ball was a pioneer, superseded native guides. His contributions included his early use, if not the first, of the depression angle method of coastal surveying, and his "Handbook of the Prismatic Astrolabe".

For many years after 1918, Ball was Director of Desert Surveys in Egypt, and then Technical Counsellor until his death. In his later years none of his interests seemed to flag. His last considerable work was his "Contributions to the Geography of Egypt" (1939)—in effect a series of essays on problems that had long claimed his attention, especially the development and history of the Nile and of its perplexing and troublesome appendix the Faiyum. In these essays all the initiative, perception and youthful enthusiasm remained, and if others may not agree with all his conclusions, nevertheless his evidence and deductions are clear for all to read.

John Ball received many honours, and perhaps those which he valued most were the De la Beche Medal of the Royal School of Mines, his D.Sc. of the University of London, the Mejidie (for his work at Philae), and the Victoria Medal of the Royal Geographical Society (primarily for his pioneer scientific work in the Libyan Desert). His wife and son survive him.

K. S. SANDFORD.

WE regret to announce the following deaths:

Prof. M. Bodansky, professor of pathological chemistry in the Texas University School of Medicine, aged forty-five.

Mr. W. H. Heaton, formerly principal of University College, Nottingham, aged eighty-five.

Prof. F. Kafka, director of the Psychiatric Clinic in the German University of Prague.

Prof. H. Klein, professor of neurology and psychiatry in the University of Leipzig, aged sixty-six.

Prof. A. Westphal, professor of neurology and psychiatry in the University of Bonn.

NEWS AND VIEWS

Book Production in War-time

After lengthy discussions last year, books were exempted from the Purchase Tax, on the grounds of their cultural value and their value as exports. Having survived the threat of ordeal by taxation, books are now confronted by the ordeal of war-time shortage of materials and labour. Lord Samuel raised the question of book supplies in the House of Lords on October 23. Apart from the fact that book production in Great Britain last year amounted to £10,000,000, of which a third was for export, he pointed out that only a fraction was what may be termed 'light literature'. Books are urgently needed in the Services, by munition workers, technicians, scientific workers and medical students. No fewer than twenty million volumes have been destroyed by enemy action. Publishers are already working with about 50 per cent of their pre-war supplies of materials; further withdrawal of materials and labour would be a serious blow to the national interest.

Lord Snell replied on behalf of the Government. He said that the Government is not indifferent to the issues raised. The real difficulty has arisen from the shortage of material for making paper. Since 1940 we have lacked supplies from Scandinavia and Finland, and have had to depend on North America. He asserted that the Ministry of Labour has reported that there is no serious shortage of labour for the production of books, and the Board of Education has had no representations of a serious shortage of books for elementary or secondary schools. He thinks something might be done to economize by using thinner paper, narrower margins and the collection of waste paper.

The significance of this reply turns on the interpretation to be placed on the words "serious shortage". Shortage there is bound to be in these days of stress and trial, even apart from the need for replacing at least some of the twenty million volumes destroyed. Nevertheless, the fact remains that many standard text-books have been unobtainable in recent months. In many cases the books are already printed and are awaiting binding. Few new books of this character are being published. Shortage of paper has little to do with this situation, as a consequence of which students of all types are deprived of essential books. As regards the suggested economies, it has to be remembered that many text-books are printed from electrotype plates. Thus the size of the page is fixed when the book is first made, and cannot be varied except within narrow limits. The low price of text-books, which are costly to produce, depends on the possibility of using such methods of production. It would seem therefore that every endeavour should be made to see that further restrictions are not imposed. Lord Samuel has done well to direct attention to the dangers of the situation.

Use of Paint in Camouflage

Sir John Graham Kerr, a member for the Scottish Universities, spoke in the House of Commons on October 23 on the use which is being made of camouflage. He divided camouflage roughly into two aspects, structural, and by pigment and paint respectively. Structural camouflage, whereby an attempt is made to disguise or even to hide a building or object, is, in Sir John's opinion, reasonably well done. Where the use of paint is concerned, as in concealing or giving a misleading appearance to an object such as a gun, he contends that present practice is ineffective. The general principles of camouflage by paint are well established, based on observations on wild animals: they are counter-shading and dazzle. Counter-shading, in which an animal is dark above and light underneath, the two regions merging into one another, reduces the appearance of relief and makes an animal appear flat. Dazzle has for its function the breaking-up of the surface and outline by violently contrasting tones of pigment. Both methods are observed operating effectively in wild animals. They have been elucidated, and also applied to warfare, by biologists. Yet the illustrations in current periodicals, and also direct observation, show that guns, vehicles, etc., are not being properly camouflaged. Sir John also referred to a recent picture of the Prime Minister against a background of guns which are "coloured, dark above and white below . . . [the colours] separated by a sharp line which does away with nine-tenths of the effectiveness that the counter-shading should have". The fundamental principles of camouflage being known, steps should be taken to apply them correctly, in order to obtain the maximum protection.

President Roosevelt on Resource and Research

In the *Bell Laboratories Record* of July is printed a report on "Research—A National Resource. Part II, Industrial Research" which was transmitted to the Congress of the United States by President Roosevelt. The report was prepared by the National Research Council, of which F. W. Willard, president of the Nassau Smelting and Refining Company, was chairman. Among members of the committee were F. B. Jewett, O. E. Buckley and R. R. Williams. The chapter on mathematics in industrial research was written by T. C. Fry. The President included with the Report the following message.

"To the Congress of the United States:

"One of the greatest resources in the arsenal of democracy is our national ability and interest in Industrial Research. For the vigorous prosecution of our defense program and for the assurance of national progress after the emergency we rely heavily

on the continued vitality of research by industry in both pure and applied science.

"Our people can justly take pride in the record of the accomplishment by American industry contained in the report on 'Research—A National Resource. Part II, Industrial Research' which I am transmitting for the information of the Congress . . . .

"The report presents a clear record of how successfully we have translated our old time Yankee ingenuity for invention into American genius for research. Our scientists have uncovered and explained the secrets of nature, applied them to industry, and thus raised our standard of living, strengthened our defense and enriched our national life. . . . I commend a careful reading of this report to the members of the Congress.—Franklyn D. Roosevelt."

Development of the British Broadcasting Service

THE president of the Institution of Electrical Engineers for the current session is Sir Noel Ashbridge, engineering controller of the British Broadcasting Corporation. In his inaugural address to the Institution given on October 23, Sir Noel reviewed the growth of broadcasting in and from Great Britain from the beginning of the public service in November 1922 up to the present time. Prior to the War, the home broadcasting service utilized transmitting stations operating on wave-lengths in the long and medium wave-bands, agreed upon at various international conferences, for the use of all European broadcasting stations. As these wave-bands would accommodate only 126 transmissions in separate channels, whereas the actual number of stations provided for was 340, it is obvious that a considerable amount of sharing of wave-lengths between two or more stations was involved. As a result of the constant attention, research and development devoted to the subject by engineers and scientific workers, it is estimated that in 1939 the B.B.C. had achieved the position whereby nearly 90 per cent of the public could obtain good reception of two programmes, and something more than 98 per cent one programme. One of the graphs illustrating the address shows that the number of British wireless licences has increased at an almost uniform rate of half a million a year from 1922 until 1939, when some nine million listeners were licensed.

An experimental broadcasting service on short wave-lengths to countries overseas was started in 1927, and continuous development and extension has taken place since then, particularly in the period 1936–39. The value of short-wave broadcasting for the rapid distribution of news, information and propaganda has been rapidly appreciated by all the belligerent countries, and it is of interest to mention that, at the present time, broadcasts in some forty different languages are radiated from Great Britain. In the field of television, Sir Noel reminded his audience that Great Britain was the first to inaugurate a regular service for reception by the public in their own homes. After two or three years of regular working, television in Great Britain is in the almost unique and advantageous position of having to make a new beginning after the War, when the settlement of some fundamental problems will affect the future of a new industry for many years to come. In the concluding section of his address, Sir Noel commented upon his experience in the recruitment of young engineers from the technical colleges and universities. He expressed the opinion that there is room for improvement in the amount of business and administrative instruction given to technical students, and also in the closeness of collaboration between teaching and industry. Several times during the address, reference was made to the difficulties which have arisen in the past concerning the international aspects of broadcasting. It is to be hoped that, after the War, a sound wave-length plan for Europe and possibly beyond, can be built up on rational principles with due regard for technical facts, and free from much of the politics which have coloured so many of the conferences in the past.

The Place of Paracelsus in Medicine

IN a paper on Paracelsus read before the Section of the History of Medicine of the Royal Society of Medicine on October 1, Dr. H. P. Bayon said that it had often been noted that Paracelsus expressed his intense scorn for all orthodox medical learning and tradition, but little had been said about his medical practice, which was that usual in his time (see also NATURE of September 20, p. 332). So far as medicine was concerned, Paracelsus was mainly a destructive fault-finder, not a constructive critic like William Harvey; moreover, much of what he propounded did not stand the test of time. Though he paid lip-service to experience rather than authority, he indulged in profuse theorizing without suitable clinical, anatomical or biological observation. His religious views helped to mould many of his doctrines, and his combination of Christian religious thought, neo-Platonic philosophy and alchemical medicine inspired the formulation of Rosicrucianism. This romantic system caused a great stir in intellectual circles in the seventeenth to the eighteenth centuries, so that the question whether Paracelsus reformed medicine is best answered by deciding whether Rosicrucianism had any part in the evolution of modern medicine, which can claim to have relieved pain, explained and conquered many infectious diseases and also to have prolonged life. Such achievements were the life-aim of Paracelsus, who had a high and noble conception of the possibilities of medicine, but failed in demonstrating how such progress could be obtained. A careful study of Hippocratic and Galenical writings would have taught him that clinical observation, prognosis and diagnosis, together with experimental therapy, would trace the path along which medicine and natural science could and did eventually advance.

The Bronze Age in Kent

AN interesting find of Bronze Age material near Canterbury has recently been announced. It appears that a mechanical excavator working at a brick-field brought to light three spearheads, several celts both socketed and winged, part of a knife and fragments of a shallow cauldron together with an ingot of

smelted bronze. Here, no doubt, we have the stock-in-trade of some travelling Bronze Age tinker collecting scrap and perhaps casting new types of tools—new lamps for old! Naturally, the date when the hoard was collected or abandoned cannot have been earlier than that of the most recent tools it contains, and these would suggest that the tinker plied his trade in the Late Bronze Age.

Such 'hoards' have been found before in Kent. The largest and most important is the so-called Minster hoard of no fewer than 143 objects, which included socketed and winged celts, swords, spear-heads, palstaves, a sickle, a knife, scrap metal, etc. Other well-known ones have been discovered at Allhallows, Broadness, Cliffe, Morden, Saltwood, Sittingbourne, Stoke, Swalecliffe and the Isle of Harty. Kent was an important part of the country in the Late Bronze Age, suffering as it then did from continental invasions which must have made life somewhat unsettled. Perhaps this is why comparatively little domestic pottery of the period has turned up. On the other hand foreign contacts did lead to an enrichment of the material culture of the district. It is perhaps noteworthy that the dead were disposed of by cremation, the ashes being placed in pottery urns which were deposited in pits dug in the ground and covered over by round tumuli.

Luminous Strontium Sulphide

The usefulness of most forms of phosphorescent paint is limited by the rapid decay in luminosity when exposed in the dark. A new preparation with an appreciably longer useful luminous glow has recently been marketed; the phosphorescent material is luminous strontium sulphide, which is applied over an undercoat of titanium oxide. The makers are British Luminous Industries, Ltd., London, N.W.10. Apart from the many obvious uses in the 'black-out' (signs and markings would be quite invisible at any distances to which aircraft might approach), it is suggested that the application of this material to the ceilings of shelters and public buildings would provide illumination in the event of the failure of the normal lighting. The luminosity immediately after activation is so strong that this suggestion seems practicable.

Theodor Ritter von Oppolzer (1841–1886)

On October 26 occurred the centenary of the birth of the Austrian astronomer Theodor Ritter von Oppolzer who from 1876 until his death on December 26, 1886, held the chair of astronomy at Vienna. Born at Prague, he was the only son of Johann von Oppolzer, (1808–71), a well-known pathologist who held chairs first in Prague, then in Leipzig and Vienna. Though he took a degree in medicine, Theodor von Oppolzer, being of independent means, devoted his time to astronomy and built a private observatory. For ten years he studied asteroids and comets, on which he published a well-known "Lehrbuch". In 1873 he became connected with the great European degree measurement, and for some years was chairman of the Austrian Commission. In his later years he studied planetary disturbances, the motion of the moon, refraction and other subjects. His most notable contribution to science, however, was his "Canon der Finsternisse", containing the elements of eclipses of the sun and moon, some 13,000 in number, from 1207 B.C. to A.D. 2162 (1887). Among the honours he received were his election as an associate of the Royal Astronomical Society and as a corresponding member of the Paris Academy of Sciences. His son Egon (1869–1907) was an assistant at Prague Observatory and professor extraordinary at Innsbruck.

Ages of American Men of Science

In view of the comments on the present-day status of youth in science, beginning on p. 511 of this issue, the analysis of the ages of men of science on the U.S. National Roster of Scientific and Specialized Personnel presented by Dr. L. Carmichael, president of Tufts College and director of the Roster, to the American Psychological Association is of interest. More than one fourth of the first sixty thousand men of science listed on the Roster are less than thirty years of age. More than half are less than forty. Only a fifth are more than fifty. The total on the Roster now is more than 180,000. The Roster is the reservoir of scientific and other personnel in the United States for the defence programme, and is similar to the Central Register of Great Britain.

Recent Earthquakes

The U.S. Coast and Geodetic Survey, in co-operation with Science Service and the Jesuit Seismological Association, has determined the tentative epicentres of four recent earthquakes from reports received from seismograph stations. On August 2 the earthquake at 11h. 41·5m. U.T. had its epicentre near latitude 30° S., longitude 178·5° W. This is in the Pacific Ocean just west of the Kermadec Islands and the Aldrich Deep so that the suggested depth of focus of 100 km. is not unusual. Deep-focus earthquakes are frequent in this area. The earthquake of August 4 at 10h. 53m. U.T. probably had its epicentre near latitude 52° N., longitude 176·5° W., which is in the north Pacific Ocean near Adak Island of the Aleutian Islands group. The depth of focus of 100 km. was somewhat unusual for the district though it was exceeded by as much as 100 km. by the earthquake of August 6 at 6h. 15·3m. U.T. The epicentre of this latter shock was on the Alaska Peninsula. On August 15 the earthquake at 6h. 9·5m. U.T. probably had its epicentre near latitude 19° N., longitude 27° W., which is in the Atlantic Ocean north-west of St. Vincent of the Cape Verde Islands. As all these shocks had epicentres distant from human habitation no damage has been reported, but had they been near centres of population they would undoubtedly have been strong enough to cause considerable damage.

During the first fortnight of September, eight large distant earthquakes were registered at Kew Observatory. All gave a full suite of pulses, the greatest being on September 9. This started recording with a probable *iPKP* wave (compressional) at 7h. 38m. 52s. U.T. from a calculated epicentre distant

14,650 km. It reached its maximum at 8h. 30m. 4s. U.T. with a wave of period 28s. and ground amplitude of 66 μ at Kew. The shock of September 4 was only a little less intense and was probably better recorded. It commenced with *ePz* at 10h. 37m. 54s. U.T. from 15,300 km., attained a maximum of 56 μ at 11h. 30m. 34s. U.T. and finished recording at 14h. 10m. Two shocks were recorded on September 14, the first at 4h. 28m. 30s. U.T. from 12,600 km. and the other at 13h. 48m. 43s. U.T. probably from the same epicentre. All identifications and calculations are tentative.

During the latter half of September 1941, four large distant earthquakes were registered by the seismographs at Kew Observatory. The first, on September 16, began recording at 21h. 59m. 1s. U.T. with a probable $iPKP_1$ compressional wave on the vertical record, and from the tentative interpretation of the record it may have come from an epicentre 17,800 km. distant from Kew. The maximum ground movement attained an amplitude of 70 μ. The shock of September 18 began recording at 2h. 24m. 46s. U.T.; but since the pulses were small and emergent no interpretation can be given with confidence. The earthquake of September 21 began recording with *ePz* at 22h. 45m. 44s. U.T.; had a possible *S* at 50m. 12s., *eLQ* at 55·5m. and eL_R at 54·5m. The shock of September 24 was greater than the two previous ones. With a possible *iSKS* at 1h. 13m. 11s. U.T., it came from a probable epicentral distance of 11,850 km. and attained a maximum ground amplitude at Kew of 27 μ at 1h. 56m. 6s. U.T.

The Night Sky in November

THE moon is full on November 4 at 2h. U.T. and new on November 19 at 0h. 4m. Lunar conjunctions with the planets occur on the following dates: Mars on November 1d. 15h., Mars 0·1° S.; Saturn on November 5d. 7h., Saturn 2° N.; Jupiter on November 7d. 8h., Jupiter 4° N.; Mercury on November 17d. 17h., Mercury 2° S.; Venus on November 22d. 10h., Venus 8° S.; Mars on November 28d. 22h., Mars 2° N. On November 17 Saturn is in opposition to the sun and on November 21 Uranus is in opposition to the sun. The distances of the planets from the earth are then 756 and 1,719 million miles respectively. Mercury, Jupiter and Neptune are morning stars; Saturn is a morning star until November 17, and after that an evening star. Uranus is a morning star until November 20 and then it becomes an evening star. Venus and Mars are evening stars. Mars is a conspicuous object, crossing the meridian at 22h. 6m. and 20h. 13m., at the beginning and end of the month, respectively. Two meteor showers occur during the month. The Leonids, associated with Tempel's Comet, are visible on November 13–14, the radiant point being about R.A. 10h., Dec. + 22°. The Andromedes, associated with Biela's Comet, can be seen during November 18–24; the radiant being at R.A. 1h. 40m., Dec. + 43°. The Leonids are visible in the morning hours and the Andromedes can be seen in the evening. The Andromedes paths can easily be traced as they are slow moving meteors.

Comet van Gent (1941 *d*)

IN NATURE of August 2, p. 139, it is stated that a new comet (1941 *d*) had been discovered by Dr. H. van Gent, of Bosscha Observatory, Lembang. Dr. van Gent, writing from the Union Observatory, Johannesburg, informs us that the comet was discovered by him from plates taken with the Franklin Adams telescope at that Observatory. The comet was also discovered, independently, by Mr. G. du Soleil, Observatoire Privé, Kilominos (Ituri), Belgian Congo, on July 12.

Announcements

AT the quarterly meeting of the council of the Royal College of Surgeons of England it was announced that Mr. D. L. Kerr has been admitted as a Macloghlin scholar, and that Prof. John Beattie has been appointed Bernhard Baron research professor. The following awards were reported: a Prophit studentship to Dr. J. Clark Davidson; a Mackenzie Mackinnon research fellowship to Dr. Geoffrey Bourne.

AT the annual meeting of the Royal Society of Edinburgh held on October 27, the following officers were elected: *President*, Prof. E. T. Whittaker; *Vice-Presidents*, Dr. Leonard Dobbin, Prof. R. Stockman, Prof. James Ritchie, Dr. G. W. Tyrrell, Prof. C. T. R. Wilson and Dr. James Watt; *General Secretary*, Prof. James P. Kendall; *Secretaries to the Ordinary Meetings*, Prof. R. J. D. Graham and Prof. W. M. H. Greaves; *Treasurer*, Dr. E. M. Wedderburn; *Curator of the Library and Museum*, Dr. J. E. Mackenzie; *Councillors*, Mr. A. Graham Donald, Dr. Alan W. Greenwood, Prof. T. H. Milroy, Dr. W. P. D. Wightman, Prof. Edward Hindle, Prof. J. R. Matthews, Sir Arthur Olver, Dr. David Russell, Dr. Robert Campbell, The Right Hon. Lord Cooper, Prof. E. W. H. Cruickshank and Sir J. Donald Pollock, Bart.

THE Royal College of Surgeons of England has announced a vacancy for a Prophit studentship in cancer research. The studentship will not exceed the annual value of £500 with an allowance not exceeding £200 for expenses of travelling, and will be for one year in the first instance, but is renewable. Further information can be obtained from the Secretary, Royal College of Surgeons, Lincoln's Inn Fields, W.C.2. Applications should be made before November 22.

ERRATUM.—Sir Arthur Hill writes: "In my article 'The Search for Economic Plants, in NATURE of July 5, p. 15 and July 12, p. 42, Ephedra was accidentally included among the plants yielding important insecticides (p. 44, line 5 from base). This is, of course, incorrect. The alkaloid ephedrine, which is derived from the dried twigs of two Chinese and an Indian species of Ephedra (Gnetaceæ), is similar in its physiological effects to adrenaline in moderate doses. Ephedra plants and seeds have been sent by Kew to suitable Colonies in the hope of producing a supply of this valuable drug."

Action of Fast Hydrogen Ions on Lithium Chloride

We have bombarded targets of various light elements in the course of experiments on nuclear resonances ($p - \gamma$ reaction), and have noticed an interesting phenomenon with lithium chloride targets.

These targets were prepared by fusion of the hydrated salt (m.p. 490–600° C.) on to molybdenum surfaces. During bombardment with hydrogen ions ($^1H^+$ and $^2H^+$ in roughly equal proportions) at current strengths up to 100 microamp. and voltages up to 600 kv., the white colour of the targets changed to purple in the regions struck by the beam. The intensity of coloration increased with increasing current density, and in the centre of the bombarded region the target was black. The effect was confined to the surface as the coloured part could be scraped off the target. On exposure to the atmosphere the colour reverted gradually to white in about 3–5 minutes.

We considered that the phenomenon was possibly due to the formation of finely divided lithium, by reduction of the chloride, which would presumably be changed to the hydroxide on continued exposure to moist air. The appearance of blue rock salt, stated by some authorities to be due to the presence of colloidal sodium, seemed to support this view. Mellor's chemical treatise[1] refers to this matter with reference particularly to cathode ray bombardment[2], and mentions also the alkaline subchlorides, for example Li_2Cl, some of which are coloured, although their composition seems uncertain. The protonic range in the target was probably less than 6×10^{-4} cm., so diffusion of air into the target might be expected to be rapid in the region occupied by products resulting from the action of the beam. The possibility of some chemical reaction with the molybdenum backing plate was unlikely. The purple coloration was not found with lithium hydroxide or oxide targets, the former turning grey on bombardment.

These experiments suggest that the purple coloration was due to the formation of a subchloride. Experiments with another halide, calcium fluoride, also led to the production of purple targets on bombardment. In this case, the colour persisted for four days, after which the target was destroyed. The effect of oil vapour from the pumps used to evacuate the acceleration tube may be ignored. It was suggested to us that the effect was due, not to the primary positive ion beam, but to secondary electrons arising at the target. This is considered an improbable process, as the energy of most of these electrons would only be ~ 100 ev. Also, the fact that the coloured areas were fairly sharply defined, and limited to the part of the target struck by the primary beam, suggests that the secondary electrons were not responsible for the effect.

In view of the fact that there is no immediate prospect of continuing the experiments, it seemed that publication of a note, even at this stage of the work, would be of interest.

Penetrating Non-Ionizing Cosmic-Ray Particles

The main part of the non-ionizing component of cosmic radiation near sea-level consists of photons[1] and neutrons[2]. A rough survey carried out by Rossi and his co-workers[3] at sea-level did not give any evidence of penetrating neutral particles. Experiments of the same type by Rossi and Regener[4] at 4,300 m. above sea-level, however, show the existence of a small number of penetrating neutral particles. We have carried out similar experiments at sea-level with positive results.

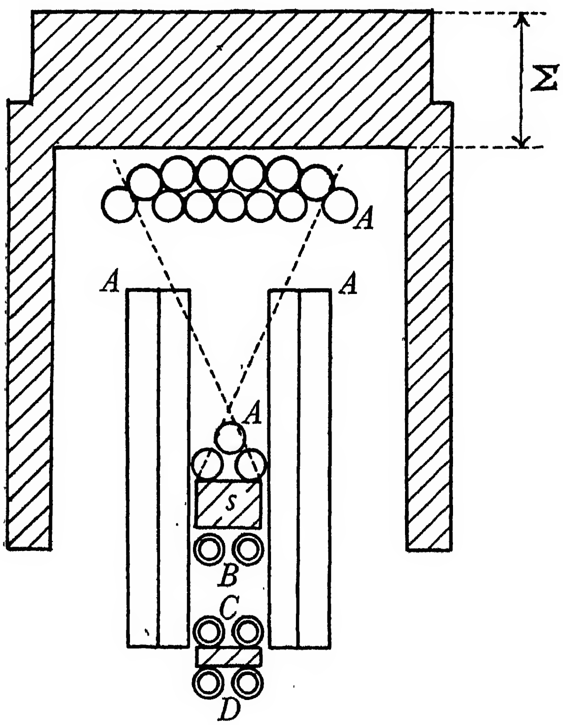
The experimental arrangement is reproduced schematically in the accompanying illustration. The threefold coincidence set *BCD* and the absorber *s* are surrounded on all sides except the bottom by an anticoincidence system *A* consisting of 76 counters in parallel. To avoid anticoincidences due to photons, the arrangement is surrounded by 5 cm. of lead. Some of our observations are given in the table below.

Σ	*BCD-A* (corrected for random coincidences *BCD, A*)		*BCD*	
Lead (cm.)	Time (hr.)	Rate (c./hr.)	Time (min.)	Rate (c./min.)
5·0	469·1	0·533±0·039	251	11·86±0·22
12·5	445·8	0·451±0·036	250	11·03±0·21
25·0	407·7	0·283±0·030	313	10·27±0·18
5·0+30·0 cm. Al	427·3	0·362±0·034	323	10·72±0·18

An anticoincidence *BCD-A* may be due to any one of the following effects: (1) A non-ionizing agent emerging from Σ, which produces an ionizing secondary in *s*; (2) a particle which travels upwards, gives rise to coincidence *BCD*, and is afterwards stopped in *s*; (3) an ionizing particle which leaks through *A*. The rate of anticoincidences due to (2) is not affected by Σ, while that due to (3) is no

more affected than the threefold rate *BCD* itself. Thus the decrease of the anticoincidences rate due to (3) when Σ is increased from 5 cm. to 25 cm. of lead is estimated to be rather less than 0·04 c. per hour. The difference of $0 \cdot 25 \pm 0 \cdot 05$ anticoincidences per hour observed between the rate with $\Sigma = 5$ cm. lead and the rate with $\Sigma = 25$ cm. lead must therefore be mainly due to non-ionizing particles.

If the anticoincidences with $\Sigma = 25$ cm. lead are taken as background, then the mean free-path of the neutral particles is about 10 cm. of lead, while the intensity of the neutral beam is estimated to be 0·03 per cent of the total cosmic ray beam at sea-level.



Anti-coincidence counter (A) ○ ◎ Coincidence counter

Comparing our data with those of Rossi and Regener, we estimate that the neutral intensity at Mt. Evans is 30–60 times greater than at sea-level. This increase, if exponential, corresponds to a mean free-path of the neutral particles of about 100 gm. per cm.^{2}, in good agreement with the observed absorption in lead.

In order to give a possible interpretation of the observations, we consider the following processes. A fast neutron suffering a head-on collision with a proton inside a nucleus can transfer almost its whole momentum to the proton. According to Heisenberg[5], the mean free-path of a neutron which is stopped according to such a process is 12·5 cm. of lead. This process alone does not account for our observations, since the reverse process of protons producing neutrons should make the neutrons reappear. It has been suggested by Jánossy[6], however, from observations on penetrating showers, that fast protons traversing matter are quickly stopped by interaction with nuclear Coulomb fields, giving rise to penetrating showers. These two processes together would give for the mean free-path of the neutral radiation a value of about 140 gm. per cm.^{2}, in agreement with the present observations.

Further, it can be shown that the above interpretation of the observations accounts at the same time for the fact that the rate of particles producing penetrating showers[6] (0·01 per cent) and the rate of neutral particles are of the same order of magnitude.

Afterglow in Mercury Vapour

IN recent papers on this subject, Moore and Garth[1] describe experiments which indicate that the phenomenon is due to the existence of excited atoms which are formed, after the excitation has been cut off, by the dissociation of molecular particles. They suggest that this particle is the 'excited' molecule proposed by Arnot and Milligan[2].

Later experiments by Arnot and M'Ewen[3] have shown that the mercury molecular ions are formed by the three processes:

$$(1)\quad \underset{4\cdot86\text{ ev.}}{Hg'(2\,{}^3P_1)} + \underset{4\cdot66\text{ ev.}}{Hg'(2\,{}^3P_0)} \rightarrow Hg_2^+ + \varepsilon;$$

$$(2)\quad \underset{9\cdot72\text{ ev.}}{Hg'(4\,{}^1P_1)} + Hg \rightarrow Hg_2^+ + \varepsilon;$$

$$(3)\quad \underset{9\cdot82\text{ ev.}}{Hg'(5\,{}^3P)} + Hg \rightarrow Hg_2^+ + \varepsilon;$$

where Hg′ denotes an excited atom and ε a free electron. The energy associated with each state is given in electron-volts. Evidence was also obtained that excited atoms in states other than *P* states do not apparently form ionized molecules by attachment even when they have more than sufficient energy to do so.

It has occurred to me that this may be due to the existence of certain unstable or repulsive states of the mercury molecule. Such states will be associated with atoms in *S* or *D* states, while stable molecular states will be associated with excited atoms in *P* states.

In accordance with the generally accepted view that positive ions formed in the discharge are the source of the excitation in the afterglow, it now appears that in mercury vapour the phenomenon has its origin in the molecular rather than the atomic ion as previously supposed.

A molecular ion capturing an electron may fall into either a stable or an unstable state. The formation of stable excited molecules will lead to the band spectrum of the afterglow. On the other hand, if the above assumption is correct, electron capture may result in spontaneous dissociation of the ion into an excited atom, in an *S* or *D* state, and a normal atom. This process will be non-radiative since any excess

energy will be carried off by the products of dissociation. Consequently the line spectrum will show strong lines originating from atoms in S or D states, and these lines will be characterized by the absence of continua. Lines originating from atoms in P states will be relatively weak, since stable excited molecules may radiate and fall to the ground-state before dissociation takes place.

Moore and Garth have made a careful investigation of the relative intensities of the lines in the afterglow spectrum and note all these features. Their calculation of the rate of direct excitation into each atomic level shows that the number of excited atoms (formed directly by molecular dissociation) in the D, S and P states are approximately in the ratio 80 : 20 : 1. This is in good agreement with the suggestion given here.

The quenching produced by electrons having a few volts energy may be due to the dissociation of the molecular ion into an atomic ion and a normal atom, a process which requires an energy of 0·87 volts. The accompanying increase in the intensity of the resonance radiation is not so readily explained. This production of atoms in the 2 ^3P states may, however, account for the recovery of the glow beyond the quenched region, since fresh molecular ions may be formed in the streaming vapour by the process (1) given above.

The Relations between Science and Ethics

I AM sorry that Dr. Waddington (NATURE, Sept. 6) allows the word 'good' to be spelt with a capital, even if only once. The use of a capital letter makes an adjective appear to be a noun, that is, a thing, which has an independent existence, and this leads to endless confusion, such as that involving "Eternal Values", etc.

A more serious lapse (especially from one who has written on the scientific attitude) is the lack of definition of the terms used. Clear definition is essential to the progress of science, for the facts upon which its theories are built cannot be verified unless they are expressed in clearly defined terms which enable other research workers to establish similar conditions for observation or experiment. Now when we consider the subject of ethics we find at once that the words 'good' and 'evil' have never been clearly defined, and consequently the application of scientific method is impossible. Words are, of course, only symbols, and unless we know clearly how they are related to events in our actual lives, that is, their meaning, the use of them in sentences is mere word-spinning and leads only to confusion.

As regards the intimate connexion between science and ethics, I should like to repeat, in a more pertinent form, a point of view which I put forward in an essay-review of the Bishop of Birmingham's Gifford Lectures (*Science Progress*, **116**, 729; 1935):

(1) We strive for the greatest mental and bodily well-being, that is, happiness (fact of experience).

(2) This is greatest when others are also happy (fact of experience).

(3) To achieve (1) we should therefore strive for "the greatest happiness of the greatest number".

(4) To achieve (3) we require knowledge of facts about the actual world, and what would be the results, or probable results, of given actions in it.

(5) This knowledge is most reliably obtained by the exercise of scientific method.

(6) In order, therefore, to distinguish between good and bad conduct (good conduct being defined as that which conduces towards the greatest happiness of the greatest number and vice versa), we require knowledge obtained by science. Thus science is intimately connected with ethics.

Sections (1) to (6) might be said, I think, to form a basis for a scientific ethic. This is not a static conception, for with the continual increase in our knowledge, it might happen that an act formerly thought conducive to the greatest happiness of the greatest number would be found not to be so. This is an advantage in a world in which the only certain thing we can say about the future is that it will be different from the past.

G. BURNISTON BROWN.

University College of London,
at University College of N. Wales,
Bangor.

DR. WADDINGTON, as I understand him, has merely *defined* the good as that which tends to promote the ultimate course of evolution[1]. On what other basis can a man of science, or any adult for that matter, state that "the direction of evolution is good simply because it *is* good"? (The Dean of St. Paul's, in the same issue of NATURE, put his finger on this; what is defined cannot thereafter be deduced.) Dr. Waddington admits as much by his diffident, and somewhat belated, statement that his meaning of good is "not unrelated to the conventional meaning"[2]. One may well ask what all the fuss is about; a definition is beyond argument. Dr. Waddington is fully entitled to take a word in common use and define it, for his own purpose, as he pleases. Most sciences contain examples of such licence, and it can usually, although not always, be said that the definition "is not unrelated to the conventional meaning of the word". One only wonders, first, why Dr. Waddington required eight columns for his definition and, secondly, what it has to do with ethics.

Dr. Needham is on very different ground when he identifies the good as defined by Dr. Waddington with the already defined Christian attributes[3]. When he boldly claims that these latter are the bonds which most effectively organize a community at the level of humanity, he must be asked to produce his evidence. He may conceivably find difficulty in indicating a representative community which has so much as tried the recipe. We can, on the other hand, point to the most highly organized community of modern times, based on quite other principles and methods. On Dr. Waddington's perfectly consistent statement that the good is that which is effective, these methods are good; does Dr. Needham say they are also those enjoined by Christ?

[2] NATURE, 148, 342 (1941).
[3] NATURE, 148, 411 (1941).

DR. WADDINGTON appears to identify 'ethical' with whatever the super-ego demands, which is surely too sweeping. Even when it presents its demands in the name of conscience the super-ego is, emphatically, *not* always a trustworthy guide. Anyone who has studied the vagaries of conscience must agree that this still, small voice (or raging dictator) may, and sometimes does, inspire appalling behaviour; and conscience, as we recognize it, is only a small and relatively reasonable portion of the Freudian super-ego. Its less rational behests, in the form of morbid compulsions, may well land its victims in gaol, or in the mad-house.

Actually, diseased super-egos are the greatest menace with which humanity has to contend. According to Freudian psychopathology, intellectual and emotional abnormality results from the deadlocking of the vital human impulses by these misguided repressive super-egos. I therefore warmly agree with Prof. Julian Huxley about the close connexion between 'evil' and what he calls "the locking up of the 'energies' by the repressive mechanisms of the unconscious", and with his contention that 'good' may result from "releasing these 'energies' from their grapplings". It will only result, however, if some other type of control, better adapted to reality (that is, what Freudians call the 'ego') can be developed to take over the regulation of these energies, since blind decontrol would be no better than blind automatic repression. I am, however, entirely in agreement that the stultification of human 'energies' is 'evil' and their utilization 'good'.

The theory underlying this view of 'good' and 'evil', to which we both subscribe, seems to be that the subject-matter of ethics is human personalities; 'evil' would then roughly coincide with intellectual and emotional disease, 'good' with intellectual and emotional growth and sanity. This is, in fact, my own present working hypothesis with regard to ethics and I believe it is very like Dr. Waddington's. Human personalities seem to be important among the results which evolution has produced and so may be presumed to have been aimed at; moreover human personalities as they mature tend spontaneously to develop their capacities more fully and regulate their conduct more realistically. I suggest that we may apply the term 'good' to this developmental tendency, or rather to the personalities which, if it were successfully carried through, would be evolved by it.

Working against this tendency, however, there appears to be a counter-tendency, the results of which I suggest we should call 'evil', which arrests and even corrupts this developmental process. I do not know whether we are justified in excluding this counter-tendency from the scheme of evolution. The disquieting progress made by this 'evil' tendency *may* be due to the institutions of our particular 'culture' and thus may be remediable, provided human beings are not too corrupted already to be willing and able to undertake the task of altering their own unhealthy 'culture'. On this question we have not the knowledge, at present, to pass a final judgment, though, obviously, we must act as though they *were* capable of it.

A word in conclusion: with reference to Prof. Joad's question: "What . . . does all this talk about the super-ego and its imposition upon the personality . . . really amount to?", if Prof. Joad would study the curious phenomenon of compulsive behaviour, most clearly exemplified in obsessional neurotics, and would then familiarize himself with Freud's theory of intrapsychic conflict, he would get some inkling of the answer he is looking for. This study might, however, still take him some years, since it does not yet seem even to have begun.

KARIN STEPHEN.

Court House,
Ash Priors,
Nr. Taunton,
Somerset.

PROF. DINGLE[1] has picked out of my essay a sentence which, given the definitions with which I was operating, is a tautologous expansion of the argument. He appears to have thought that it was intended as an empirical statement, and he denies that it actually is empirical. From this basis he proceeds to reject my opposition to the apriorist view of ethics on the grounds that the opposition is itself apriorist, since it is not based on observation. He even states that it has no application to experience, although it clearly implies that in making an ethical choice we should pay more attention to the probable effects of the alternative courses of action in relation to the scientifically ascertained direction of evolution than to our own or other people's ethical intuitions or any system of ethical rules, etc.

The whole misunderstanding depends on the implicit adoption by Dingle of the traditional, and to my mind quite unsatisfactory, theory of the nature of an ethical aim as something absolute and without history. Thus, in a recent publication[2], he wrote: "It is clear that since the [ethical] principles of action must in essence be independent of the consequences of action, these latter being usually unknown, they cannot be expressed in terms of a rationalisation of past experience". Now the grounds advanced here for the independence of principles from their consequences are quite inadequate, since the consequences of our actions are never certainly known even when we guide them by an obviously empirical working hypothesis. One suspects that the independence is asserted merely on the basis of the introspection of an adult man who disregards entirely his own development. But however it has been arrived at, this view discounts at the outset the possibility of observing the genesis of aims, and thus any statement about their origin must appear non-observational. The apriorist view in fact becomes a tautology, since it has been smuggled into the discussion at the very beginning under cover of a theory of nature of aims in general.

It is, however, by no means impossible to observe the genesis, and thus the nature, of an aim; I mentioned in particular psychological and anthropological observations. The possibility of such a study has been overlooked in traditional thought partly because of the late appearance of an interest in evolutionary and developmental problems in general, and partly on account of the spurious 'absoluteness' of ethical aims, towards an elucidation of which both Prof. Huxley and I made suggestions. But it is the total neglect of such considerations which lies behind both the simple objections of Prof.

Joad and the more sophisticated ones of Prof. Dingle. It also robs of much of their cogency the discussions of Prof. Broad, to which Prof. Ritchie referred me, couched as they are in terms of non-developmental concepts of 'reason', 'emotion', 'pleasure', etc.

It is again an awareness of developmental considerations which I miss in Dr. Burniston Brown. The utilitarianism which he puts forward can, I think, be regarded as one of the historical forerunners of the line of thought which I suggested. His formulation, however, neglects all the advances made in our understanding in the last hundred years, and does not refute, or circumvent, the well-known difficulties of the theory. Thus he takes me to task for not defining my terms, and indeed the comments on my article show that in many cases I was not successful in indicating the subject of my remarks; but his first premiso seems to me untrue if 'pleasure' is defined in the ordinary way, and without significance if the definition is adjusted to make the sentence true. I think these difficulties are surmounted, and that Prof. Dingle's objection cannot be sustained, if, instead of saying that to achieve goodness we should strive for the greatest happiness of the greatest number, we state that our ideal of goodness is presented to us by a certain part of the personality, that the function of this part is the furtherance of evolutionary progress, and that the task of reason is to clarify that aim.

Dr. Childs is wrong in supposing that I "merely *defined* the good as that which tends to promote the ultimate course of evolution". In science one does not, except when teaching mechanics in an old-fashioned way to third forms, define concepts in the sense in which geometrical concepts are defined and which allows deductions to be made. A scientific definition, which I hope was the kind I was employing, consists in indicating the phenomenon which one intends to call by a certain name. What I did was to use 'ethics' in the first place for the ethical judgments of an individual. I then advanced three propositions about such judgments; first that they are a part of the super-ego, secondly that they are built up as a result of experience; and thirdly, that the function of the super-ego is to implement those aspects of the personality (such as those on which social life depends) which are the most recently evolved. My statement that "the direction of evolution is good simply because it *is* the good according to any realist definition of that concept" is a summary of those three propositions; I am sorry to find that it is apparently such a deceptive summary, but perhaps the critics might be asked why they always omit the latter half of the sentence.

That these propositions are real, and not fake, ones is made clear by the fact that they can be denied. Dr. Stephen, in her very interesting and constructive letter, raises certain difficulties about the first and third of them. As to the first, she points out the fact, which I should not dream of denying, that the demands of the super-ego do not always correspond with generally accepted ideas of the good. But I think one must, in spite of this, admit that what an individual's super-ego demands is what the good means to him, however it may contravene other people's principles. It is, however, the function of a rational theory of ethics to aid the ego in guiding the development of the super-ego, and for this we require a description of the good derived from a basis wider than the experience of a single individual, so wide in fact that it applies to mankind as a whole. I suggested that the nature of this wider basis becomes clear when we notice that (my third proposition above) the function of the super-ego is to subserve evolution.

It might seem that the existence of the "misguided super-egos" stands in the way of our acceptance of this third proposition; but that is not so. The existence of deleterious genotypes does not prevent us from realizing that evolution depends on the properties of genotypes; and the fact that some super-egos may be retrogressive should not tempt us to deny the evolutionary functions of that aspect of the personality.

Dr. Stephen does not take up this part of my thesis, and it is, I suggest, a consequence of that neglect that she is left without any criterion for identifying her 'good', 'healthy' tendencies. The spontaneous development of which she writes tends towards sanity only in those individuals whose super-egos are not too misguided; in other cases it ends in the mad-house or the gaol. It is in fact no more a criterion of good, from the point of view of humanity in general, than is the individual super-ego. But I think that when Dr. Stephen characterizes the good tendencies as healthy, she is approaching my point of view, since health means something very near to evolutionary fitness.

I am, of course, in entire agreement with her and Prof. Huxley that the conscious part of the mind (the ego) should exert itself to control, not only the physical mechanism of evolution, but, even more, the psychological mechanism, the fantastic, slap-dash character of which has rendered man's social evolution so miserably slow and full of set-backs. But until one realizes that this mechanism does produce evolution, one is not likely to be able to assist it in doing so.

I am in general agreement with the remarks of Dr. Darlington and Prof. Haldane[3], although the latter does not seem to have penetrated far enough into my essay to have discovered this. I also accept in general the thesis so ably argued by Dr. Needham[4], that the ethical principles formulated by Christ and the great ethical teachers are those which have in the past few thousand years tended towards the further evolution of mankind, and that they will continue to do so in the foreseeable future. This is, surprisingly enough, called in question by Dr. Childs in the second paragraph of his letter. He claims to be able to "point to the most highly organized community of modern times, based on quite other principles and methods". He does not do so, which makes his remark somewhat obscure; but I imagine that the community meant is Germany. The most charitable interpretation of such an unorthodox point of view is to suppose that Dr. Childs has become confused through using "most highly organized" first to mean "furthest advanced in social evolution" and second to mean "having the most rigidly formulative structure". Dr. Needham and I are, of course, both talking about the first sense, not the second.

RESEARCH ITEMS

Early Uses of Iron

AN interesting article by H. H. Coghlan on early iron-working appears in *Man* (July–August). Among other points the author suggests that iron was not smelted as early as copper-tin (bronze), because without further elaborate treatment it was useless on account of its softness. It was not until the manufacture of what nowadays would be described as mild steel was developed that the product became superior to bronze, this manufacture having involved a more intricate knowledge of the processes of metallurgy, including particularly the use of tongs and the heavy sledge-hammer, than had at first been achieved.

Chinese Freshwater Medusa

A LITTLE more than sixty years ago interest was aroused among zoologists by the discovery of large numbers of a little freshwater jellyfish in the *Victoria regia* tank at the Royal Botanic Gardens, Regent's Park, London. The presumption was that, in some way or other, the medusæ came from South America along with plants of the Victoria water-lily. Since the discovery of these creatures was made by William Sowerby, director of the gardens named, they became known as *Limnocodium sowerbii* (Allman and Lankester). Arthur de Carle Sowerby contributes a short article on this jellyfish in the February issue of the *Hong Kong Naturalist* (10, 186–89). He points out that Ray Lankester named the genus *Craspedacusta* but that Allman a few days later suggested the generic name of Limnocodium which Lankester, in his subsequent writings, adopted. Priority of publication, however, demands the use of Lankester's original name—a point of view which Mr. Sowerby advocates. He gives data indicating that the medusa obtained in the Yangtze River in China, in 1907, is none other than *Craspedacusta sowerbii* although it was named *C. kawaii* by the Japanese zoologist Oka. The writer of the article referred to concludes that its original home is the waters of the Middle and Upper Yangtze River Valley whence it has from time to time been transported with perhaps the water-hyacinth (Eichhornia) to various parts of the world.

Larva of Ranina

HIROAKI AIKAWA ("Additional Notes to Brachyuran Larvæ", *Records of Oceanographical Works in Japan*, 12, No. 2, March, 1941) describes the first zoea of the crab *Ranina ranina*, hatched out in the aquarium of the Mitui Institute of Marine Biology. This proves that the curious larva figured by Claus (1876, 1885) as Acanthocaris is undoubtedly very closely related if not identical. Gurney has already placed Acanthocaris in the Raninidæ ("Bibliography of the Larvæ of Decapod Crustacea", 1939). The larva of *Ranina ranina* has affinities with the Brachyrhyncha on the one hand and the Anomura and Macrura on the other. Aikawa suggests that the Raninidæ should be grouped with the Dromiidæ and Homolidæ and now regards *Lithozoea kagosimœnsis* and *L. multispinosa* (Aikawa 1933) as larval Raninids. The larva of Dromia, however, differs so much from Ranina that a very close relationship seems improbable. Another crab zoea, hatched in the Misaki Marine Biological Station, belongs to *Macrocheira kœmpferi*. It is usually regarded as an Inachid, in the sub-family Inachinæ, but it is shown here to be nearer Hyas and Chionecetes in the sub-family Hyasteninæ of the Majidæ.

Diurnal Variation of Barometric Pressure

T. R. TANNAHILL has recently contributed an account of a new investigation into the diurnal variation of barometric pressure (*Proc. Roy. Soc. Edin.*, 61, Part 1, No. 7). The material analysed is a portion of the old records maintained on the summit of Ben Nevis (4,407 ft.), namely, the hourly pressure records for January and July 1884–1904. These are divided into clear days (mean cloud amount not greater than $\frac{7}{10}$) and cloudy days. It is pointed out that the diurnal variations found by Buchan and Omond in 1902 from the analysis of three years observations divided into similar groups differed mainly because of the method of selection, the tendency being for clear days to occur near the time of a barometric maximum and therefore on a convex part of the curve of pressure variation, and on the other hand for cloudy days to be more common near a barometric minimum when the curvature is concave, an effect to which attention was first directed by Bartels in 1927. Tannahill eliminates this effect in order to find the true diurnal variations by a method previously used by him and Robb when studying the lunar atmospheric variation at Glasgow, and finds that with one exception the differences from the normal variation obtained for all days regardless of cloud amount is insignificant except for the first harmonic for January, which shows an increase of $0{\cdot}123 \sin (x + 352°)$ millibars on clear days, x being measured from 1 a.m. This variation, although so small, is regarded as real, notwithstanding its absence from the corresponding data for July.

Ground Tilt at Wellington, New Zealand

TILTOMETER records made at the Dominion Observatory, Wellington, during the periods 1930–1934 and 1937–1939 have been analysed by R. C. Hayes and R. D. Thompson, and possible causes of the various movements discussed ("Ground Tilt at Wellington, New Zealand", by R. C. Hayes and R. D. Thompson, Dominion Observatory Bulletin, No. S-60, *New Zealand J. Sci. and Tech.*, 3*B*, 166*B*–182*B*; 1940). Most of the prominent movements recorded can be traced to meteorological causes, particularly temperature. In particular, the E–W component exhibits a marked diurnal wave which appears to be closely related to local ground-temperature changes at a depth of 1 ft. Normal day-to-day changes are controlled mainly by temperature, but appear also to be influenced to some extent by local precipitation. Occasional large tilts appear to be associated with abnormal meteorological conditions, particularly falls of snow or hail in the surrounding region. Other movements recorded consist of (1) a somewhat doubtful seasonal variation with a period rather less than twelve months; and (2) a general drift westward or south-westward during most of the periods concerned. The authors state

that they do not offer any satisfactory explanations for either of these movements, but they find that their evidence points to the westward or south-westward drift being a local movement, possibly due to settling of the Observatory building. No evidence of tilt due to tidal loading has been found. One of the principal objects in making tilt observations in seismic regions is to ascertain whether any pre-seismic tilts can be detected which might be of value in foretelling the occurrence of earthquakes. Considerable tilts have been observed to correspond with lava movements in volcanoes in Hawaii and Japan, and some tilts may be associated with movements of earth blocks with which also earthquakes have been associated. So far tiltometer records at Wellington have not shown any definite pre-seismic tilts or any movements which can be definitely attributed to tectonic causes. The authors suggest that a network of tiltometer stations may be of use in determining movements of earth blocks, or that single tiltometer records might be useful in thermal and volcanic regions such as exist in the North Island of New Zealand.

Reactions of Ozone

A STUDY of the separation of ozone from other gases and of the determination of ozone and nitrogen dioxide in the atmosphere has been made by J. L. Edgar and F. A. Paneth (*J. Chem. Soc.*, 511, 519; 1941). The separation of ozone in a concentration of as low as a few parts in a hundred million of other gases may be effected by the condensation of the ozone on the surface of a specially prepared silica gel at low temperature, when it is frozen out quantitatively. By raising the temperature it is recovered without decomposition, and by fractional evaporation it may be separated from nitrogen dioxide and hydrogen peroxide, the other oxidizing agents which might be present in air. The concentration of ozone so separated enables it to be identified by its ultraviolet absorption spectrum. The iodometric titration method of Ladenburg and Quasig was found satisfactory for the chemical determination of ozone. By making use of these methods, the ozone and nitrogen dioxide contents of some samples of air were determined. The ozone content varied from $0 \cdot 5$ to $2 \cdot 9 \times 10^{-6}$ per cent by volume, and when nitrogen dioxide was present its amount was of the same order. The state of the weather is given for each determination, but no very obvious correlation appears in the results (cf. Paneth and Glückauf, NATURE, 147, 614; 1941).

Crystal Structure of Alanine

THE difficult problem of the structure of proteins may be approached from the examination of simple amino-acid molecules, and a detailed X-ray investigation of *dl*-alanine $CH_3NH_2CHCOOH$ has been made by H. I. Levy and R. B. Corey (*J. Amer. Chem. Soc.*, 63, 2095; 1941), who give a full interpretation of the results with diagrams of molecular models. A brief statement of the many quantitative data given would be that the crystals are built upon an orthorhombic unit containing four molecules. The interatomic distances within the molecule are: C–O, 1·25 and 1·23 A.; C–C, 1·54 A.; C–N, 1·42 A. These give rise to important problems, discussed in the paper. The alanine molecules are linked together by a three-dimensional framework of hydrogen bonds, which is responsible for the abnormally close approach (3·64 A.) of methyl groups of adjacent molecules. The positions of the hydrogen atoms are fully discussed in terms of the intensity data and the results are structurally plausible. From the point of view of proteins, the great difficulty in selecting the most probable model from the many possible ones in the present state of knowledge is emphasized. The present results emphasize the probable importance of the directional properties of hydrogen bonds between nitrogen and oxygen atoms in determining atomic and molecular arrangements.

Periods of Eclipsing Binary Stars

H. HORROCKS has discussed the variations of the periods of certain eclipsing binaries (*Mon. Not. Roy. Astro. Soc.*, 101, 4; 1941). He has investigated the constancy or otherwise of the periods of a number of eclipsing binaries the periods of which are between 4 and 20 days. Oscillatory variations are suggested for *SY* Cygni and *W* Delphini; in the former, the period is about 2,000 orbital periods, that is, 30 years, and the amplitude is 0·07 day; in the latter, the period is about 3,600 orbital periods, or 50 years, and the amplitude 0·046 day. In the case of the three stars *RS* Canum Venaticorum, *SW* Cygni and *RT* Lacertæ, the periods of which are known to be variable, Horrocks suggests that the variations of period are due to oscillatory terms, but the observations at present available are inadequate to reveal their true character because the periods are long. Investigations carried out on six stars for which a variation of period has not been established showed that only two—*TT* Lyræ and *RS* Vulpeculæ—reveal rates of change of period with probable errors which are not excessive. The question of the rotation of the apse, due to a non-spherical form in the case of close components, or perhaps to the presence of a third body in the system, is discussed in connexion with four stars the orbital eccentricities of which are deduced.

Stellar Absolute Magnitudes

THE intrinsic luminosities of stars of different spectral types are now fairly well known where the nearer, less luminous, stars are concerned. The absolutely bright stars are usually so far away that calibration of spectroscopic surveys by means of trigonometric parallaxes is impracticable. This applies equally on one hand to the super-giants of all spectral types, and on the other to the early-type stars of all luminosities. Two recent papers by R. E. Wilson (*Astrophys. J.*, 93, 212; 94, 12; 1941) provide valuable information on the luminosities of stars in both these classes. The first paper deals with the non-variable *c* stars and establishes, from considerations of radial velocities and of proper motions, that contrary to previous belief their mean absolute magnitudes decline from − 5·4 for *cBO* to − 2·0 for *cK5* stars. Luminosities of the variable *c* stars, the Cepheids, are lower and run in the opposite direction. In the second paper Dr. Wilson deals with the stars of types *O5* to *B5* and concludes from a study of about 1,000 radial velocities and 1,500 proper motions that their luminosities fall from −3·7 for *O8* stars to −0·8 for class *B5*. These stars thus fit in well at the high-luminosity end of the "main sequence" and show that the known rise of brightness with temperature is continued among the hottest stars. The emission-line stars are not significantly different in magnitude from the others, whether they are members of the main sequence or super-giants.

ADRENALINE TREATMENT *IN VITRO* AND LIVER GLYCOGEN

By J. R. BENDALL AND H. LEHMANN (BEIT MEMORIAL FELLOW)
School of Biochemistry, Cambridge

FOLLOWING the elucidation of the initial stages of glycogenolysis, largely due to the Coris and their collaborators, it has been possible to reproduce *in vitro* several processes known to influence the blood-sugar level and glycogen metabolism *in vivo*.

1. It has proved possible to give a biochemical basis to the homoiostatic function of blood-sugar level (Soskin) by showing that glucose *in vitro* regulates glycogen breakdown by inhibiting glycogen phosphorylase (Lehmann[1], Gill and Lehmann[2]). The glucose concentration needed *in vitro* was, however, somewhat higher than the normal blood-sugar level. There is another effect of glucose concentration *in vitro* which is fairly obvious but which we shall put into a quantitative form shortly.

The amount of glycogen formed by liver slices in an oxygenated glucose solution is greater the higher the concentration of the surrounding glucose, an optimum being reached at 3,000 mgm. per cent in rabbit and 4,000 mgm. per cent in rat. Higher concentrations are inhibitory, probably by damaging the cells.

2. The effect *in vivo* of asphyxia increasing the production of reducing sugar from glycogen is in part due to the absence of oxidative re-synthesis. It was possible, however, to show a marked increase of reducing sugar from glycogen and phosphate in dialysed muscle extract (that is, under conditions in which no re-synthesis takes place) when reducing agents were added (Gill and Lehmann[2,3]). The exact point at which this acts is the step at which Cori ester (1 ester) is transformed into the reducing Robison ester (6 ester). This precise step is inhibited by oxidizing and increased by reducing agents (Lehmann[4]). But taking into account the minor importance of this step for the production of reducing sugar in liver which is largely produced by a direct dephosphorylation of the Cori ester, and considering the fact that liver tissue is normally in a highly reduced state (Lee and Richter[5]), the effect of anoxæmia on liver may be almost entirely due to suppression of glycogen synthesis.

3. The action of insulin in preventing the breakdown of muscle glycogen has also been reproduced in muscle extracts (Lehmann[6], Gill and Lehmann[2]). Insulin inhibits *in vitro* the step in which Cori ester is transformed into Robison ester. The concentrations used, however, were much higher than those necessary *in vivo*.

4. Failure of storage of liver glycogen from carbohydrate food in suprarenal deficiency (Cori) was reproduced *in vitro* by demonstrating that liver slices of the adrenalectomized rabbit have a five times lowered power to synthesize glycogen from glucose as compared with normal tissue (Holmes and Lehmann[7]).

5. Injection of adrenaline first increases sugar production from glycogen in liver (Blum) and leads to a glycogen storage later on (Pollak). This after-effect has hitherto been thought to be due, not to the hormone itself, but to lactic acid accumulation in the blood resulting from the action of the hormone on the muscles (the "Cori cycle"). We have now been able, using physiological concentrations, to reproduce *in vitro* both the effect of adrenaline on sugar production by the liver cell and the increase of glycogen some time after the primary action. The old explanation for the first effect was that it deprived the liver of oxygen by contracting its arteries. Anoxæmia (as mentioned under 2) has in fact a glycogenolytic influence. The resynthesis of glycogen is an oxidative process and anaerobiosis disturbs the balance between the forces which keep the liver glycogen in a steady state. But the theory that adrenaline acted via an anoxæmia was disproved by Fröhlich and Pollak[8] in 1914 by showing the action of the hormone on the isolated frog liver under conditions in which its secondary effects such as anaerobiosis were carefully avoided. Since then, the general conception was that it acted by accelerating the glycogen breakdown as such. It has never been possible to demonstrate an effect in liver extract and liver brei. There is, however, a finding recorded by Cross and Holmes[9] that adrenaline—as they suggested by accelerating glycogen breakdown—prevented the appearance of glycogen in liver slices shaken with glucose. About as much adrenaline by weight per sample was needed, as glycogen formation was suppressed in a two hours experiment.

We want to record experiments which lead back to the old conception of adrenaline acting like asphyxia, though we no longer think that it acts by suppression of blood supply to the tissues. Three typical experiments showing the effect on glycogenolysis may be quoted.

GLYCOGENOLYSIS (MGM. GLYCOGEN LOSS/GM. LIVER) IN RABBIT LIVER SLICES SHAKEN IN KREBS RINGER BICARBONATE (TISSUE : FLUID, 1 : 6) 38° C. 30 MIN.

Initial glycogen (mgm./gm. liver)	95% O_2 5% CO_2	95% O_2 5% CO_2 *M.*/5000 adrenaline	95% N_2 5% CO_2
84·8	2·5	14·6	16·7
106·3	0 (+7·7)	11·5	11·9
59·9	11·8	18·3	17·9

These figures might suggest that adrenaline accelerates glycogen breakdown by preventing, like anaerobiosis, but not necessarily at the same stage, the resynthesis of glycogen. We observed the same effect on rat liver slices in winter. In summer, rat liver slices do not synthesize glycogen from glucose under the conditions of our experiments, and little difference was found in glycogenolysis in oxygen, oxygen plus adrenaline and nitrogen. So there is in fact a parallelism between an absence of glycogen synthesis and a failure of adrenaline to influence glycogenolysis. If adrenaline acts primarily on glycogen synthesis, no effect can of course be expected under conditions in which no synthesis can be demonstrated (for example in brei and extracts).

The reason that Cross and Holmes found no effect on slices at physiological concentrations is a twofold action of the hormone. Using a molarity of 1/200000 (which is 0·9 mgm./litre), a twofold effect can be seen if observations are made at several intervals of time. The treatment with adrenaline at first inhibits the synthesis of glycogen and later on increases it, thus masking the earlier effect. The following is a typical experiment.

SYNTHESIS OF MGM. GLYCOGEN PER GM. LIVER.

Liver slices from rabbit starved 39 hours (2·68 mgm. glycogen/gm. liver) shaken in Krebs Ringer bicarbonate (1 : 6) 95% oxygen ; 5% carbon dioxide ; 38° C. ; 0·5% glucose.

Time (min.)	Synthesis control	Synthesis *M.*/200,000 adrenaline	Effect of adrenaline (per cent)
0–120	9·00	8·35	−7
0–60	4·64	2·54	−45
60–120	4·36	5·81	+33

The synthetic effect can be shown best if slices are shaken with adrenaline for some time before the substrate glucose is added. Again a typical experiment may illustrate this point.

SYNTHESIS OF MGM. GLYCOGEN PER GM. LIVER.

Liver slices from rabbit starved 35 hours (0·55 mgm. glycogen/gm. liver) shaken in Krebs Ringer bicarbonate (1 : 6) 95% oxygen ; 5% carbon dioxide ; 38° C.

	30 min. 1 % glucose direct		30 min. 1 % glucose after 60 min. incubation without glucose	
	—	*M.*/100,000 adrenaline	—	*M.*/100,000 adrenaline
Synthesis	2·16	1·07	2·14	3·09
Influence of adrenaline	−50%		+45%	

(This work was aided by a grant from the Ella Sachs Plotz Foundation.)

CONTINUOUS WAVE INTERFERENCE WITH TELEVISION RECEPTION

AN article by C. N. Smyth, of Kolster Brandes, Ltd., Sidcup, on continuous wave interference with television reception, is published in *Electrical Communications*, 19, No. 4 (1941). Interference with television reception can be very severe due to the large band width employed for this service, and is a much more serious problem than interference with sound broadcasting. Fortunately, however, both have much in common in the methods which can be used to effect suppression.

Interference is divided into two main categories: damped wave or impulsive type interference and continuous wave interference. The former is caused mainly by radiation from the ignition systems of motor vehicles, sparking in electrical machinery and appliances and from harmonics of spark-type transmitters on certain ships. Thermal agitation, noise in circuits and Schott noise in tubes also produce interference of this type within television receivers. The latter type of interference is caused by radiation from short-wave radio or television receivers, quite apart from any outside sources, due to unwanted couplings between certain circuits causing harmonics of the sound or vision, medical diathermy apparatus used in hospitals, and harmonics from powerful broadcast and amateur transmitters. Continuous wave interference patterns may also be produced within telephone receivers, quite apart from any outward sources, due to unwanted couplings between certain circuits causing harmonics of the sound or vision intermediate frequencies to react with the incoming signal, or due to hum voltages derived from the power supply frequency and its harmonics, or voltages derived from the harmonics of the scanning frequencies being injected into the receiver picture amplifier.

Interference-free reception of sound in television can only be effected if it is possible to locate an aerial where the signal-interference ratio is sufficiently large, and where the signal strength is sufficiently strong, to swamp the effects of losses in the transmission line and interference encountered in the receiver itself; then, providing the receiver is well screened and the power supply adequately filtered, the receiver will reproduce the signal-interference ratio present in the aerial in the frequency pass-band of the receiver. If the signal interference ratio is not sufficiently good, then advantage may be taken of the directional and polarizing properties of aerials, and an aerial employed which receives waves coming only from the effective direction of the transmitter, and with the desired angles of polarization. Beyond this, the signal interference ratio cannot be improved without reduction of picture quality, by reduction of band width or the use of interference suppression circuits which limit the peaks of picture modulation or leave gaps in the picture where interference signals would normally appear. Such interference suppression circuits are only applicable to impulsive type interference.

Further improvement lies in the direction of suppression of the interference at the source, but before this can be undertaken with any certainty of success, it is necessary to have an exact knowledge of the degree of suppression which is desirable.

By continuous wave interference is implied the production of spurious modulation frequencies superimposed on the picture signal in the output of the receiver, and appearing as a steady or slowly changing pattern on the picture screen. This effect is often described as a herring bone or feather pattern superimposed on the picture.

The annoyance value of the interference, that is, its property of destroying the entertainment value of a television programme, depends on the signal to interference ratio on the resultant picture, or what

is almost the same thing, on the output of the receiver revision amplifier or on the grid modulating device.

Mr. Smyth has made a series of visual observations and recorded them photographically to study the effects of interference on test signals and also on actual programmes. No marked divergence of opinion was expressed by any of the observers as to what did or did not represent interference-free reception. Measurements were also made to determine whether continuous wave interference was more noticeable by reason of its effect on synchronization rather than on modulation of the picture brightness. Several photographs are given which illustrate well the effects of change of frequency on interference.

The main conclusions which have been deduced from Mr. Smyth's observations and tests are as follow. Interference 40 db.(decibels) below the level of the picture modulation has no visible effect; at 30 db. below a slight effect is produced; while at 20 db. or less the entertainment of the picture is seriously reduced. The annoyance value of the interference is not affected by the brightness level at which the picture is reproduced provided the picture is reproduced with reasonable fidelity. A simple picture such as black lettering on a white background without any half-tones can be reproduced without appreciable loss of detail in the presence of considerable interference if the amplifier or light-source is over-modulated in both the black and white directions.

TEAK PLANTATION YIELD TABLES

RECENT research work exemplifies the close collaboration maintained between the Central Research Institute at Dehra Dun, India, and the local research officers maintained in the various provinces of the country. It also furnishes evidence of a wider connexion. The first yield tables for plantation teak were made by Bourne in 1919–21 for the Nilumbur teak plantation situated some forty-five miles up the Beypur River from Calicut on the west coast of Madras. This famous plantation was started by the collector of the district, Conolly, in 1844, and was for long regarded as the pioneer in this work. But in Java the Dutch had commenced to plant teak successfully at an earlier date; for in 1932 Dr. Wolff von Wülfing compiled some yield tables for teak plantations in Java which include trees up to one hundred and ten years of age.

Whether teak grown in pure plantations can ever equal in quality of timber the article produced when grown in a mixed forest, which is commonly Nature's own method, is perhaps doubtful. Owing, however, to the much higher price the timber fetches in comparison with that of its associates, it has been planted more extensively than any other single species ; and the cult has spread to Africa where it is an exotic. Existing plantations in India and Burma are now estimated to cover an area of roughly three hundred square miles, and about ten square miles are being added annually.

Until recently Bourne's Nilumbur yield table had been the only standard of reference available for teak grown in even-aged plantations. As it was based on growth measurements obtained from a single plantation it had considerable limitations in its application elsewhere. The Java 1932 yield tables were based on a greater range of quality and age; they were translated by Prof. H. G. Champion into English units[1]. It has been found that the tables recently compiled by the sylviculturist at the Research Institute[2] compare favourably with those of Dr. Wolff von Wülfing for Java ; height-growth trends and the intermediate quality class boundaries for both the Indian and Javan tables almost exactly coincide, thereby rendering it possible to make close comparisons between the data given in the two tables. The authors express their thanks to Dr. Wolff von Wülfing for his permission to reproduce his tables in English units.

FORTHCOMING EVENTS

SATURDAY, NOVEMBER 1

SOCIETY OF CHEMICAL INDUSTRY (Food Group) (Joint meeting with the South Wales Section) (in the Physics Lecture Room, University College, Cardiff), at 3.15 p.m.—Dr. Magnus Pyke: "The Chemical Determination of Vitamins".

MONDAY, NOVEMBER 3

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 3 p.m.—Sir John Russell, F.R.S.: "Reconstruction and Development in Eastern Poland, 1930–39".

TUESDAY, NOVEMBER 4

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 2 p.m.—Prof. Charles Edward Inglis, F.R.S.: Presidential Address.

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 2.30 p.m.—Mr. L. R. Braithwaite: "The Ileo-Gastric Syndrome" (Moynihan Lecture).

WEDNESDAY, NOVEMBER 5

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Sir Edward Crowe: "Co-operation for Production".

THURSDAY, NOVEMBER 6

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 3.30 p.m.—Dr. W. E. Gye, F.R.S.: "Cancer of the Breast" (Imperial Cancer Research Fund Lecture)

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned :

ACTING HEADSHIP OF THE DEPARTMENT OF GEOGRAPHY—The Registrar, University College, Hull (November 6).

LECTURER IN PHARMACOLOGY—The Secretary and Registrar, University, Bristol (November 8).

GRADUATE LECTURER IN THE ENGINEERING DEPARTMENT—The Secretary, North Gloucestershire Technical College, Lansdown Road Branch, Cheltenham (November 10).

INFORMATION OFFICER, who should be a graduate in applied science —The Manager, Wrought Light Alloys Development Association, 34, New Street, West Bromwich (November 15).

ORGANIZING SECRETARY—The Secretary, Association of Assistant Mistresses in Secondary Schools, Stoney Cockbury, Winchcombe, Gloucester (endorsed 'Appointment') (November 25).

RESEARCH ASSISTANT IN VETERINARY SCIENCE under the Alan, Duke of Northumberland Memorial Fund—The Hon. Secretary, King's College, Newcastle-upon-Tyne (November 29).

SENIOR GEOGRAPHY MISTRESS—The Headmistress, County School for Girls, Beckenham, Kent (endorsed 'Geography').

EDUCATION OFFICER—The Wardens, Educational Settlement, Pontypool, Mon.

RESEARCH ASSISTANT IN THE ECONOMICS DEPARTMENT—The Registrar, University College, Exeter.

INTERNATIONAL COMMODITY CONTROL

THE second Inter-Allied meeting, held at St. James's Palace on September 24, fully justified the hope expressed by Mr. Eden at the conclusion of the first, held on June 12, that the meeting might represent the inauguration of a new phase by which peace will be maintained after victory. This second meeting indeed owes its chief significance, not to the accession of the Soviet Union to its counsels or to the adhesion of the Allied Governments to the common principles of policy set forth in the Atlantic Charter, affirmed at the meeting, important as these may be, but rather to the agreement on concerted action for reprovisioning Europe after defeat of the Nazi regime. That agreement, together with the support and interest of the United States indicated in the statement Mr. Eden was authorized to make on its behalf at the meeting, afford weighty evidence that this time the United States and the individual allies will collaborate in the peace after the war has been won. The importance of American collaboration was indeed confirmed very emphatically by Mr. Sumner Welles in a speech delivered on October 5, in which he discussed the urgent need for plans for reconstruction and condemned the policy of restricted trade followed by the United States during the period between 1918 and the outbreak of the War.

The resolution adopted by the meeting affirmed the common aim of the Governments represented to secure that supplies of food, raw materials and articles of prime necessity should be made available for the post-war needs of the countries liberated from Nazi oppression. It contemplates the co-ordination of the efforts of the individual Governments on behalf of their own peoples, and pledges the Allied Governments and authorities to prepare the requisite estimates of kinds and amounts, and to indicate the order of priority in which delivery of the supplies is desired. Plans for the most efficient use of individual and Allied shipping resources are also envisaged, and as a first step the resolution proposes the establishment in the United Kingdom of a bureau with which the Allied Governments and authorities would collaborate in framing estimates of their requirements, and which, after collating and co-ordinating these estimates, would present proposals to a committee of Allied representatives under the chairmanship of Sir Frederick Leith-Ross.

In proposing this resolution, which implements the policy set out in the fourth, fifth and sixth points of the Atlantic Charter, Mr. Eden referred to preliminary work which has already been carried out under the British Government. In addition to the Leith-Ross Committee, a Ministerial Committee

on Export Surpluses has been established, of which the Minister without Portfolio is chairman. While these Committees have been in the main concerned with the arrangement of purchases, mostly within the British Empire, of commodities which have become surplus to current demand, and primarily to stabilize the economics of the territories concerned, they have been mindful of the value of such purchases as a potential relief store for the European peoples at present being ruthlessly denuded by Germany, and have also started inquiries as to probable human needs.

The framing and co-ordination of estimates of probable requirements is the first task, and the proposal for the establishment of a central bureau is intended to co-ordinate such estimates and provide a practical working approach to a survey of all needs on a common basis. Mr. Eden stated further that the Ministry of War Transport has already been considering what shipping might be available, and the proposed declaration on shipping policy is evidence that the mistake made in 1918 in abandoning immediately after the Armistice the Inter-Allied Food Council and the Allied Maritime Transport Council is unlikely to be repeated.

These developments hold real promise of the establishment of the effective central authority which is essential, and that the international co-operation in the economic field during the crucial period when 'first aid' is required will be built so far as possible out of organizations existing before the armistice. Nevertheless, the more distant horizon is beset with greater difficulties, which even now must be faced if long-range planning to meet such needs is to be possible. A successful attempt to discover means to overcome such difficulties may well depend on an early discovery of the best path to follow.

These reasons give pertinence and urgency to the plans outlined by Mr. Eden, as well as to a number of discussions of various phases of the subject which have recently been opened. Some attention to these problems was given at the recent British Association Conference on "Science and World Order", notably in Sir John Russell's brilliant paper on restoring the scorched earth and in Mr. W. L. Kelly's exposition of the ideals developed in Australia on the disposal of gluts of food as a remedy for trade depression. They have also received attention in Mr. F. L. McDougall's paper on "Empire Primary Products in Relation to Post-War Reconstruction", read before the Royal Society of Arts, and they are analysed in some detail in a P E P broadsheet on commodity control schemes.

Mr. McDougall, after reviewing the failure to improve economic conditions which led to the consideration by the League of Nations of the relation of nutrition to health, agriculture and economic policy, emphasized once more the futility of the Dominions concentrating upon economic nationalism. Reliance upon their own local markets offers no solution, and he suggested that in the word 'welfare' we might find the right and possibly the only solution of post-war economic problems. The Empire primary producer is vitally concerned in the third freedom of President Roosevelt—freedom from want everywhere in the world. He is directly concerned with food and raw materials of clothing, and his own vital interests require accordingly an economic policy in all countries directed towards higher standards of nutrition, housing, clothing and other factors of social welfare.

If at the same time we succeed in translating into action President Roosevelt's fourth freedom—freedom from war—with what it involves in relief from expenditure on armaments, Mr. McDougall believes that the nations would be able to devote a larger proportion of their resources to social welfare. He suggested indeed that the industrial nations will find that they cannot afford not to put a rising standard of living in the forefront of economic policy; and he pointed out that in India and in most of the British Colonies the internal problem also demands the reorientation of agriculture designed to secure plentiful supplies of health-giving food to the producers themselves.

Mr. McDougall's paper was delivered a considerable time before the historic meeting of Mr. Churchill and President Roosevelt, and is of particular interest as indicating the way in which opinion in the Dominions already recognizes its vital interest in the vision and policy of a *Pax oceanica* opened up in the Atlantic Charter. The *Pax oceanica* can no longer be maintained by Great Britain alone, and not the least significant feature of the Atlantic Charter is the evidence it affords that the United States is completing her evolution from a continental into an oceanic power. The Dominions are vitally interested in maintaining the *Pax oceanica* as the basis of world order and freedom, and it is clear that they are ready to recognize not merely this obligation, but also that it can only be pursued in relation to Continental Europe. The economic expansion of the Dominions can only be achieved through the raising of standards of living, which is a world-wide problem.

A policy tending towards the creation or re-creation of world markets, whether by developing the welfare of the Colonial peoples or by European reconstruction, involves co-operation in the creation of markets. It means making the consumer and not the producer the starting-point of policy; the organization of consumption takes precedence over the organization of production. The old

programme of freedom of trade is transformed into a new programme of freedom from want.

The policy of direct attack upon economic stagnation and social backwardness in the Colonies, like the idea of minimum standards in nutrition, health, social services and education stressed by Dr. Julian Huxley in "Democracy Marches", involves a new approach to commodity control schemes. As the P E P broadsheet shows, the existing schemes all imply some degree of conscious planning and co-ordination of action, and their development has been in the hands of pioneers whose ability and honesty of purpose have both varied. Even during the War, great advances are being made in the technique of economic control, and education in the uses and limits of control is being widely diffused. Much is being learnt from the almost world-wide application of 'lease-lend' procedure and the working out of shipping programmes for essential supplies, while the significance of organized research and planning in this field under Sir Frederick Leith-Ross is far-reaching.

The P E P broadsheet gives a concise analysis of the commodity schemes already in existence, their characteristic features and actual results achieved during the last twenty years. This analysis is inevitably much slighter than that in the report of the League of Nations committee for the study of the problem of raw materials, or in the Royal Institute of International Affairs information paper on raw materials and colonies. The most valuable feature of the broadsheet is accordingly its discussion of the purpose of commodity control and of the methods of establishing it, based upon the conclusions drawn from experience already available.

Despite the inherent disadvantages of commodity schemes and the frequent abuse of monopoly power, there can be no doubt that control has come to stay. Without its continuance, problems involved in the handling of world commodities by international co-operation after the War cannot be solved. Functional, as distinct from geographical or national, organizations are likely to play an increasingly important part in economic life, and it is important to learn the utmost from mistakes in the past, so that such functional bodies can be made fully accountable to the community as a whole by a strengthening of political authority—national and international. The commodity control scheme of the future, international in its control of supply and of markets, should be subject to public supervision and allow for a substantial representation of consumers.

This development should remove the two main criticisms levelled against past restriction schemes —the maintenance of prices at an unreasonably high level, and the persistence of inefficient production under restriction schemes. The measures now being taken to deal with the problem of surpluses, however, involve further problems. The holding of stocks on a commodity control basis affects the financial issue. Some means must be found of bringing finance into line if commodity control schemes are to function satisfactorily in the post-war period.

Now that Governments have entered the market as large-scale buyers, they are likely to continue to do so after the War, both for unwanted surpluses and for key raw materials and foodstuffs. One centralized Government organization which controlled the marketing of such products would be in a stronger selling position than a number of individual producers and mechants, and would also be able to ensure fair distribution. In schemes established after the War for commodities in which there are shortages, consumer interest will undoubtedly play a much more important part. So, too, the barter arrangement between the United States and the British Government holds possibilities for development in the post-war period, the main economic task of which will be to build up a system which is not subject to the violent fluctuations characteristic of the period 1920–39, but which stimulates a steady expansion of economic activity and makes adjustments possible with the least dislocation of economic life.

This task is parallel with the political task of building up a stable world order which fosters co-operation between nations. Control of the production and marketing of raw materials, if organized on a comprehensive international basis, is of the first importance in both tasks. Moreover, commodity control in such an economic order involves not merely eliminating past defects so as to make a reformed pattern of commodity control an accepted part of the economic structure. It involves also market surveys and forecasting of a comprehensive type, which are scarcely possible save under a strongly organized international scheme. It requires, too, a concerted effort to avoid the existence of surpluses of foodstuffs and raw materials at one point and shortages at another, which under commodity schemes before the War were frequently found in neighbouring countries. It involves also control over the industrial potential of every nation and therefore over its power to pursue policies of aggression, and the steady and continuous enforcement of peaceful measures rather than occasional belated attempts to stop wars.

Recognition of the economic and political objects of post-war commodity control leads Political and Economic Planning to suggest the formation of an international raw materials union for all commodities, built up on the lines of the International

Postal Union and affiliating the international and national associations controlling particular commodities. This union could be set up in the first instance by the Governments of the Allies and of the United States as a non-political body, the chief concern of which would be to promote economic welfare. Only key raw materials would be brought in at the start, and the union would not concern itself with particular commodities but with the general structure to be adopted in particular commodity control schemes and the terms of supply and of purchase to be observed by bodies affiliated to it.

One important function of the suggested union would be the publication of regular reports analysing trends in price and consumption of controlled commodities, indicating successful innovations for adoption elsewhere and defects to be avoided in future schemes. Common services, such as technical and economic research or exchange of personnel, would be organized by the various commodity controls for their own commodities, and by the union in respect of wider interests. The union would also promote co-ordination between the various commodity schemes in neighbouring groups of territories, for example, by creating regional reserve stocks, developing storage capacity, encouraging diversification in areas too dependent on one or a few products, and assisting exchanges of surpluses.

On the further question of the function of such a union in enforcing economic sanctions, the broadsheet merely indicates the possibilities, with a pointed reference to the measures which the United States and the British Commonwealth are belatedly taking against Japanese aggression. The suggestion is indeed too tentative to be judged in detail, but it does indicate the value of establishing some such union during the War, and the way in which it could facilitate the work of the International Reconstruction Commission which will assuredly be required afterwards in place of the unco-ordinated effects of individual Governments which proved so ineffective twenty years ago. The same basic idea has been outlined by Dr. Julian Huxley in "Democracy Marches", and it is implicit in the fourth and fifth points of the Atlantic Charter. No reader of the P E P broadsheet can remain unaware of the difficulties with which this problem bristles, but that they should be stated clearly and thoroughly discussed is the first step, not merely towards meeting immediate needs, but also to the long-term planning and co-operation upon which the reconstruction of world trade and the development of a new and more stable world order depend.

ONTOLOGICAL EVIDENCE OF DEITY

Mind and Deity

Being the Second Series of a Course of Gifford Lectures on the General Subject of Metaphysics and Theism given in the University of Glasgow in 1940. By Dr. John Laird. Pp. 322. (London: George Allen and Unwin, Ltd., 1941.) 10*s*. 6*d*. net.

PROF. LAIRD gives us here the second half of his recent Gifford Lectures (the first half having already been published under the title "Theism and Cosmology"). "Theism and Cosmology" was exclusively concerned with the two types of theistic proof "which appeal more directly to the scientific mind", the "cosmological argument" for a "great first cause", and the argument from design. The centre of interest in the present volume is different; we are concerned with the "ontological proof", which if valid would show that God's existence cannot be denied without flagrant self-contradiction, and the various forms of the "moral argument". The consideration of the latter leads to much interesting discussion of the sense in which omnipotence, benevolence, personality can be ascribed to God, and of the possibility of "pantheism". The conclusion of the whole matter reached in the final paragraphs is that while none of the theistic "proofs" is convincing or even highly plausible, theism is a tenable, though not demonstrably true, metaphysical theory of the universe which is more plausible than most of the possible alternatives. The verdict is the Scots "not proven" (which, by the way, commonly means that the jury knows pretty well what to think of the case). This finding will not satisfy all philosophical theists, though it should not perturb those of them who are Christians, familiar with the thought of faith as a *venture*, an assent of the mind to what is not forced on it by demonstration.

Few readers of NATURE will be likely to quarrel with the contention that the "ontological proof", whether in Anselm's version or in Descartes', is a fallacy which has been once for all exposed by Kant, and that its pretended resuscitation by Hegel is really a substitution of assertion for proof. I am not equally convinced by the reasoning of the chapters on "Value and Existence" and "The Moral Proofs of Theism". Prof. Laird is always fair-minded,

acute and critical, but he has not, I think, allowed sufficient weight to the simple but impressive argument from the unconditional validity and imperativeness of the moral law to a divine moral law-giver. It is not easy for me to believe that any confusion between the moral law of right and wrong and the edicts of a political superior can account for this felt imperativeness of a law which there is no political superior to impose, and with which political superiors are only too apt to 'play ducks and drakes'. Here, I believe, Prof. Laird might have learned more from Kant than he is willing to do ; I believe more attention to Kant would have made him a little suspicious of the merits of what he calls (in his chapters on "Providence" and "Pantheism") an impersonal theism. It is argued that if as a fact existence is on the whole a boon, and virtue and success, on the large scale, go together, this adequately safeguards all that is essential in the doctrines of divine benevolence and providence ; that the "impersonalist" would ascribe this result to an unintentional *trend* in Nature is a negligible detail. But is it ? The love and gratitude which are the proper response to intentional benevolence can scarcely be evoked by a blind trend except through a romantic illusion, and it is hard to see how our destiny can be apportioned to our inward goodness of will, unless, as Kant said, by a "reader of hearts".

I would remark also that in the subtle and interesting discussion of "pantheism" Prof. Laird is probably over-hasty in inferring from the language of Christian theologians about God's omnipresence in all His creatures that these theologians are with half of their minds asserting a pantheism incompatible with the theism of other parts of their teaching. Most of the theologians in question—perhaps all—would accept the scholastic principle that no predicate (not even existence) can be asserted univocally of God and of any "creature". If the pantheistic propositions quoted by Prof. Laird are read with this qualification, their meaning may be seriously affected.

I much regret that considerations of space compel me to be content with so inadequate a notice of a scholarly, candid and most acute study which I heartily commend to all readers of NATURE.

A. E. TAYLOR.

RELATION OF ONTOGENY AND PHYLOGENY

Embryos and Ancestors

By Dr. G. R. de Beer. (Monographs on Animal Biology.) Pp. x+108+2 plates. (Oxford: Clarendon Press ; London: Oxford University Press, 1940.) 7s. 6d. net.

IN 1930 Dr. de Beer published a small and stimulating book under the title "Embryology and Evolution". In it he attempted to reorientate general views relating to 'recapitulation' in evolution. Beginning with a statement of Von Baer's laws, he described their modification at the hands of Haeckel, who in his biogenetic law abandoned Von Baer's principles of progressive deviation and instead implied, as Dr. de Beer puts it, that phylogeny is due to the "successive tacking on of new final stages to the existing adult stages of animals". Haeckel's biogenetic law had, of course, come under considerable fire before Dr. de Beer attempted to redefine the problem. Its main shortcoming was the fact that the order in which characters appear in phylogeny is frequently completely different from that in which they appear in ontogeny. The term heterochrony is applied to this alteration in the sequence of stages.

The main purpose of Dr. de Beer's original essay was to show that variation in the order and rate of appearance of structures in successive ontogenies can have considerable influence on phylogeny. Thus, if a structure which normally appeared in the young stage of an ancestral animal appears in the adult stage of the ontogeny of a descendant, large structural changes occur without loss of plasticity, a process to which Dr. de Beer refers by the name of pædomorphosis. On the other hand, characters which normally made their appearance in the adult stage of an ancestral animal might appear in the young stages of a descendant, when they would cause little structural change but considerable loss of plasticity. To this process Dr. de Beer refers by the term gerontomorphosis. Dr. de Beer's conclusion was that pædomorphosis and gerontomorphosis "act intermittently in the phylogeny of the race, the former producing racial juvenescence, the latter racial senescence".

Dr. de Beer has now republished his original book, which has been out of print for some time, under the new title of "Embryos and Ancestors". He states in his preface that much new evidence has become available in the intervening years but that nevertheless he sees "no reason to alter the plan" of his former book "in the slightest degree". The same chapters are there, but some have been extended with more recent examples.. In its new form his book is just as stimulating to read as its

ancestor, and just as provocative. Some disappointment may be felt at Dr. de Beer's failure to consider some aspects of the problem in greater detail than he has done. The most striking instance of neotony which is usually emphasized is the view that man became differentiated from his fellow primates by a process of fœtilization, and it is this example of neotony which Dr. de Beer describes most fully. His arguments are the same as those which he presented in 1930, and are derived in the main from Bolk. Unfortunately Bolk's views on this subject scarcely stand up to close examination. It may be possible to recognize a process of neotony or fœtilization in human development if we are not too critical about the choice of the details of the developmental processes which form a basis of comparison between the development of man and that of non-human primates. It is, however, certainly impossible within the limits of the order of mammals to which man belongs to recognize an orderly process of increasing fœtilization.

While Dr. de Beer's lack of reference to such shortcomings of the general principles he discusses may be regretted, there can be no doubt that he has put the central issues of the general relation of ontogeny and phylogeny clearly and vigorously. His book will with little doubt influence a coming generation of biologists no less than did his earlier essay.

S. ZUCKERMAN.

A NATURALIST IN NORTHERN IRELAND

Birds of the Grey Wind

By Edward A. Armstrong. Pp. xv+228+32 plates. (London, New York and Toronto: Oxford University Press, 1940.) 12*s.* 6*d.* net.

IT is said that no Nature book can be successful nowadays unless its illustrations are good. "Birds of the Grey Wind" has a number of really excellent photographs. That of the fulmar in flight is outstanding, but almost as good are those depicting peregrine and sparrow hawk, sandpiper and water ousel. Of special interest is the photograph of a chough feeding her young. This is the first close-up photograph I remember having seen of a chough—a rare bird, nesting in the twilight of caves—and it is perhaps because of under-exposure of the negative that it has been necessary to touch up the bills of the young choughs. There is an unusual illustration showing a mute swan chasing away a Bewick's swan on Lough Neagh.

The book describes mainly the birds of Northern Ireland. There are chapters on Rathlin, Strangford Lough and Lough Neagh; on the heron and cuckoo, red-breasted merganser, swan and cuckoo. Mr. Armstrong writes clearly and sympathetically on the birds of his Irish home. He has spent long days and nights studying them, has watched the herons' flight into their wood above Belfast Lough, mergansers displaying in the sea on a calm November day, tree-creepers roosting in the gnarled bark of some great Wellingtonia, whistling choughs soaring with wide-open primaries above Rathlin, and a young cuckoo (an excellent series of pictures illustrates this) ejecting a hedge sparrow's egg from the nest. He has a leaning for the tales of long ago: Columba awaiting the arrival of the weary crane from Eire upon his spray-drenched island of Iona; Saint Patrick landing to preach the faith at Strangford Lough—surely Lough Cuan, the old name of that lough, signifies Lough of the Sea, and not, as Mr. Armstrong says, Harbour Lake!—and the fate of the Children of Ler who were compelled to ride the stormy sea for centuries in the guise of swans.

The book contains many interesting notes on birds. We are told that Irish magpies are believed (p. 20) to be the descendants of a flock of some dozen birds from England which were blown out of their course by an easterly gale and arrived exhausted on the Wexford coast about the year 1676; that two thousand wagtails roost (p. 8) in a certain tree in a Dublin street; of the nesting of a merganser (p. 109) on a tall conifer in the old nest of a grey crow. The story (p. 34) of a kestrel bitten and killed by a stoat it was carrying off reminds me of the fate of a golden eagle not far from Cape Wrath, which rose with a stoat to a great height, then fell lifeless to earth with a great wound in its throat, the stoat, strangely enough, unharmed after its strange experience. Mr. Armstrong (p. 7) believes that the moorhen never loses its timidity even when living with other birds that are tame. But I recall that at Fallodon there was a moorhen which used to take bread from Lord Grey's hand, almost as readily as his tame ducks.

There is one small slip in Mr. Armstrong's chapter on the great auk. He describes (p. 217) Stack an Armin as being in the Orkneys: it is, as a matter of fact, a high rock rising from the Atlantic just off Boreray, one of the St. Kilda group of islands.

SETON GORDON.

CONSERVATION OF NATURAL RESOURCES*

By C. H. Desch, F.R.S.

THE natural resources of the world fall into two main groups. The one, represented by the products of agriculture and forestry, may be renewed, either annually or at longer intervals, by cultivation, and may be consumed as income, while the other, including mineral wealth, must be regarded as capital, and once consumed is not renewed. Soils should perhaps form a third category, for while they may be maintained in fertility for thousands of years, as in China, they are only too easily ruined by careless or greedy exploitation, leading to exhaustion and erosion, or by mining operations, which may cause subsidence as in parts of England, or burial under debris through hydraulic mining as in California. This paper is mainly concerned with the conservation of those mineral resources on which modern industrial civilization increasingly depends.

Mineral deposits have too often been regarded as inexhaustible, and it is only lately that the possibility of exhaustion in a measurable time has attracted attention. As industrialization becomes more intense in Western societies and continually extends to regions which were purely agricultural, the rate of consumption of mineral capital is accelerated to an extent which is not always appreciated. Sir Thomas Holland has shown that in the first twenty-five years of the present century the quantity of minerals extracted from the earth was greater than that raised in the whole previous history of the world, or, say, six thousand years since copper was first mined. A report to a committee of the League of Nations in 1937 by Prof. Högbom gave diagrams which showed that over a period of about sixty years the annual production of coal doubled itself in a little less than seventeen years, of pig iron at about the same rate, of oil in eight and a half years, of copper in twelve and a half years, and of tin in eighteen years, the general trend remaining remarkably constant in spite of temporary fluctuations. Coal, for reasons which have been given by Sir Harold Hartley, ceased to increase after 1913, but in most instances, after an initial rate of growth which may be irregular, as for aluminium to-day, a stable rate is reached which gives a straight line when plotted logarithmically.

This does not mean that the production in any one country follows this law. The older producing regions may show a slower rate of increase, but this is compensated for by the opening up of new sources as the demand grows. It may seem impossible that such a fantastic rate of growth could long be maintained, but the standard of living which calls for such a consumption of metals and power applies as yet only to the Western nations. China consumes little metal, its enormous population depending on the use of renewable natural wealth rather than on mineral capital, but it represents a vast potential consumption, and the same may be said of India and, perhaps in a more distant future, of Africa.

It is extremely difficult to form an estimate of the existing mineral reserves. The total quantity of each element in the earth's crust, down to a certain fixed depth, has been estimated with some accuracy, and the figures are surprising. Nickel proves to be ten times more abundant than lead and fifty to a hundred times more than tin. Vanadium is more abundant than copper. But it by no means follows that they can be recovered in those proportions. For the most part, metals are very finely disseminated in the rocks, and extraction is only possible where local concentration has occurred through geological causes. Nearly 90 per cent of the world's nickel comes at present from a single great deposit in Ontario, and there are few other important sources. The deposits of tin are also highly local. The concentration which is necessary for profitable working varies very widely; thus the ore of the Rand may be worked when it contains one part of gold in 150,000, while hydraulic mining has been used on deposits containing only one part of gold in three millions. On the other hand, an ore containing 20 per cent of iron is of low grade.

The estimates of world mineral reserves given by standard authorities fluctuate from year to year, but there is a certain complacency in the statement regarding some important minerals that the reserves will last for several decades. Where essential capital, which there is no possibility of replacing, is concerned, we have to consider a more distant future. It appears that coal and iron may last for several thousand years, but the known reserves of oil, gold, tin and perhaps copper suggest a life of less than a century. That life may be extended in two ways: by the discovery of new deposits, or by improvements in methods of mining and extraction. The first is always possible, and there are regions such as the mass of ancient rocks in Canada still covered by

* Paper read at the Conference on Science and World Order on September 27.

forest which may prove to be valuable, but the areas unsurveyed are constantly dwindling, and there are vast regions which are mineralogically barren. By far the greater part of the mineral production of the world comes from countries bordering the North Atlantic, and ore deposits of importance are limited in the main to the fringes of the great oceans and a few mountain ranges.

It is, however, possible to improve greatly the methods of mining and of concentration. To take the latter first, the enrichment of sands and crushed rocks by mechanical separation is as old as mining itself, but it has been greatly perfected in the last century, and the introduction of new physical methods, such as magnetic separation, froth flotation (depending on surface tension) and electrolysis have made possible the working of ores of low grade. Further inventions of this kind may revolutionize the extraction of minerals, and in that case the estimates of the life of deposits now accepted may be too pessimistic.

Improvements in mining may make it possible to extract a larger proportion of the useful material from a given deposit, and this seems particularly likely in the case of oil, but it must be remembered that mining operations are usually wasteful. The extraction of the rich ore from a mine frequently renders inaccessible a larger quantity of ore of lower grade which it does not pay to bring to the surface. Under the usual conditions of exploitation there is a natural tendency to 'skim the cream' from a deposit, extracting only that material which is immediately profitable, and this is most likely to occur where a concession is being worked, perhaps in a politically unstable country, by a foreign company. This is one of the factors to be taken into account in a scheme for an international control of raw materials.

Each new technological advance is apt to create a fresh demand for some material, which may be of scanty occurrence. The electrical industry is much dependent on the unique qualities of certain varieties of mica, and the engineering industries call for steels and other alloys containing the rarer elements, such as nickel, tungsten, molybdenum, cobalt and vanadium. The light alloy industry is of very recent origin and has opened up great new fields of usefulness, and this again will in future make greater use of some of the rare elements. Little is known as to the available reserves of these metals, but the deposits containing them are usually small and are highly local. Some of them must be within measurable distance of exhaustion.

One possible mineral source as yet but little explored may be mentioned in passing. Owing to the disintegration of rocks by weathering and the transport of the products by water, all the elements present in the rocks are found in the sea. It is true that they are in an extremely dilute state, but recovery is not impossible. The fiasco of 'gold from sea water' of some years ago may seem to make this unlikely, but modern physical chemistry suggests possible means of concentration. Already magnesia is recovered from sea water in quite large quantities, the great volume of water which has to be handled not proving an obstacle.

Most minerals, once extracted from the earth, find application in industry, and after a period of usefulness which may be long or short become waste. Some of them, but not all, return in part in the form of scrap. Steel is made from pig iron, and until 1914 the world's production of pig iron was greater than that of steel, the balance being used in the foundry. In 1914 the curves crossed, and since then the production of steel has been greater, and increasingly so, than that of pig iron, owing to the very large quantities of scrap which are returned to the steel furnace. Not all of it comes back, corrosion and waste accounting for a considerable proportion. The use of recovered or 'secondary' metal, as it is called, is also becoming important in other metal industries, such as that of aluminium. Unfortunately, the key elements used in small quantities in alloy steels are largely lost, and it is here that a shortage is soonest likely to be experienced. Research is needed to devise means of recovering these essential and irreplaceable materials when the objects which contain them become scrap.

Much is now heard of substitutes for materials which have become scarce, and in Germany especially great efforts have been made to reduce to a minimum the quantities of metals used, such as nickel and tin, which cannot be produced at home, but it cannot be said that any startling success has been obtained in this direction. The new field of plastics offers genuine substitutes for metals for a variety of purposes, and as some of them can be manufactured from agricultural products they represent a real contribution to the cause of conservation.

There is one instance of a mineral which has been almost entirely replaced by an artificial product. Chile nitrate, for long the only source of artificial nitrogenous fertilizers, and occurring only in certain rainless districts of South America, where it had been formed under quite exceptional geological conditions, was clearly limited in its reserves, and its exhaustion could be foreseen. In 1898 Sir William Crookes, in a famous address to the British Association, painted an alarming picture of a decline in the supply of wheat owing to the exhaustion of soil nitrogen. Nitrogen compounds synthesized from the air have now replaced Chile nitrate, and the supply of them is inexhaustible. Radium, the

ores of which are very rare, is being supplemented for medical and similar purposes by artificial radioactive elements, but substitutions of this kind are obviously very exceptional In the main, we can only look to a more economical use of metals and to more complete recovery as a means of conservation. Another fertilizer, phosphate, is mainly derived (apart from that which is a by-product of the basic steel industry) from a few sources of limited extent, and our present highly inefficient means of dealing with sewage leads to the greater part of the phosphates being discharged into the sea. This is a form of waste which is closely linked with the general question of the fertility of the soil, and the problem will call urgently for a scientific solution in the very near future.

The case for a planned conservation of mineral resources may not seem so strong as that for energetic action to conserve soils and forests. Even minerals of which the known reserves are small may last for several generations. The future of the rarer and increasingly important elements is more difficult to foresee because of the imperfect survey so far made of their scattered deposits, but it is likely that the demand for them will increase more rapidly than that for the more common minerals. However, many of the errors of the past have come from lack of foresight, and a planned world economy must take account of conditions a century or more hence, when our descendants may find themselves hampered by the wasteful exploitation of natural resources in our own day.

That an international control of raw materials will be needed after the War is a natural consequence of such a promise as that of equal access contained in the fourth aim of the Atlantic Charter. A recent issue of *Planning* (P E P) has suggested a means by which such a control could be introduced, tentatively at first by application to a small number of commodities, the international raw materials union of producers including representatives of Governments in their capacity of consumers as well as producers. Such an authority would have many functions outside the scope of this paper, but as it would be in possession of the fullest information as to production, consumption and reserves it would be able to consider, in the light of that knowledge, the question of the possible exhaustion of reserves, and to recommend, or if its constitution should permit, to enforce, greater economy in use or a restriction of exploitation.

ECONOMIC ASPECTS OF THE BLOCKADE AND COUNTER-BLOCKADE

By PAUL EINZIG

THE relative importance of the economic factor among the factors determining the outcome of the War has increased considerably as a result of the progress in the mechanization of the armed Forces. Requirements of weapons and equipments of raw materials necessary for their manufacture and of motor fuel are now incomparably larger and more diversified than they were during the War of 1914–18. The striking power of the armed Forces is now dependent on the industrial capacity and the importing capacity of the belligerent countries to a much higher degree than in previous wars. The belligerent countries are now incomparably less self-sufficient than they were in the past. For this reason the duration and outcome of the present War depends to a very large extent on the results of blockade and counter-blockade.

It is essential to avoid exaggerating the relative importance of economic warfare ; but it is equally important to avoid going to the other extreme. The exaggeration of the relative importance of the blockade during the early months of this War was largely responsible for the slackness of Great Britain's war effort in other directions during that period. After the disillusionment that followed the German victories in Western Europe, the pendulum swung in the opposite direction, and for some time it was all but generally believed that economic warfare in general and blockade in particular was incapable of producing any noteworthy results. The truth lies somewhere half-way between the two extremes. In order to defeat Germany it is indispensable to win a decisive military victory. Such a victory is inconceivable, however, unless and until Germany's vital economic resources have been materially reduced as a result of offensive economic warfare. It is an equally essential condition of victory that offensive economic warfare waged by Germany in the form of counter-blockade and air bombing should be prevented from reducing Great Britain's economic resources.

The argument of those who underrate the importance of offensive economic warfare among our weapons against Germany runs broadly as follows :

The relative extent to which Germany's economic resources can possibly be affected either by air

bombing or blockade is moderate. Germany's industrial capacity is so vast, her plants and stocks are so widely dispersed over the territory of the Reich and of the occupied countries, that the R.A.F. would be incapable of destroying more than a relatively small fraction of these resources. As for the blockade, its significance has become materially reduced as a result of the acquisition of new sources of raw material through the conquest of the greater part of Europe, and as a result of the development of the production of synthetic materials. There is a great deal of truth in this contention. It seems an altogether hopeless task to try to reduce Germany's economic war potential in general by means of an economic offensive. On the other hand, it is by no means beyond the realms of possibility to reduce certain key resources of Germany.

During the earlier phases of the War it was hoped that the German war machine could be paralysed by concentrating upon the reduction of German stocks of oil, rubber, textiles and rare metals such as tungsten, molybdenum, wolfram, etc., required for hardening steel. In the meantime, this list became shorter, partly because Germany succeeded in seizing large stocks of special metals and partly because the necessity for concentrating on a small number of materials had become obvious. Indeed, in my own view, maximum results could be achieved by simply concentrating on oil. Assuming that Germany will be unable to seize the Russian oilfields—or at any rate that even if she should seize them they would be in a hopelessly damaged condition—there is every reason to hope that the British economic offensive would be able to paralyse the German war machine and economic system by bringing about a reduction of Germany's oil supplies. While in most other respects the blockade does not inflict upon Germany an intolerable burden, in respect of oil it is capable of preventing almost completely the arrival of consignments from outside Europe. Moreover, if the air offensive is concentrated upon the oilfields under German control in Poland, Rumania, etc., and on synthetic oil plants, refineries, storage tanks and pipelines, then Germany's producing capacity and stocks could be materially reduced. By pursuing such a policy, economic warfare would be made to play a decisive part in preparing the ground for military victory.

Hitherto we have confined ourselves to examining the possibilities of Allied offensive economic warfare against Germany. Let us now consider the problem of the defence against German offensive economic warfare. The British economic system has no Achilles' heel comparable to the German oil position, for the simple reason that so long as mastery of the sea is retained, deficiencies in particular materials can be made good by importing from overseas. For this reason, while German air bombing is capable of inflicting considerable losses upon life and property, it is in itself incapable of paralysing the British war machine and economic system in the same way as British air bombing is capable of paralysing the German war machine and economic system if concentrated upon oil production and supplies. The only way in which German economic warfare against this country could play a decisive role would be through cutting off Great Britain's lifeline. This is exactly the object of the German counter-blockade.

While Germany largely relies upon the production of food and raw materials of conquered Europe, Great Britain depends to an even larger extent on economic assistance from the United States and from the British Dominions. Neither of the belligerents is able to prevent the other from making use of these vast auxiliary resources outside their own territory. Judging by the progress to date of the Battle of the Atlantic, the German counter-blockade has so far failed to achieve this end. Judging by the expenditure of vast quantities of oil by Germany in the offensive against Russia, the results of the British economic offensive in the restricted sphere of oil have also been far from complete. These facts do not, however, prove that the economic weapon is of relatively small importance. After all, during the War of 1914–18, it took four years for the British blockade to produce its full effect upon Germany. It would be unduly optimistic to assume that the Battle of the Atlantic has been won and that Germany is entirely incapable of preventing Great Britain from benefiting by American and other overseas economic assistance; and the mere fact that certain statements concerning the effect of the British blockade on the German oil position have since proved to be at least premature does not mean that sooner or later the British economic offensive will not deprive Germany of her vital oil supplies.

Blockade and counter-blockade tend to produce a profound effect upon the economic structure. The result of the British blockade is an intensification of the German self-sufficiency drive, and its extension over German-controlled Europe. Under the necessity of war requirements many new branches of production are established and existing ones are expanded. The German counter-blockade affects the British economic system in a different way. It is true that in some respects self-sufficiency is aimed at in order to economize in shipping space. For example, in Great Britain food production tends to increase, largely as a result of the German counter-blockade. The same factor also works, however, in the opposite sense. It requires less

shipping space to import the finished products than to import raw materials required for their production. Partly for this reason many new plants have been established in the British Dominions in preference to their being built at home. In order to reduce the dependence of the British Forces in the Middle East and the Far East upon the lifelines from Great Britain, exposed as they are to German attacks, munition industries have sprung up in India, Australia and New Zealand. These Dominions are unable to depend on imports from Great Britain, and tend to become much more self-sufficient through the development of industries of their own.

The same is true concerning neutral countries. Lack of shipping space, among other reasons, prevents Great Britain from supplying her Latin-American markets to the same extent as before. The British blockade prevents these countries from buying manufactures from Germany, Italy, or other German-controlled industrial countries. Nor are the United States or Japan in a position to fill the gap. Consequently, blockade and counter-blockade leads to the industrialization of Latin-America. In any event, since the blockade and counter-blockade have made it more difficult for the Argentine, Brazil, etc., to sell their products either in German-controlled Europe or in Great Britain, they could ill afford to keep up their imports at pre-war level.

It seems probable that to a very large degree these effects of blockade and counter-blockade will be of a lasting nature. This was the case with the economic effects of the Continental system and the British retaliatory measures adopted during the Napoleonic wars, and also with the effects of blockade and counter-blockade during the War of 1914–18. It is true, there is a great deal of idealistic agitation in favour of free trade after the War. The fact, however, that by the termination of hostilities the degree of international division of labour will be much smaller than it was in 1939 will have to be borne in mind. Overseas countries will be reluctant to de-industrialize themselves. Most countries will be anxious to retain and develop industries required for national defence. As for Great Britain, the permanent loss of many of its overseas markets and the decline of its income from overseas investments will make it necessary to continue to produce at home more food than it did before the War. The task of 'unscrambling the eggs' by demobilizing new industries abroad and by letting the millions of newly sown acreage in Great Britain go once more out of cultivation will be more difficult than is generally realized.

The lessons learnt from experience in economic warfare during this War are likely to influence the peace terms. The victors will want to disarm their vanquished opponent not only in a military sense but also in an economic sense. The reversal of Germany's trend towards self-sufficiency would provide some safeguards against another war; a compulsory demobilization of some of her industries producing synthetic key materials would go a long way towards discouraging a repetition of 1914 and 1939, simply by rendering Germany more vulnerable to blockade.

SEISMOLOGY AND EARTHQUAKE-PROOF DESIGN

By Ernest Tillotson

On May 7, 1940, Mr. D. Laugharne Thornton read a paper on "Earthquakes and Structures" to the Royal Society of Arts[1], in which he stressed the need for the co-operation of engineers and seismologists for the purpose of mitigating the effects of earthquakes on buildings. Mr. Thornton's paper showed that engineers are fully alive to the situation, while the work seismologists have been doing to this end is perhaps not generally realized. Most of the work has been done with actual earthquakes, though much useful information has been obtained by the use of shaking tables and artificial earthquakes caused by dynamite explosions. (The results might be of immediate use in 'bomb-proof' design.) As Great Britain is an island in which strong earthquakes are rare, adequate results would not repay the setting up of strong-motion instruments, and most results have, therefore, been obtained in the United States and Japan. Mr. Thornton stated in his paper that "the first great earthquake in which scientists were ready with a wide distribution of instruments including some capable of recording strong motion, occurred so recently as September 1, 1923, at Kwanto, Japan". It may well be that the first adequate and reliable results for certain purposes were obtained then, though ever since the time when Milne and Knott were in Japan valuable information has been accumulating. Certain institutions and individuals have also long been obtaining noteworthy results in the United States, though it was late in 1932 when the U.S. Coast and Geodetic Survey inaugurated a programme of recording strong ground movements in seismically

active regions of the country to obtain data needed in the design of earthquake-resisting structures. The Survey has published much of the work, and the latest publication has recently been received[2].

Several types of strong-motion seismographs are used, but only the accelerographs and displacement meters give results of wide scientific value. These instruments do not operate continuously on account of the paper cost and the necessarily large speed of the record during the earthquake, but are automatically started through a pendulum-starting device by any earthquake which attains a certain strength. After a time the photographic record is automatically stopped. It is then removed and developed.

Seismographs are themselves pendulums especially devised for the purpose they have to serve. The accelerographs are so called because their period of 0·1 sec. is relatively short compared with that of the principal earthquake waves which cause damage, and therefore their acceleration is measured. The displacement meters have a period of 10 sec., and, since this is relatively long compared with the period of the principal waves in which we are interested, they record approximately the displacements. There are now thirty-five accelerographs in California, four in Arizona, four in Montana, one in Utah and one in the Panama Canal Zone. There are six displacement meters in operation, all in California, but each is installed near an accelerograph.

The positions of the instruments are important, since it is necessary to distinguish between ground movement and building movement. The accelerograph mostly used is more compact and satisfactory in operation than the displacement meter, and the chance of obtaining acceleration records is so much greater than that of obtaining displacement records that the former is often installed and the approximate displacements calculated. To do this the acceleration records are first enlarged and then, on the assumption of simple harmonic motion, these are integrated to obtain velocity curves which are in turn themselves integrated to give displacement curves. The mathematical principle is simple, but owing to the irregularities of earthquake motion there are many complications in the actual operations. These problems have all been solved, and in a private letter Dr. L. O. Colbert informs me that it is now the regular practice in his department to integrate the more important records, the others having to be omitted only because of necessity. Engineers are interested in all three sets of curves, namely acceleration, velocity and displacement.

In addition to the accelerographs and displacement meters several strong-motion seismographs of a type invented by Mr. Arthur J. Weed of the University of Virginia are in operation. This is an inverted pendulum device of period 0·2 sec. with oil-damping, and registers on smoked glass in three dimensions. The pendulum is always working, and when the vibrations become sufficiently intense a trigger action starts the clockwork which drives the smoked plates. Calibration is necessary. Since in the United States the various instruments are well distributed over the regions subject to earthquakes, a considerable number of records have been obtained, and all the principal earthquakes since and including the Long Beach earthquake in California of March 10, 1933, have produced records. The most informative records have been the three records of the Long Beach earthquake (one obtained in the business centre of Los Angeles), the records of the Imperial Valley, California, shock of 1934, those obtained for the shock at Helena, Montana, in 1935, and especially those of the earthquake of May 18, 1940, also in the Imperial Valley. The latter was of special interest as the instrument was only seven miles from the epicentre and a slightly greater distance from where there was slipping of 12 ft. along the fault.

Earthquake work in Japan is largely organized by the Earthquake Research Institute of the Tokyo Imperial University. Since the early part of 1939 economic depression has cut down the work of this Institute. Transport difficulties have also decreased the amount of information received from Japan so that the present state of Japanese seismology is somewhat unknown. Undoubtedly important work is proceeding there, as prior to 1939 great strides had been made. Early in 1931, Prof. Mishio Ishimoto perfected his acceleration seismograph, since which time it has taken various forms, all recording on smoked paper. The pendulum period is 0·15 sec. and the static magnification is about 200. An acceleration of 1 cm./sec.^{2} gives an amplitude on the record of 1 mm. There is a considerable number of these instruments in operation, but their present whereabouts are not known exactly since they are sometimes moved to get a better distribution.

The acceleration and displacement have in general proved to be greater than anticipated. For the northern California earthquake of September 11, 1938, the Ferndale accelerograph south-west–north-east component registered an earth wave period of 0·18 sec. with a maximum acceleration of 93 cm./sec.^{2} and a maximum displacement of 0·075 cm. This was not one of the great earthquakes of California, though the acceleration stated is above the average for 1938. Investigations at the University of California, California Institute of Technology and the Massachusetts Institute of Technology, have been made to deter-

mine the relation between actual damage and the measured motions.

One interesting utilization of the displacement curves is for the control of shaking platforms on which working models of buildings can be tested. This has been done at all the institutions mentioned, and photo-electric cell controls have been devised so that the motions can be closely reproduced. At the Massachusetts Institute of Technology the interesting experiment has been made of placing the accelerograph which recorded the Long Beach earthquake at Los Angeles on the shaking platform, subjecting it to the deduced displacement of that earthquake, and then reproducing the accelerogram. The reproduction, though not perfect, was quite satisfactory.

Since the destructive elements of motion are not fully known and are ascribed variously to acceleration, velocity, and period (because of resonance induced by the earthquake wave having the same period as the natural period of the structure) other observations are needed. The periods of thousands of buildings in various cities of California have been measured and are being analysed in regard to the type of building. It is proposed to re-measure the periods in selected types of buildings after a major earthquake. To measure the period the buildings are shaken by an eccentric fly-wheel device which is of variable speed, so that one of its periods corresponds to the natural period of the building. From the records, the period or periods of the building are readily obtained. The recording is done by a vibration meter, generally constructed on the principle of the Wood-Anderson torsion seismometer, or on a Neumann–Labarre vibration meter. Dominant ground periods have been reported from Göttingen, Germany, and Tokyo, Japan. In the United States a large-scale ground shaker has been built, but the high sensitivity Neumann–Labarre horizontal vibration meter and the Patterson vertical vibration meter show several distinct periods in California, none of which is dominant. It is recognized that a large earthquake might shake a thicker layer or layers of the earth's crust and thus produce a different period or periods. The general purpose of the work is to see whether a more logical method can be developed than that of providing in the buildings for a horizontal force equal to some percentage of gravity. Ten per cent is effective in Japan where the structures are simple and low, but it does not serve for the multitudinous array of buildings in California, or for all the other types of buildings in other parts of the world which are frequented by earthquakes.

Experiments have been made, mostly in Japan, in connexion with the vibration of various parts of a building. Records were obtained with a vibration meter orientated in various directions and placed successively on various floors of the steel-framed eight-storied tower and four-storied wings of the Imperial Diet building in Tokyo at various stages of construction, by Prof. Akitune Imamura. These showed that when the ground period was near 0·4 sec. the vibration was like that of a frame fixed at each end, whereas with a ground period approaching one second it was like a frame fixed only at one end. The former experiment suggested that the frames were too slender for their massive top load. The designers thereupon reinforced the weak parts of the building and thus increased the seismic stability of the structure. Prof. Katsutada Sezawa and Dr. Kiyoshi Kanai have subjected ideal cases to mathematical investigation and have found formulæ to represent the dissipation of vibrational energy. Fitting one of these formulæ to special boundary conditions, the greatest damage was found to occur in buildings at places where there was maximum bending moment as deduced from the formula. One building in their work is considered to be a circular cylinder constructed on a frame and having several stories. The columns in which the greatest bending moment is induced differ with difference in the value of $Ej^2\varepsilon/\mu l^3$ where E is Young's modulus of the structure, j is radius of gyration of the section, ε is radius of the structure, l is length of structure, and μ is elastic constant for earth. When $(Ej^2\varepsilon)/(\mu l^3)$ is 0 the columns in which the greatest bending moment is induced are those below the first floor. The larger the value of $(Ej^2\varepsilon)/(\mu l^3)$ the more the columns of floors still farther up partake of the greatest bending moment. In the limiting case where $(Ej^2\varepsilon)/(\mu l^3) = \infty$, the floor under consideration is that which is immediately below the roof or that a few floors below the roof. Friction in buildings may also damp down earthquake stresses.

Another distinct line of research has been pursued by the U.S. Bureau of Mines and other investigators, including Prof. L. Don Leet. When dynamite is used to shatter and remove rock, a by-product of the operation is the dissipation of a small fraction of the energy of explosion in the form of elastic vibrations which travel away from the blast through the ground. The types of waves have been studied in connexion with the geological formations through which they pass, and the dissipation of energy investigated. High frequencies (25–50) and short duration (about 0·5 sec.) are typical of records on rock. Lower frequencies (3–5) and longer duration (maximum observed in one set of experiments 23 sec.) are recorded on unconsolidated deposits particularly if the deposit exceeds twenty feet or so in thickness. The range of amplitudes for various distances and sizes of charge can now be predicted within limits which are narrow

enough to be of practical engineering value in estimating probable effects on structures.

In Great Britain very few earth tremors and no large earthquakes are experienced, but earthquake regions do exist in the British Dominions and Colonies, and British insurance companies often have interest in regions subject to earthquakes. It is well to point out that a body of information on strong-motion seismology does exist and that methods are available to those interested for the study of problems relating to the construction of earthquake-proof buildings. In various parts of the world building codes are in operation, and in such of these areas as are subject to earthquakes, buildings, bridges, dams and other structures financed in part or wholly from public funds, together with such structures as are built under the control of the authority, are designed in some measure to withstand earthquake stresses. It cannot be too strongly emphasized that this part of seismic science is progressing rapidly and that a study of observations obtained either from natural phenomena or from experiments, in addition to providing us with useful information, enables us to ask more intelligent questions in the future.

PRESERVATION OF THE BRITISH FLORA*

By Dr. J. Ramsbottom, O.B.E.

MANY societies, leagues, associations and other bodies have concerned themselves in the past with the preservation of native British plants. The appeal is often made on æsthetic grounds. This is a sound policy, but occasionally it has seemed to get a little out of hand, and even sometimes to have defeated its object.

It is probable that far more damage is done by trampling down the plants than by picking the flowers. Many plants, as for example the common heather or ling, cannot endure trampling, whereas the effect of picking the flower of a bulbous plant is seen with daffodils and tulips every year in our gardens. Reasonable and careful picking of the commoner wild plants does little harm, and the joy that comes from flowers is one that it seems senseless to chide. It is really at bottom the spirit that prompts crowds to flock to Kew, Hyde Park, Bushey Park, Hampton Court, etc. This spirit should be encouraged in other directions.

Most of our attractive wild flowers are so abundant that little harm follows a reasonable amount of picking. The digging up of plants is a totally different matter. Plants with a successful method of reproduction such as bulbs, or corms, and perennial plants, do not disappear if only the flowers are removed: other plants suffer only in so far as there is a loss of seed production. But it is obvious that if plants are dug up there will be a gradual disappearance, no matter whether they are as prolific as are primroses and ferns in the south-western parts of England. Practically every civilized country has recognized the danger; in most there are societies which have laws prohibiting activities subversive to the welfare of the native flora.

In 1931 many societies, councils and institutes which are interested in various aspects of plant preservation elected representatives to the Wild Plant Conservation Board, which works under the auspices of the Council for the Preservation of Rural England. In 1914 the Selborne Society, through its Plant Protection Section, had prepared a Bill for presentation to Parliament, but legislative action was prevented by the outbreak of war. However, there is a good deal of scope provided by the Local Government Act of 1888, which empowers county councils to adopt by-laws for the preservation of wild plants.

Botanists and ornithologists have viewed with concern the effects of cutting verges and lopping hedges in country lanes. Here we meet with difficulties. The lanes must be kept tidy if on no other grounds but those of safety to users. There are various weeds which the Corn Production Acts say the farmer must destroy, and it is unreasonable to expect him, or roadmen, to carry out this obligation if botanical discrimination is added to the task. There are signs, however, that some county councils realize that there is no necessity for ruthless and indiscriminate cutting, or that spring or early summer is necessarily the period for the tidying process.

With rarer plants the problem is different. Some of these are unattractive to the non-botanist and are not likely to suffer except through excessive collecting. One or two are reputed to have vanished on this account, and the evidence from herbarium sheets gives support to some of the accusations that have been made.

* From the presidential address to the Botanical Section of the South-Eastern Union of Scientific Societies, delivered at Kingston-on-Thames on July 26.

On the other hand, some of the rarer plants are showy. An attractive plant may be protected because of surviving in more or less inaccessible places, such as the Cheddar pink. It seems to me that the only way to ensure the safety of others is to arouse a local interest in their protection. Local pride would do a good deal to preserve such rarities, especially if the habitats were known and the danger of extinction appreciated.

But there is also a wider problem which is not concerned with thoughtless or witless destruction. At the time of Cæsar's invasion of Britain we know that it was largely forest. During the Roman occupation much of the land was cleared and roads were built. With the cutting down of forests there is a difference in rainfall and always soil erosion, sometimes, as is more clearly understood in those countries which are paying the price, to the extent of causing deserts. When roads are made there is always an alteration to the drainage. With the building of towns cattle were put to pasture rather than driven from place to place. From all these processes at work there must have resulted an enormous influence on vegetation. I am not suggesting that any species were lost, though there might well have been. On the whole the number of species in the British flora is small; this is explained by the fact that more were not able to advance into Great Britain after the last retreat of the ice. The Channel has acted as a barrier to the invasion of plants from the Continent. If, therefore, any plant species were wiped out, that finished the matter; they did not come again.

The settlement by the Romans started changes which have continued to the present day. The old highways with their droves of cattle and wide expanse must have had an enormous influence on vegetation and consequently upon individual species. Later the spread of towns and the effect of smoke and other pollution consequent upon this have all had their destructive effect. The drainage of the Fens which began in the Middle Ages enormously affected the vegetation of the areas concerned. Neither must we forget the effects of farming, forestry and other forms of cultivation.

What we get as a gradual effect of civilization is an alteration in or a destruction of primitive vegetation. The change has taken place and most of it could not have been prevented even if this had been desirable.

As London extended, known localities of rarities were built over. Some of the habitats mentioned in the herbals now make strange reading. The one probably most quoted is that of the small bugloss given in Johnson's edition of Gerard's "Herbal", 1633, *Buglossa sylvestris minor* (*Lycopsis arvensis*)—"On the drie ditch-bankes about Pickadilla".

The lost habitats best known to London botanists are those of Battersea Fields, Chelsea Fields and Brompton Marshes, which disappeared as the Thames Embankment was built. A number of interesting species remain between Putney and Kew. Clusius, in his "Historia Plantarum Rariorum" (1601), records that the daffodil was "in such abundance in the meadows close to London, that in that celebrated village of Ceapside the country women offer the flowers in profusion for sale in March, when all the taverns may be seen decked out with these blossoms"; L'Obel (1605) also says, that in February and March the London flower-market is full of it.

Such losses are inevitable. As towns spread, especially in the old haphazard way, places famous as collecting-grounds from the time of the herbalists become just building sites to be developed. London has been fortunate in having royal parks and commons which are sterilized against such development; and a far-sighted policy reserved such forests as Epping and Burnham Beeches and is now organizing a green belt.

It is possible by sensible town planning not only to arrange proper means for fresh air and recreation for everyone, but also to prevent the sprawling ribbon development which has made some by-pass roads by-words. There are certain other consequences which it would be out of place here to mention. The point that can be legitimately made is that the countryside around such roads is ruined.

We are faced, however, with a much more serious problem at the present time as a direct result of the War. Aerodromes and military camps have multiplied over the countryside, and the carrying out of various exercises and other preparations for defensive or offensive war have made a sorry mess of some areas. I simply state the fact about our flora just as I would about the destruction of many famous buildings: it would be absurd to do more considering all that is at stake. Before the outbreak of war the Air Ministry paid due attention to the representation of those interested in different ways in the areas in which it was proposed to build aerodromes, and I understand that, even under the strain and stress of war, regard has been paid so far as is expedient to what is now popularly styled the amenities of the countryside. This enlightened policy is one of the most hopeful signs that we may look forward to the after-war period as one of 'reconstruction' in every sense of the word. It is obvious to everyone with eyes to see that there are a great many new blots on the landscape. After the War it may be that some of these will have to remain, but it should be a definite policy to remove, so far as possible, those which are no longer serving the purpose of national defence. Moreover, it may not be amiss to suggest that when an area is in occupation by H.M. Forces,

vegetation should not be wantonly or carelessly damaged. Trees which are knocked about, for example, do not invariably survive—and trees do not grow in a night.

Let us see to it that when salvaging our material possessions after the War we take care that our countryside is looked after.

When the time comes local bodies should make it their aim to get rid of all objectionable signs of war activity in their areas and they should be pressed to do so by local natural history societies. A derelict camp still with obvious signs of previous occupation is a sad sight, and does not improve with the years. Heaps of bully beef tins and other refuse left by our troops in the South African War are still to be seen in some parts of the Karroo. Organic material is soon dealt with by fungi and bacteria, but bricks, petrol tins and barbed wire are beyond their efforts.

In recent years there has been a strong movement on the part of several societies and associations for the establishment of national parks: roughly the objects they have in view may be classed as landscape preservation, public access and protection of wild life.

The idea of national parks seems to have been put forward first in 1832 by George Catlin, who suggested that the country around the geysers near the head of the Yellowstone River should be reserved as a public park.

The Yellowstone Park, sixty-five miles long by fifty-five miles broad, was reserved in 1872. The Oxford Dictionary defines a national park as "an extensive area of land of defined limits set apart as national property to be kept in its natural state for the public benefit and enjoyment". The definition is excellent so far as it goes, but there may be differences of opinion about the interpretation of the words "public benefit and enjoyment". The national park movement has spread rapidly in those countries where there are great stretches of unaltered vegetation. In Great Britain it is obvious that we cannot emulate Yellowstone Park, Jaspar Park, Kruger Park, that of Belgian Congo or those of Angola and the islands of the Gulf of Guinea now under consideration by the Portuguese Government.

What it is possible to do should be carefully considered—and then done Probably nowhere in southern England—though possibly in the north, in Wales and in Scotland—could we fix on an area sufficiently extensive to fulfil all the objects in view. But this does not mean that no attempt can be made to preserve tracts of countryside representative of our scenery. These tracts may be called national parks, or what you will; they should be sufficiently extensive and isolated not to suffer from suburban suffocation.

Recreation is a vital necessity for the public if there is to be real health of body and mind, but there is no reason why this should not proceed hand in hand with preservation. Sanctuaries could be set aside in the larger areas for preserving any species which need protection, in addition to smaller areas scattered about the country as nature reserves. If the public are educated up to it they will demand that such species be protected; education is more effective than *Verboten*—just as "Reserved for the protection of . . ." is than that wooden lie "Trespassers will be prosecuted". The way in which the general public obey some very annoying present-day restrictions gives ample proof of the fact that a law or regulation is the more powerful the more the reason for it is comprehended.

Strange as it may seem, it is often overlooked that it is the vegetation which is the key to the position. If plants are preserved then the scenery remains pleasant, and birds, animals and insects are for the most part safe. Perhaps the best way to appeal to the public is to make a point about the scenery: "Preserve the country's scenery"—and the rest follows. The general aim could then be stated as the desirability of preserving the various types of representative British scenery in sufficient numbers as to be reasonably accessible.

It is obviously impossible to sterilize a sufficiently large area in the British Isles to include all types of scenery or vegetation. The type of vegetation depends in the first instance upon the character of the soil, the altitude and the amount of rainfall, and as any large park or parks would need to be in a mountainous district we obviously cannot envisage such a park as providing an epitome of the country's vegetation. For that we must have several areas and, for special protection, areas set aside in these. No plan will succeed which attempts to exclude free access by the public. Those of us who know Richmond Park, Wimbledon Common, Burnham Beeches, Epping Forest and Virginia Water will have no qualms about the bad effect of open access to pedestrians. But it would be advisable to restrict motoring and horse-riding. Motoring brings obvious evils in its train, and those following excessive horse-riding in Epping Forest were causing an outcry in the last year or two.

The prevalent opinion seems to be that where areas are set apart for preservation Nature should be left to its own devices and then all would be well. In Switzerland each canton has its laws for the preservation of plants and there are several Nature reserves; there is also the Swiss National Park situated in the Lower Engadine. Here the following rules and regulations are in force. Human interference is absolutely excluded from

the whole region. Shooting, fishing, manuring, grazing, mowing and wood-cutting are entirely prohibited, no flower or twig may be gathered, no animal killed and no stone removed—even the fallen trees must remain untouched. In this way absolute protection is secured for scenery, plants and animals: Nature alone is dominant. Any one may visit the Park, but only simple Alpine shelter-huts are provided, no hotels being allowed to be erected. Camping and the lighting of fires is prohibited.

Some would like similar regulations made for any national park we might have. But it should be pointed out that only in areas of primitive vegetation is it possible to leave well alone and be certain that it will not alter. The vegetation of Great Britain as it is now is largely the result of interference; many of the types of vegetation are not as they would be if they were not controlled by various factors. So long as these factors remain the same, the vegetation remains the same. Taking it as a whole the vegetation of Great Britain is not static. For every type of soil there is a type of vegetation which is called a climax and there is a natural gradual change towards this. Everyone must have noticed hawthorn and other bushes 'invading' grassland adjoining woodland, but it is not always realized that this is a natural process leading to the climax vegetation—for forest is the climax.

The idea is often expressed that "Education of the average adult to respect our wild flowers may seem well-nigh hopeless. He is not interested". Certainly the normal place for beginning education is the school, and much can be done there to inculcate a proper appreciation of our native scenery and the duty of preserving vegetation from spoliation. But education does not end at school, and the B.B.C. and the cinema have brought home to many an interest in green things growing.

When the present War is over it is possible that eventually there will be many changes in our normal mode of life. Maybe some benefit other than speed will accrue from the increase in the use of mechanical devices. To one not versed in the refinements of economics the conclusion seems justified that if work is done more quickly by fewer men there must either be unemployment or shorter hours. We certainly had unemployment before the War, and in the future reconstruction we may well look for shorter hours for those engaged in manual labour, though not I fear for the rest of us. If this desirable state of affairs eventuates, we are then faced with the basic problem of education, how to spend one's leisure time.

When leisure time is short, sports and spectacles are sufficient as relaxation for most; but with longer periods of freedom normal people will need something in addition. Some will doubtless be attracted by the study of natural history. Men and women of the Forces and evacuee children will be unlikely to be content to stay put, and we shall probably have a greater number exploring the countryside than ever before. Let us have wide open spaces, call them what you will, let us keep them so that they will ever show what Great Britain was by showing what she is, let us realize that it is to the community's interest to preserve wild life, be it plant, bird, animal or insect: then when we have the same pride in our natural possessions as we have in our race we shall have gone far along the way to preserving our flora.

OBITUARIES

Mr. W. H. Caldwell

WILLIAM HAY CALDWELL died at Morar Lodge, Inverness-shire, on August 28. In the 'eighties he was notable as an original young Cambridge zoologist who had revolutionized the process of cutting paraffin sections. Born at Portobello in 1859, he went from Loretto to Gonville and Caius College, Cambridge, in 1877, and attended Francis Maitland Balfour's lectures on animal morphology. He was scholar of his College during 1878–83, and obtained a first class in the Natural Sciences Tripos of 1881, beside Walter Gardiner the botanist, who survived him three days[1]. Research on the development of Phoronis occupied his first graduate year, which was marred by Balfour's untimely death on the Alps (July 1882)—thirty years old and of world-wide reputation.

Adam Sedgwick, aged twenty-seven, manfully faced the task of carrying on the school founded by Balfour. Balfour's professorship had been created for him and died with him when he had held it seven weeks; so when as a freshman I entered the new Morphological Laboratory, just completed by the University for Balfour but never seen by him, Sedgwick, Trinity lecturer, presided over it. Caldwell was appointed University demonstrator of comparative anatomy in succession to J. J. Lister; Sedgwick and Caldwell, with fourteen-year-old "John" for laboratory boy, forming the entire staff.

So I found the advanced lectures on invertebrates being delivered by an attractive young man, on the tall side of middle height and well made, with finely cut features, fair wavy hair and a carefully twisted little fair moustache; this was Caldwell. On the

bench in front of me he was faced by about eight third-year men—the very best third-year that Cambridge zoology has ever known—only two years junior to himself. He had a charming deprecatory smile, which I saw first then as he faced these fierce young critics. Lecturing was not his *forte*, but I carried away a vivid recollection of his lectures on his own work, shortly before he read his "Preliminary Note" to the Royal Society[2].

This paper made some stir. The effects have not all disappeared of his argument, from the well-known metamorphosis, that the long axis of the worm-like Phorŏnis is dorso-ventral, and that this appears[3] "to furnish the explanation of the relations of the surfaces in Brachiopoda, Polyzoa and perhaps the Sipunculoid Gephyrea . . . Caldwell's views were accepted by Lankester in the 9th edition of this work [*Enc. Brit.*], the Phylum Podaxonia being there instituted to include the groups just mentioned, together with the Pterobranchia". MacBride[4] concluded in 1914 "that Polyzoa Ectoprocta alone can be regarded as having affinities with Podaxonia, and that Polyzoa Entoprocta cannot be included in this group as defined by Lankester". So, after a third of a century, the new proposal of this first paper was still a matter for lively discussion.

During his research, Caldwell was cutting paraffin sections one day with a transverse razor on Jung's microtome: two or three sections stuck together in line. "I say," said Caldwell to Weldon, looking on, "if we could make them all stick together, we should have the whole larva on one strip !" He devised the plan of coating the hard paraffin with soft paraffin, and so was born the ribbon method of cutting sections. He asked Threlfall of Caius (afterwards Sir Richard Threlfall) to study the Jung and design a similar microtome to be worked by a water motor, with a travelling band to carry the sections. This was constructed and set up in the Balfour Laboratory, where it worked constantly and successfully for half a century; a version for sale is described and figured in the *Quarterly Journal of Microscopical Science* as "The Caldwell Automatic Microtome"[5]. Threlfall told me that this latter was technically inferior—some question of centres of gravity, I think, and the five-point support; he had a second example of the original made for himself because he was proud of it as a perfect machine. Caldwell busied himself over the question of the razor's edge; I saw him once heating a razor red-hot over a Bunsen and plunging it into cold water: he explained that he tempered the razor as soft as possible before honing it and then tempered it absolutely short before using it, so as to have the edge as stiff as possible. He discussed the possibility of getting very thin sections by freezing both blade and paraffin during the cut.

In 1883 Caldwell was appointed the first Balfour student, to study, as Balfour had suggested to him, "the development of the peculiar Australian Mammalia and *Ceratodus*". As student he received £200 a year for three years—extended to a fourth year—and the Royal Society furnished £500 for equipment from the Government grant. He was made a fellow of Caius before he left for Australia, which he reached in September 1883. With camps on the Burnett River and elsewhere and laboratory at Sydney, he obtained much marsupial and monotreme material and complete series of the development of Ceratodus. He sent home two papers for the *Quarterly Journal of Microscopical Science*[6,7], and on August 29, 1884, he telegraphed to the British Association at Montreal: "Monotremes oviparous ovum meroblastic"[8], a much noticed telegram which at first astonished and puzzled newspaper readers in the cryptic confusion of "Caldwell finds monotremes viviparous ovum blastodermic"[9]. But on Tuesday, September 2, the President (Moseley) was able to assure Section D that no "more important telegram in a scientific sense had ever passed through the submarine cables . . . these mammals laid eggs and the development of those eggs bore a close resemblance to the development of the eggs of the Reptilia; proving that those animals were more closely connected with the Sauropsida than with the Amphibia"[10].

By December 1886 Caldwell had finished and sent home the first instalment of his *magnum opus*: "The Embryology of Monotremata and Marsupialia. —Part I". On January 27 he married Margaret Gilchrist, daughter of Mr. J. B. Watt, of Sydney; they sailed for England, where, on March 17, he read to the Royal Society the paper he had sent home[8]. It describes, with three coloured plates, the ovum and egg-membranes of Echidna, Ornithorhyncus, Phascolarctos and Hypsiprymnus; prefacing the description with a brief narrative of his studentship.

This "Part I" in the *Philosophical Transactions* ends Caldwell's contribution to biology. He and Mrs. Caldwell came to Cambridge and in 1888 bought "Birnam", a house in Chaucer Road. A room at the laboratory housed his collections, on which he worked for many years, but no further biological papers have ever appeared.

About 1893 he left Cambridge and zoology to become a paper-manufacturer in Scotland (I believe that an uncle left him the paper-mill). He resumed possession of his house for a short time in 1904, but was not in Cambridge for the meeting of the British Association in the Long Vacation. He stayed by his mill, away in Inverness-shire, and was scarcely ever seen in Edinburgh; he had ceased to be a member of the Savile Club in London already in 1896. A writer in *The Times* of September 19, 1941, states that "several of his methods for increasing the sensitiveness of photographic emulsions have been adopted . . . while his work on paper-making processes also had practical application . . . he gave much of his time to biochemical work, and especially to the chemistry of the enzymes and digestion . . . at the beginning of the last War he was attached to the staff of the 1st Highland Mounted Brigade, and later on took up the problem of vaporising heavy oils for internal combustion engines, and also the manufacture of acetyl cellulose". There is some published work by Caldwell on vaporizers and steam-generators, but no papers on enzymes, emulsions, or any other subject by him is known to physiologists, biochemists or colloid chemists.

In 1937 he asked Prof. Reinhard Dohrn for a

table in the Zoological Station at Naples; I think he stayed there a year. Making some inquiries from me before starting, he gave a most keen and enthusiastic description of what he was going to do (something biochemical based on something he had done already, in Paris if my memory serves).—"Where will you publish?" "Oh, there is a lot to be done before there is any question of publication." This was at the age of seventy-eight.

He died at eighty-two leaving three daughters; he lost his son in the War of 1914–18.

My own guess is that he had early set himself an impossible ideal of perfection and completeness in scientific papers; in the 'eighties we were still labouring under the illusion of monographs which should be final. It is possible that, when Caldwell found after five years work at Cambridge that he could not write a definitive and perfect treatise, he grasped at the chance of a new life and rid his scientific conscience of the burdensome duty of publication. Henceforward he worked at varied scientific problems for his own intellectual pleasure or financial profit.

He was undoubtedly gifted with good powers of observation, easy mastery of technique and a capacity for clear reasoning and incisive writing. Much was hoped of him by his seniors, particularly Foster and Adam Sedgwick, and Sedgwick was a great friend. Sedgwick in 1910[11], summarizing the results of biological expeditions, cites that "of W. H. Caldwell to Australia (1883–1884 [*sic*], discovery of the nature of the ovum and oviposition of *Echidna* and *Ceratodus*)". That represents his friend's summary of Caldwell's contribution, after 1883, to zoological knowledge.

But let all biologists always remember that they owe the ribbon method of cutting paraffin sections to the twenty-two-year-old William Hay Caldwell, brilliant bachelor scholar of Gonville and Caius College. G. P. Bidder.

Mr. H. Standish Ball, O.B.E.

Harry Standish Ball was born in South Africa in 1888 and died at Haslemere after a long illness on September 26. He was a distinguished mining engineer with wide experience of South African and American methods, and during the War of 1914–18 became one of the recognized authorities on military mining. But it was his work as principal of that famous School of Metalliferous Mining at Camborne (Cornwall) by which he was best known to mining engineers.

Ball spent his school days in Johannesburg and obtained his early technical instruction at the Transvaal University College, where he won many prizes and supplemented his theoretical work by a thorough practical training in the gold mines of the Witwatersrand. Afterwards he went to McGill University, where he graduated in the Mining School. On returning to South Africa he obtained employment in various official capacities in the mines, thereby laying the foundation of his knowledge of practical mine management.

Shortly after the outbreak of war in 1914, Ball joined the Royal Engineers (Tunnelling Corps) and served throughout in France, ultimately becoming commandant of the First Army Mining School and technical military mining instructor to the American Expeditionary Force. He wrote several official treatises on military mining, was mentioned in dispatches four times and awarded the military O.B.E.

After the end of the War in 1918, he returned to South Africa, where he held various mining appointments, and during 1921–33 held posts in South Africa and South America, and made many reports on mining and oil properties in these countries as well as in Canada.

In 1933 Ball came to England and was appointed principal of Camborne. The School has long been famous as a training centre for metalliferous mining engineers and, being situated in the heart of the Cornish mining-field, the students have great opportunities for studying the art as well as the science of mining. Before Ball's time some critics considered that too much attention was paid to the practical side, and the new principal, with a sound background of scientific knowledge, recognized this. He set to work slowly and methodically to revise the syllabus, raise the entrance standard and improve the training during the course. His methods were most successful, and he had the satisfaction before the commencement of his last illness of seeing the reputation of the School of Mines raised to a higher plane than it had ever attained.

Besides possessing great technical ability, Ball was an able administrator and in himself a charming man and delightful companion. His death is a sad loss not only to his old students all the world over, but also to his innumerable friends of maturer years.

J. A. S. Ritson.

We regret to announce the following deaths:

The Right Hon. Lord D'Abernon, P.C., G.C.B., G.C.M.G., F.R.S., on November 1, aged eighty-four.

Prof. W. F. Ganong, emeritus professor of botany in Smith College, Northampton, Mass., known for his work on plant physiology and botanical education, on September 9, aged seventy-seven.

Sir Arthur Hill, K.C.M.G., F.R.S., director of the Royal Botanic Gardens, Kew, since 1922, on November 3, aged sixty-six.

Dr. Victor Jollos, formerly associate professor of zoology in the University of Berlin, known for his work on heredity and mutation, on July 5, aged fifty-four.

Dr. J. S. Plaskett, F.R.S., director of the Dominion Astrophysical Observatory, Victoria, B.C., Canada, during 1917–35, on October 17, aged seventy-five.

NEWS AND VIEWS

American Mathematicians and the U.S.S.R.

The Soviet Embassy in Washington has recently received for transmission to Soviet mathematicians a statement of solidarity signed by a number of their most distinguished American colleagues. The document carries signatures of ninety-three mathematicians of forty-seven American universities and colleges. Prof. Marston Morse, president of the American Mathematical Society, is a signatory, as also are eight past presidents of the Society. Fourteen are members of the National Academy of Sciences. Among the signatories are several well-known German mathematicians who now reside in the United States and who know from personal experience the destruction Hitler has wrought in German culture. These include Profs. E. Artin, R. Courant, W. Mayer, H. A. Rademacher and O. Szasz.

The statement reads as follows: "We ... send our greetings and express our heartfelt sympathy to our colleagues of the Soviet Union in their struggle against Hitler fascism. What the future of mathematics would be in a Hitler-dominated world we know from the unprecedented destruction of mathematics in Germany after the advent of Hitler. We are deeply impressed by the heroic stand of the Soviet peoples and know that the mathematicians of the Soviet Union are doing their part in this supreme effort. The bonds between mathematicians in the United States and the Soviet Union are particularly strong since during the past two decades the center of world mathematics has steadily shifted to these two countries. We know many of you personally and more of you through your scientific writings. We know that you are fighting alongside your fellow-countrymen in their brave struggle against the invading tyrant and we assure you that we here are doing everything in our power to aid all peoples struggling against fascism. With best wishes for a successful fight against the evil forces of fascism, we remain, fraternally, your colleagues in the United States."

Commonwealth Grant to Australian Universities

Under the Australian federal system, public education is a function of the State Governments, and the six universities look to these bodies for financial support. Five years ago, however, the Commonwealth Government undertook a share of this responsibility by providing £30,000 a year to meet costs of research in the natural sciences and in economics, and of training young graduates in research technique. The funds are administered by the Council for Scientific and Industrial Research in consultation with the Vice-Chancellors' Conference. The Commonwealth has now announced its intention to raise its contribution to £40,000 a year, commencing in 1942, on condition that at least £9,000 a year be devoted to social science studies bearing on problems of post-war reconstruction.

American Anthropology

Anthropological Papers, Numbers 13–18, have been recently published by the Smithsonian Institution (Bureau of American Ethnology, Bulletin 128). These include "The Mining of Gems and Ornamental Stones by American Indians", "Iroquois Suicide", "Tonawanda Longhouse Ceremonies", "The Quichua-speaking Indians of the Province of Imbabura", "Art Processes in Birchbark of the River Desert Algonquin" and "Archæological Reconnaissance of Southern Utah". The last of these, by J. H. Steward, will appeal especially to archæologists interested in the ancient history of the New World. The article is based on the surveys of Judd (1926) and Steward (1933 and 1936), and deals with a culture apparently based on that of the Basket-maker Pueblo peoples of the San Juan River basin. A large number of sites were visited and are described, and the material culture found in them is catalogued and illustrated. Painted pottery, naturally, occurred as well as flint implements. It is a pity, however, that these latter are so inadequately figured—mere outlines of the tools being all that is given. An interesting series of rock-drawings was also discovered, showing conventionalized figures of animals and human beings, as well as signs of various kinds, including the spiral.

Indian Jute Production

A brochure containing much valuable statistical material on the jute trade and industry, including estimates which are not available elsewhere, has been issued by the Indian Central Jute Committee, Calcutta, under the title "World Consumption of Jute" 1938–39 and 1939–40 (Economic Research Bulletin No. 1, R.1, 1*s*. 6*d*.). The estimates of the total consumption of jute in the world given in this bulletin for the period 1933–34 to 1939–40 indicate that consumption reached its peak in 1936–37 with an aggregate consumption of about 123 lakhs of bales, but world consumption in 1938–39 fell to 107 lakhs of bales, and only rose again to 109 lakhs of bales in 1939–40, in spite of the hectic buying at the beginning of the War. Independent estimates of the yield of the jute crop are also included for the 1938–39 and 1939–40 seasons.

The War has seriously affected the export of raw jute, but this was more than compensated by the rise in the export of jute manufactures, the countries within the British Empire considerably increasing their consumption of Indian jute manufactures, although there was a substantial reduction in the normal commercial demand for jute goods. The consumption of raw jute by the Indian mills fell in 1938–39 but increased considerably in 1939–40, and the total stock of raw jute for the Indian mills was 20 lakhs of bales at the end of 1939–40, or about 9 lakhs of bales less than the stock at the end of 1937–38. The total yield of the jute crop in the 1938–39 season was a little more than 80 lakhs of bales, which was less than the world total demand

for the year by 17 lakhs of bales. The yield of the crop in 1939–40 was more than 109 lakhs of bales and the jute crop of 1940–41 is expected to give a record yield of 125 lakhs of bales. The consumption of raw jute this season is likely to be abnormally low, and a considerable quantity of jute is expected to be left over from the crop of 1941. The bulletin embodies the results of investigations carried out by the Economic Research Sub-Section of the Committee.

Cements for Glass Inserts in Electrical Apparatus

THE fixing of glass or porcelain insulators to metal parts by means of cement in the construction of switch gear and other apparatus has been a practice employed since the early days of electrical apparatus. At one time a mixture of sulphur and ground glass was extensively used for porcelain, the well-known litharge and glycerine cement being employed for the finer classes of work. This latter material is still in extensive use, but much work is also done with cements of the calcium sulphate type. As certain new products of this latter class have been introduced, an investigation has been carried out by the British Electrical and Allied Industries Research Association in order to elicit information bearing on the performance of these materials in practice (Technical Report, Ref. *G./T.* 131, "Recent Experience with Calcium Sulphate and other Types of Cement for Glass Inserts in Flame-proof Enclosures". By A. P. Paton). A table is given in the report summarizing the information collected on the quantities of cement mixed at a time and used for each article, and the time necessary before the articles could be released from the jigs. The latter varied from a maximum of 48 hours to a minimum of a quarter of an hour. This latter figure was exceptional and referred to meter glasses and windows fixed with Hawkins iron cement. A minimum period of $\frac{1}{2}$ hour was given for flame-proof lighting fittings and cover glasses of housings fixed with C. Fine Keene's cement. The figures, however, varied somewhat and were not closely connected with the type of cement. In one case it was stated that $2\frac{1}{2}$ lb. of gum arabic to a gallon of water was used in making up C. Fine Keene's cement. No difference in strength was found, and the cement adhered more firmly to glass or metal.

In certain conditions, C. Fine Keene's cement may give rise to electrolytic action if used with Bakelite. This cement is essentially an anhydrous calcium sulphate, which is slightly acid, due to the addition of a small percentage of alum. The presence of this potassium salt is considered undesirable when the cement is in contact with insulation of the synthetic resin impregnated type. Alternatives which have now been developed are termed Kaffir Plasters. They consist of calcium sulphate hemi-hydrate and are manufactured by Messrs. Cafferata. The product hydrates almost fully within about two hours, so that 'dry out' is almost impossible. The report states that it is a little unfortunate that the word plaster conveys to the general public the idea of a product which is inferior in strength and performance to a 'cement'. Actually, it is technically accepted in the gypsum trade that a cement is a high-temperature dead-burnt product, and that, without exception, all hemi-hydrates are designated plasters. The specially prepared hemi-hydrates known as Kaffir Plasters, while chemically similar to plaster-of-Paris, are different in their mechanical and physical properties, and give strength figures many times higher than those of plaster-of-Paris. They harden rapidly, and jigs may be fixed in 2–3 hours.

Health of the Sudan

IN his recently issued report for 1939 Dr. E. D. Pridie, director of the Sudan medical service, maintains that in spite of the occurrence of epidemic diseases, especially cerebrospinal fever, relapsing fever, smallpox and measles, the health of the Sudan in that year was very satisfactory. The epidemic of cerebrospinal fever which broke out in Equatoria and was not suppressed by the end of the year, comprised 2,714 cases with 647 deaths—a fatality-rate of 25 per cent against an expected rate of 60 per cent. The mortality at the onset of the epidemic was 80 per cent, but treatment with drugs of the sulphamide class reduced it to about 10 per cent. There were 1,000 cases of relapsing fever with 92 deaths, and 502 cases of smallpox which originated in French Equatorial Africa. On the other hand, the incidence of typhoid fever and bacillary dysentery was low. Although the range of most of them was limited, practically every endemic tropical infection was present in some part of the Sudan.

Earthquake in Alaska

THE United States Coast and Geodetic Survey, in co-operation with Science Service and the Jesuit Seismological Association, has determined the provisional epicentre of the earthquake of July 30, 1941, which took place at 1 h. 51·5 m. U.T. This was at latitude 60·9° N., 149·2° W. which is very near the railway between Seward and Anchorage, Alaska, and about midway between these two places. It is not known whether or not there was any damage due to the earthquake. Alaska and the Aleutian Islands form part of the circum-Pacific ring of instability, around which earthquakes and tremors are fairly frequent. Recently earthquakes have been very frequent among the Aleutian Islands, and what was probably the most notable earthquake of recent years on the mainland occurred on April 26, 1933, to the north-west of the Kenai Peninsular. (NATURE, May 27, 1933, p. 757.)

University of London

DR. H. L. EASON retired from the office of principal on September 30 and Mr. Harold Claughton entered upon his duties as acting principal on October 1.

The title of reader in geography in the University has been conferred on Dr. R. E. Dickinson, in respect of the post held by him at University College.

The degree of D.Sc. has been conferred on the

following: Mr. W. P. K. Findlay (Imperial College of Science and Technology), Mr. P. L. Hsu (University College), Mr. Louis Hunter (Queen Mary College), Mr. R. A. Kekwick (University College), Mr. A. R. Martin (Imperial College of Science and Technology) and Mr. J. R. Nicholls. The degree of D.Sc. (Engineering) has been conferred on Mr. W. K. Wilson.

Dr. Timothy Richards Lewis (1841-1886)

DR. TIMOTHY RICHARDS LEWIS, a pioneer in tropical medicine and medical parasitology, was born on October 31, 1841, at Llanboidy, Carmarthenshire. He received his medical education at University College, London, and qualified at Aberdeen in 1867. He entered the Army Service at Netley in 1868 and successively held the office of assistant surgeon, surgeon and surgeon-major. After working for three months with Max von Pettenkofer at Munich, he went with his friend D. D. Cunningham to Calcutta in 1869, and for the next ten years collaborated with him in the study of cholera and other Indian diseases. In 1870 he gave the first authentic account of amœba found in man, and in the same year described *Filaria sanguinis hominis*. In 1878 he described the non-pathogenic form of trypanosoma found in rats. In 1883 he was made assistant professor of morbid anatomy at Netley, and in 1885 he was appointed honorary secretary of a committee convened by the Secretary of State for India with Sir William Jenner as president to investigate Koch's discovery of the cholera bacillus. He was recommended by Council for the fellowship of the Royal Society, but died on May 7, 1886, before this honour was conferred upon him. At the time of his death he was carrying out an extensive series of cultures and inoculations of bacilli in the human alimentary canal.

Jean Victor Audoin (1797-1841)

JEAN VICTOR AUDOIN, an eminent French entomologist, was born in Paris on April 27, 1797, the son of a lawyer. His early interest in natural history prevented him from following his father's profession, for which he was first intended, and he took up medicine, qualifying in 1826 with a thesis on the natural history and the chemical, pharmaceutical and medical aspects of cantharides. He had already in 1823 founded with J. B. A. Dumas, the chemist, and A. Brongniart, the geologist, the *Annales des Sciences Naturelles*. In 1824 he became assistant to H. Latreille, professor of entomology and director of the Natural History Museum in Paris. In 1832 he was one of the founders of the Société Entomologique de France, and in the following year succeeded Latreille. In 1837 he was elected to the Paris Academy of Sciences in the Section of Agriculture. His best-known investigations were carried out with Milne-Edwards on the anatomy and physiology of Crustacea, and on the parasites of the vine and silk-worm. He died on November 9, 1841. At a meeting of the Academy of Sciences on August 13, 1844, D. Gruby gave the name of *Microsporum* (afterwards changed to *Microsporon*) *Audouini* to the fungus causing ringworm of the scalp, a term still in current use, in recognition of Audoin's having directed attention to parasites which destroy the living tissues of animals.

Comets

Comet van Gent (1941 *d*). The elements of an orbit of this comet, and an ephemeris, assuming parabolic motion, have appeared in NATURE (148, 139, 370, 530; 1941). Davidson and Sumner have computed a new orbit, using the observations of Mr. W. T. Hay at Hendon, and have found that it is slightly hyperbolic. Another orbit will be computed, using later observations of Hay, and as these extend over a period of a month, August 29–October 3, it will be possible to give a definite pronouncement on the nature of the orbit.

Comet du Toit-Neujmin. This comet was discovered by du Toit at Bloemfontein on July 18 and also independently by Neujmin at Simeïs. Its magnitude at the time of discovery was 10. The aphelion of the orbit lies close to the orbit of Jupiter and the last close approach to the planet probably occurred in 1824, when the planet may have annexed it as one of its family. The elements of the orbit, computed by H. R. H. Grosch, are given below, and also an ephemeris.

T	1941. July 21. 18766 U.T.			Ephemeris		1941.0
ω	69° 10′ 33·3″	1941·0			α	δ
Ω	229 37 07·2	1941·0	Nov. 6	22h.	40·5m.	−4° 34′
i	3 14 49·4	1941·0	14	0	52·3	3 55
a	3·095176		22	23	03·9	3 10
e	0·5789569		30	0	15·6	2 20
P	5·4456 years.					

The geocentric and heliocentric distances on November 30 are 1·89 and 2·3, respectively. As it is receding from the earth and sun, it is becoming fainter.

Periodic Comet Schwassmann-Wachmann (2), 1921 *l*. This comet has been discovered by Dr. H. M. Jeffers at Lick Observatory, its magnitude at the time of discovery, September 20, being 17. In "The Handbook of the British Astronomical Association, 1941", there is an ephemeris based upon the orbit computed by Mr. W. P. Henderson and Dr. H. Whichello, planetary perturbations being taken into consideration. The comet was discovered almost exactly in the predicted place, a discrepancy of only 18^s in the right ascension occurring.

New Asteroid. Harvard College Observatory Card No. 606 has announced that an object, probably a new asteroid, has appeared on the 40-in. reflector plates used at the U.S. Naval Observatory. An orbit will be computed later.

Announcements

THE Lord President of the Council has appointed Sir Franklin Sibly, vice-chancellor of the University of Reading, to be a member of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research. The Right Hon. Viscount Falmouth has retired from the Council on completion of his term of office.

ERRATUM.—In NATURE of October 25, p. 479, the Lawrence referred to was not, of course, T. E. Lawrence (of Arabia), but D. H. Lawrence.

A Mendelian Situation in the Birthcoat of the New Zealand Romney Lamb

DR. T. M. OLBRYCHT[1] finds it difficult to believe that our N-type coat[2] can have a comparatively simple genetic basis. That conclusion was adopted very tardily here, as papers published show[3,4] and, as stated before, we have bred a few N-type animals in which, from breeding data, the genetic basis is regarded as multifactorial. In these animals, we suspect, the factors responsible interact to produce very high abundance of halo-hairs in geometric, not just additive, fashion. The early experiments dealt in differences in the abundance of halo-hairs on the back of not-N lambs, and revealed strong multifactorial inheritance. Lambs are graded by eye when not more than a few days old. N-type has one halo-hair to an average of about nine curly-tip fibres. In not-N six grades are distinguished, ranging from no halo-hairs at all in Grade I to one halo-hair to about 200 curly-tip fibres in Grade IV, and one to about 27 in Grade VI. Lambs of high Grade VI may be called borderline-N, and for our present purpose all Grade VI lambs are called near-N. There is good evidence, strengthened in 1940, that some near-N animals carry the same factors for N-type as typical N-type sheep of our 'mendelian' stock. In determining ratios, N and near-N are counted together, but it will be seen that the near-N lambs are few compared with the N-type. We now give the results up to 1940 most pertinent to the point at issue.

Mendelian ratios. On mating together N or near-N animals which from their parentage we regard as heterozygous (for an N-complex on one chromosome) there have been born 42 N, 4 near-N, 1 V, 4 IV, 2 III, 4 II, 3 I. This gives 46 N and near-N combined and 14 not-N; a good 3 : 1 ratio.

In back-crosses of N and near-N deemed heterozygous, put to mates with no or few halo-hairs on the back (Grades I and II) or of unknown grade (supplied by the College Sheep Farm and virtually certainly not-N), we have obtained: 146 N, 35 near-N, 7 V, 8 IV, 37 III, 110 II, 50 I. N and near-N together number 181 against 212 not-N. On testing this departure from equality we find $\chi^2 = 2{\cdot}45$. On our present hypothesis a slight excess of not-N is in fact expected on account of crossing over between closely linked duplicate factors. The scarcity of lambs of intermediate grades in these back-crosses affords good evidence for the simplicity of the genetic situation.

Homozygous rams. Four N-type rams, with both parents N-type, but with one grandparent on each side not-N, were back-crossed in 1940. One proved heterozygous, siring 6 N, 1 near-N, 12 not-N. Three had families containing only N and near-N lambs, the individual results being: 14 N, 1 near-N; 14 N, 1 near-N; 7 N. Another N-type ram bred in a way that need not now concern us was back-crossed in 1940 and sired 28 lambs, every one of them N-type. These four homozygous rams clinch our argument.

Monofactorial explanation inadequate; suggested comparatively simple hypothesis. The results presented may suggest a single dominant factor. Things are not quite so simple, as we realized earlier, and we have further to report that an N-type ram which, in experiments referred to in our previous communication, mated with not-N ewes not its own daughters, had sired 2 N and 57 not-N, all of low grades, was mated in 1940 with its own daughters. Its lambs were 6 N, 1 near-N, 6 not-N. This is taken to be a 1 : 1 ratio.

We are used to changing our views, and we may be right or wrong in now postulating two pairs of linked duplicate factors, with two doses necessary to give N-type, and any two doses able to produce N-type unless there is present a suppressing factor, which we think exists, but is scarce. Our point is that the genetic situation is a relatively simple one.

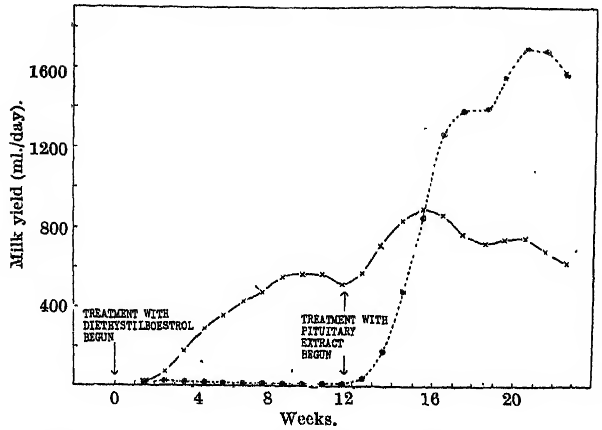
Artificial Induction of Lactation in Virgin Animals

THE discovery by Folley and his co-workers that treatment with diethylstilbœstrol alone will induce copious lactation in virgin goats[1] and heifers[2] has recently been confirmed for the goat by Lewis and Turner[3]. Since the administration of a crude extract of ox anterior pituitary gland strikingly stimulates the milk production of the cow during the normal decline of lactation[4], it was of importance to determine if the production of milk resulting from treatment with diethylstilbœstrol could be further increased by injections of anterior pituitary extract.

Two nulliparous 'scrub' goatlings, which had been dry for some months after having been brought into artificial lactation with diethylstilbœstrol during the previous year, were subjected three times weekly to inunction of the udder with 1·0 gm. of 1 per cent diethylstilbœstrol ointment. In one case lactation quickly set in and the yield rose to a maximum of about 570 ml. daily, and then began to decline. It is of interest to note that this peak yield was approximately the same as in the previous artificially induced lactation. At this point, subcutaneous injection on alternate days of 5 ml. of an alkaline extract of ox anterior lobe (10 ml.=2·5 gm. fresh tissue) was begun and the inunctions continued. The milk yield rapidly rose to about 870 ml./day and thereafter declined somewhat despite continuation of the treatment with both œstrogen and pituitary extract. Pituitary treatment therefore increased the peak yield induced by diethylstilbœstrol alone by some 40 per cent.

The other goat, rather surprisingly in view of the fact that similar treatment had induced substantial



MILK YIELDS OF VIRGIN GOATS TREATED WITH DIETHYLSTILBŒSTROL AND ANTERIOR PITUITARY EXTRACT. MILK YIELDS ARE EXPRESSED IN TERMS OF THE AVERAGE DAILY YIELD FOR EACH WEEK.

Diethylstilbœstrol. x——x. Inunction of udder with 1 gm. of a 1 per cent ointment effected three times weekly for 18 weeks. ⊙ – – – – ⊙ Inunction of udder with 1 gm. of a 1 per cent ointment effected three times weekly for 6 weeks, then with 2 gm. of 1 per cent ointment for 4 weeks. Over the remainder of the experiment the original dose was used.

Pituitary extract. 5 ml. (equiv. to 1·25 gm. of fresh ox anterior lobe) given on alternate days from the twelfth week of the experiments onwards.

lactation in the previous year, secreted no more than 20 ml. daily of milk during the period of inunction alone, even when the dose of diethylstilbœstrol was doubled for a time, but addition of anterior pituitary treatment immediately evoked copious milk secretion, the daily yield rapidly rising to nearly 1,700 ml. This amount is comparable with the peak yield expected in a normal lactation period from such an ill-bred animal, and is about 20 per cent above that attained on the previous occasion with diethylstilbœstrol alone. Chemical analyses (fat, non-fatty solids, nitrogen partition, lactose) showed that the milk secreted by both goats was normal.

These experiments, which are being continued, indicate that, in the goat, combined treatment with diethylstilbœstrol and anterior pituitary extract can produce a much more intense lactation than with the former alone. It seems likely that under suitable conditions the artificial lactation so evoked may rival that normally following parturition, which is not surprising in view of the fact that its genesis presumably simulates the mechanism whereby normal lactation is induced.

This work has been aided by a grant from the Agricultural Research Council.

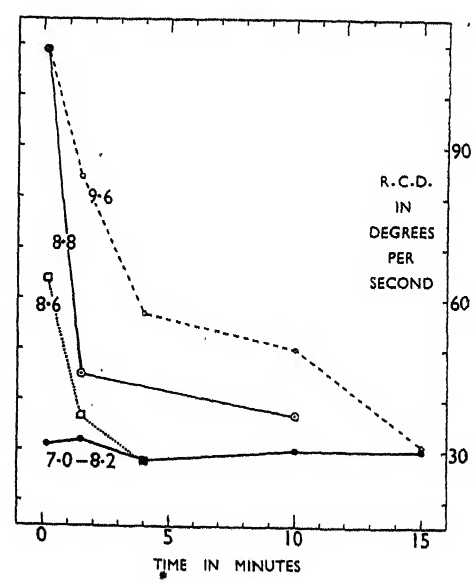
Klino-kinesis of Paramecium

IT has been shown by Ullyott[1] that the aggregation reaction of the flatworm, *Dendrocœlum lacteum*, in a gradient of light intensities, can be described in terms of the rate of change of direction and the process of sensory adaptation in the eyes. This reaction has since been named 'klino-kinesis'[2]. More recently[3], it was suggested that the well-known 'phobo-taxis' ('avoiding reaction', 'trial-and-error') of Paramecium might be sufficiently similar to be included under the same name. Preliminary experiments by one of us (B.M.W.), which cannot now be continued, provide support for this suggestion. Briefly, the experiments consisted in transferring Paramecium from the culture medium at pH 8·0 to various strengths of acid or alkaline media, and finding the rate of change of direction as soon as possible and at intervals afterwards. It was found that it did depend on the change in pH at first, and that it soon fell to the original basic level; these are the essential features of the klino-kinesis scheme.

The amounts of acetic acid and sodium carbonate required to produce the required changes in the pH of the culture medium were first determined. The Paramecium were pipetted, in a known volume of culture medium, into a watch glass and the appropriate amount of acid or alkali was added; the liquid was rapidly mixed with a pipette and some of it transferred to a suitable slide. The first reading began 6–10 seconds after adding the acid or alkali. A reading consisted in drawing free-hand the tracks of animals taken at random, as seen under the microscope, and marking the tracks at 5-second intervals, with the aid of a metronome; further readings were taken after 1–2, 3–5, 10 and 15 minutes. At least ten tracks were made in each case. The amounts of turning carried out by the organisms were estimated from the drawings, the angles being measured to the nearest 5°.

The accompanying graph shows that on transfer to culture medium made neutral or slightly alkaline (actually pH 7·0, 7·6, 8·0 and 8·2), the rate of change of direction is about 30° per second after 6–10 seconds and remains at that basic level; but on transfer to medium made more alkaline, it is at



pH	Rate of change of direction in degrees per second				
	After 6–10 sec.	1–2 min.	3–5 min.	10 min.	15 min.
4·6	70	41	27	42	23
5·2 and 5·6	42	33	30	30	29
7·0 to 8·2	31	32	28	30	30
8·6	64	37	28	—	—
8·8	109	45	—	37	—
9·6	109	84	57	50	31

first raised and then falls to the basic level. The table gives more extended data and shows a similar effect when Paramecium is transferred to acidified culture medium. On the whole, the greater the change in pH, the greater the rise in rate of change of direction and the longer the time taken to revert to the basic value.

In a further experiment, specimens which had been kept for 15 min. in acidified culture medium (pH 5·6) were transferred back to culture medium at pH 8·0; the rate of change of direction was 58° per sec. after 3 sec. and fell to 31° per sec. after 3 min. This indicates that the rate of change of direction depends on the change in the medium, even when that change is a return to the original culture medium at pH 8·0.

It cannot be said that this work is more than indicative and preliminary. The reactions may not be towards the pH of the medium but may depend on the particular acid or alkali used, and so on. The methods used do not reveal the amount of turning carried out in the first few seconds after transfer to a new pH, when, as the graph suggests, rate of change of direction is likely to be much higher than it is at the time when the earliest reading could be taken. The behaviour during these first few seconds must be most important if the reaction in a gradient is to be effective. The results of the experiments encourage belief in the validity of the description of the behaviour of Paramecium in terms of klinokinesis, and thus help to avoid using terms like 'trial-and-error', which may carry unjustifiable implications.

Flour and the Growth of Tribolium

IN a recent paper, Fraenkel and Blewett[1] described experiments on the growth of Tribolium on flour. They conclude that for this insect: (1) the addition of vitamin B_1 (aneurin) to patent flour does not in the least alter its nutritional qualities; (2) the nutritional difference between patent (40 per cent extraction) and N.S.R. (73 per cent extraction) flour is almost entirely due to lack of riboflavin in patent flour.

Experiments on Tribolium conducted in these laboratories do not support these conclusions, as a few examples will show. Like Fraenkel and Blewett, the growth period was taken as being the time between the hatching of the larva from the egg and the formation of the pupa.

Temperature, 30°C. Relative humidity, 75 per cent. 20 Larvæ per sample.

		Days in larval period	Number of pupæ
Patent flour (35 per cent extraction)	i	46·8	18
	ii	46·3	18
Patent flour + aneurin (20γ/gm.)	i	41·7	20
	ii	42·4	19
Patent flour + riboflavin (3γ/gm.)	i	29·7	20
	ii	28·5	18
Patent flour + nicotinic acid (3γ/gm.)	i	29·7	20
	ii	28·7	19

It will be seen from this experiment that the addition of B_1 to patent flour does produce a significant increase in growth, while the addition of *either* riboflavin *or* nicotinic acid induces a great improvement, since the larval period is reduced by a third. Moreover, the amount of riboflavin added was only about one fifth of the lowest quantity employed by Fraenkel and Blewett, and thus bears a truer relationship to the actual amounts of riboflavin present in germ (0·2–0·3 mgm. per 100 gm. germ)[2]. The fact that the addition of nicotinic acid to patent flour brings about the same rate of increase as an equal amount of riboflavin disposes of Fraenkel and Blewett's argument that white flour is *specifically* lacking in riboflavin.

For critical experiments on the vitamin requirements of any animal, vitamin-free diets should be employed. In the subsequent experiments with Tribolium, the following vitamin-free diet (here called *A*) was used: vitamin-free casein (15 per cent), fat (3 per cent), Osborn-Mendel salts (4 per cent), starch to 100. It has been known for a long time that the addition of germ or dried brewers' yeast to this vitamin-free diet will supply optimal growth conditions for Tribolium. Further, it has been shown by Street and Palmer[3] that the addition of aneurin alone to such a vitamin-free diet is not sufficient to bring about pupation in this insect, whereas in the presence of aneurin plus autoclaved yeast (in which the aneurin has been destroyed) pupation takes place normally. The following experiments with dried brewers' yeast and autoclaved yeast are relevant in this connexion.

Temperature, 30° C. Relative humidity, 75 per cent. 20 larvæ per sample.

Diet	Days in larval period	Number of pupæ
1. *A*	—	0
	—	0
2. *A* + 10 per cent yeast	18·1	20
	17·5	19
3. *A* + 1 per cent yeast	20·3	18
	21·4	20
4. *A* + 0·625 per cent yeast	24·7	17
	24·8	20
5. *A* + aneurin (20γ/gm.)	—	0
	—	0
6. *A* + 10 per cent autoclaved yeast	—	0
	—	0
7. *A* + 10 per cent autoclaved yeast + aneurin (20γ/gm.)	23·6	18
	23·8	19

In some further experiments to discov[illegible]hich other members of the vitamin B complex are[illegible]uired for the pupation of Tribolium, it was found that neither riboflavin nor nicotinic acid, either alone or in conjunction with aneurin, will bring about pupation. On the other hand, pupation would take place in the presence of aneurin plus a factor present in liver or yeast eluate. The particular sample of liver eluate used was stated to contain [illegible] riboflavi[illegible]t to be rich in vitamin B_6 (adermin). Unfortun[illegible], the amount of adermin present was not known. It is

known, however, that the amount of adermin in whole wheat is at least three times as great as the riboflavin content[4]. Later, by using a pure sample of vitamin B_6 it was confirmed that pupation will take place in the presence of this vitamin plus aneurin. These results are summarized below.

Temperature, 30° C. Relative humidity, 75 per cent. Number of larvæ per sample, 20.

Diet	Days in larval period	Number of pupæ
1–9. A, with riboflavin, nicotinic acid, aneurin riboflavin, liver filtrate factor and liver eluate factor, alone and in various combinations	— —	0 0
10. A + aneurin (20γ/gm.) + liver eluate factor	60·4 59·8	10 14
11. A + B_6 (10γ/gm.)	— —	0 0
12. A + B_6 (10γ/gm.) + aneurin (20γ/gm.)	62·3 64·5	14 17
13. A + B_6 (10γ/gm.) + aneurin (20γ/gm.) + riboflavin (3γ/gm.)...	61·8 63·4	15 16
14. A + B_6 (10γ/gm.) + aneurin (20γ/gm. + riboflavin (3γ/gm.) + nicotinic acid (30γ/gm.)[5]	60·7 60·9	16 17

It should be noted that although pupation does not take place in the presence of vitamin B_6 alone, yet the larvæ remain alive and healthy for as long as 70 days and increase considerably in size, whereas in the riboflavin or nicotinic acid mixtures they die off in about 30 days.

It is evident from these experiments that although aneurin and vitamin B_6 are essential for pupation, there must also be present, even in patent flour, some other growth factor which is as important as any of the known members of the vitamin B complex in promoting rapid growth and pupation.

I am indebted to Mr. A. L. Bacharach for supplying the samples of liver filtrate and eluate, riboflavin, nicotinic acid and vitamin B_6.

Surface Tension and Molecular Dimensions

THE following argument is advanced in support of the hypothesis that the molecules of long-chain compounds tend to stand up like a carpet pile in their own liquid surfaces just as they do on substrates such as water. By the application of the usual thermodynamical reasoning to the following cycl[illegible]) transfer 1 gm. of substance isothermally fro[illegible] liquid to the surface and thereby increase the area by A sq. cm.; (2) carry out a small adiabatic expansion; (3) transfer 1 gm. of substance isothermally from the surface to the liquid at the lower temperature; (4) carry out an equal adiabatic contraction—we obtain the equation

$$\text{[illegible]iency} = \frac{dT}{[illegible]} = -\frac{AdS}{H}\text{; that is, } \frac{H}{T} = -\frac{dS}{dT}A, \quad (1)$$

[illegible]re S is the surface tension.

The surface energy, or total work of transfer, per gram of substance, is

$$SA - T\frac{dS}{dT}A = \left(S - T\frac{dS}{dT}\right)A, \quad . \quad . \quad . \quad . \quad (2)$$

This is usually obtained in the form:

$$\text{Surface energy per sq. cm.} = S - T\frac{dS}{dT},$$

by an argument involving 'stretching the film'. We consider the standard Kelvin method is faulty, because what is called 'stretching the film' is actually a transfer of molecules from the liquid to the surface state. Equation (2) can only apply when the surface is practically complete, that is, the probability of the vapour state can be neglected.

It is well known that, for this region of low vapour pressure, the $S-T$ curves for many liquids are very approximately linear, so that the surface energy per sq. cm. is practically constant. We suggest that this is so because the surface area per gram of substance is changing but slowly, and that it is really the surface energy per gram that is constant. The linear portion of the $S-T$ curve, extrapolated to cut the axis of T, intercepts it at T_c, which is approximately the same as the critical temperature obtained from vapour pressure measurements. This gives the constant surface energy as $-T_c\frac{dS}{dT}A$. Per gram-molecule this constant surface energy is $-T_c\frac{dS}{dT}AM = nRT_c$. The surface area per molecule will then be

$$\frac{AM}{N} = -\frac{nR}{N\,dS/dT} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

We further suggest that the number 'n' in the above equation is the same for all chain-molecular liquids. Substitution of values AM/N, the basal molecular area obtained from X-ray diffraction patterns of aliphatic compounds in the solid state, suggests that $n = 1{\cdot}5$. The constant surface energy is thus equal to the kinetic energy of translation at the critical temperature. Using this value in equation (3), we can find molecular lengths if we assume that the density in the surface state is not very different from that in the liquid state. If l is the length per molecule,

$$l = \frac{1}{\rho_s A} = -\frac{M\,dS/dT}{\frac{3}{2}R\rho_s} \quad . \quad . \quad . \quad . \quad (4)$$

Since l is the molecular thickness associated with the molecular weight M, we see that the surface tension is independent of chainwise association in the surface layer.

The values obtained for a typical series are given below:

Alcohol	Formula	$-\frac{dS}{dT}$	$a \times 10^{16}$ cm^2.	$l \times 10^8$ cm.	Increase per CH_2
Methyl	CH_3OH	0·0875	23·8	2·82	
Ethyl	C_2H_5OH	0·0875	23·8	4·05	$1{\cdot}23 \times 10^{-8}$ cm.
n-propyl	C_3H_7OH	0·0820	25·4	4·88	$0{\cdot}83 \times 10^{-8}$ cm.
n-butyl	C_4H_9OH	0·0840	24·8	6·12	$1{\cdot}24 \times 10^{-8}$ cm.
n-octyl	$C_8H_{17}OH$	0·0820	25·4	10·35	$1{\cdot}06 \times 10^{-8}$ cm.
Miricyl	$C_{30}H_{61}OH$	0·0780	26·6	32·6	$1{\cdot}01 \times 10^{-8}$ cm.

The approximate equality of the values of dS/dT for the above series indicates that the molecular basal area is approximately the same for all the

members. The same is true in each of the aliphatic series studied.

We wish to thank Dr. W. T. Astbury, of Leeds, for encouragement and for advice with regard to the form of this communication.

Poultry as Food Converters

MR. E. E. JONES, in his letter in NATURE of October 18, states that the goose is the only grass-eating bird available for egg production. While the main object of his communication, which is to encourage the breeding of a superior kind of goose, is no doubt of value, he would seem to infer that the hen does not eat grass. It is true that on a confined run with plenty of other food and no supply of fresh young grass the hen does not because there is none, not because she would not if it were available.

On a limited run, the hen willingly eats cabbage leaves for the sake of fresh green-food, and is often made to jump for it for exercise, but with a large area of good grass on which to roam, a hen will not touch cabbage. I used to let out the hens for an hour to forage in the garden, and they used to dive at once into the edges of the borders in the lawn where, among the leaves collected there, they found plenty of 'creepy-crawleys'. But I noticed that they ate with avidity large quantities of the young grass on the edge where it is freshest and greenest, preferring this to the abundance which they had in their own territory. While no doubt the proportion of grass in their diet is not so great as it is with the goose, it is still an important item if they can get it, but not when it is denied to them.

Will geese any more than hens keep on laying if they are not provided with concentrated food, which it is the object of Mr. Jones to save ?

A British-American Scientific Reconstruction Expedition

ONE of the points generally agreed upon during the proceedings of the Conference on Science and World Order arranged by the Division for the Social and International Relations of Science of the British Association was that careful scientific planning is essential for post-war relief and reconstruction work ; and Sir Richard Gregory, in his concluding speech, stated that the Council of the British Association will appoint, at an early date, committees to study the problems and make appropriate recommendations. One problem, however, did not receive the attention of the Conference, a problem which in my opinion is of the greatest importance in planning the reconstruction of the smaller European countries.

The small European countries actively involved in the present War have lost a considerable proportion of their scientifically trained youth. A large number of the leading scientific personalities, professors and members of the staffs of the universities, social and administrative workers have been killed. It is the deliberate policy of the Nazis to destroy cultural and scientific centres, and thus to deprive conquered nations of the backbone of future reconstruction. Germany is doing everything to make the revival of the nations as difficult as possible. This is exemplified not only by the murder of the leading minds of each nation and of scientifically trained youth which could replace their masters and continue their work, but also by the destruction or removal of scientific equipment, by burning libraries, pulling down essential buildings, etc.

There can be no doubt that after an armistice has been signed, the smaller countries of Europe will need help from the outside world to re-establish scientific centres. There is no purpose in planning co-operation of scientific bodies on an international scale if such bodies in the various countries are unable to organize their work, or may not even exist, because of the lack of personnel to revive them and to carry out the work.

I know that Britain and the United States will be willing to do their utmost to help, but in order that assistance may be rendered in the most efficient way plans and foundations for it must be laid immediately. I suggest, therefore, that a detailed scheme be drawn up now for a British-American Scientific Reconstruction Expedition to the smaller countries of Europe.

A plan ought to be devised in collaboration with scientific workers from Nazi-dominated countries who have happily managed to escape and are at present continuing their work in hospitable British scientific centres, so that, immediately hostilities come to an end, arrangements might be made to send into each of the liberated countries a unit of scientific workers, which will be able to administer 'scientific first aid' and to establish in the shortest possible time conditions suitable for carrying out scientific work, and where necesary to initiate it. Not only will senior scientific workers be required to take over the lead and direct the work of reconstruction, but also a considerable number of younger workers, with up-to-date knowledge in the different branches of science, will be essential to pave the way for science during the first post-war years, before the huge loss in scientific man-power of these nations is made good again.

The Scientific Reconstruction Expedition will have to be able to provide scientific instruments, to re-equip laboratories, to rebuild essential buildings, to re-stock libraries, and perhaps also to provide the necessary funds. Like the Red Cross in the field of medicine and human welfare, the Scientific Reconstruction Expedition would be a mission of goodwill in the field of science. Its aim would be to help to restore the life of the smaller nations by assisting to re-establish their national centres for scientific work, and by doing so, to serve the cause of science throughout the world.

RESEARCH STUDIES IN EDUCATION

IN the last few years the U.S. Office of Education has published an annual Bibliography of Research Studies in Education. The most recent volume to hand* reveals activity in the sphere of education which must be without parallel anywhere else in the world. Altogether, for the year 1938–39, it lists 3,569 theses, submitted by research workers in 174 institutions. Taken in the broad view they give one the impression that in the United States the whole field of education is open to inquiry, that policy is in no way bound down by tradition; instead, accepting democratic principles, it is adjusting itself to the continual changes taking place outside school and college. These research studies provide the material for informed opinion, which cannot fail to exert a beneficial influence upon teachers, administrators, parents, and incidentally upon the pupils, too.

Of the papers listed in the Bibliography almost a half are concerned with curriculum studies and with problems met with in the teaching of individual subjects. Some measure of the interest taken in developments in the different subjects, in their American setting, may be gathered from the number of papers devoted to each. There are, for example, 135 papers on physical training and recreation, 115 on scientific subjects, 109 on commercial education, 108 on reading, 103 on mathematics, 84 on music, 69 on home economics, 65 on English, 56 on agriculture, 43 on health education, with only 27 papers devoted to art, 22 to history, 14 to modern languages and 12 to the classics. One gains the impression that formal methods of teaching are yielding place to more varied and more actual lines of approach. Attempts to build up logical unity are being abandoned for methods based upon the pupil's own experience and active co-operation. The conception of education is broadening, not only to fit pupils into suitable occupations in adult life, but also to see that they take their part as useful members of the living community. This emphasis on the social side of education is exerting an influence upon teacher-training, for it is found that teachers who are maladjusted professionally are often maladjusted in other walks of life.

Many other papers deal with the organization of education and administrative problems. Much thought is being given to fitting the school into its proper place, a question which is looked upon more from the personal and communal angle than as a matter of national concern. The same line of thought accounts for many papers devoted to the development and present position of education, treated both historically and on the comparable basis of what is happening in other countries. Given certain types of social and economic setting, and certain standards in pupil and parent requirements, it is clear that American educational institutions are meeting fairly adequately such demands as are made upon them.

As one might expect, the large majority of the papers are almost purely descriptive in nature, or they survey known facts and existing circumstances in the attempt to shed new light upon them. Nevertheless, in spite of their short range and empirical character, suggestive results are obtained, some of which are capable of broad application. One investigation, for example, shows that children are more interested in the text than in the format of the books they read, and another, based upon differing interests, points to separate reading-books for girls and boys. Studies in child vocabulary indicate that many books read in school contain words which lie far beyond the child's own age experience. This point applies with some force to science text-books, and deserves more attention than it has so far received. The way is clear for an accepted vocabulary for school use, expanding as the child-mind develops.

Surveys of pupils' leisure time activities show that there is among girls a desire for more physical activity in place of sedentary occupations. Man craves for physical exertion. The school camp is becoming a definite part of the school programme. A number of surveys indicate that inadequate attention is given to health education, in which application lags behind the pupil's own actual knowledge. A comparison between farmers and future farmers in Pennsylvania revealed little difference in total scientific knowledge. The farmers excelled in biological and health knowledge, the young boys in the exact sciences. The fathers were slightly more superstitious than their sons, and both groups tended to correct misconceptions by direct experience. Almost inevitably, an investigation of pupils' honesty showed that there is a positive correlation between cheating and the importance attached by the teacher to the particular test; and for the pessimists, an experiment in trying to teach secondary school students to resist propaganda showed that the instruction offered was ineffective.

One paper reports that mathematics feature considerably more in the curriculum in Great Britain than in the United States, and that British mathematical teachers are more intensively drilled. The theses on scientific subjects are nearly all concerned with general science, biology and chemistry, with scant attention being devoted to physics in education. There is one paper on astronomy and three on geology. Nearly all these papers are taken up with details of teaching technique and with the comparative study of text-books and syllabus requirements within the framework of existing conditions. Relating the science teaching more directly to the pupil's own experiences has a beneficial effect upon their work. Nevertheless, except for some interest in wild life, soil conservation and consumer requirements, there is little evidence of any attempt to lift science teaching on to a plane which would give it broad contacts with human life and with human thought.

Few inquiries have been directed to nutritional standards in the school population, and while in the United States access to educational facilities is widely available to children of all social grades, almost no studies have been concerned with the relation between education and social opportunity, except for those dealing specifically with the Negroes. Much work has been done on the reliability of intelligence tests and on the psychology of memorizing, but little thought has been given to the relations between intelligence, personal effectiveness and physical well-being, and between intrinsic intelligence and success in later life.

Altogether, it is the long view which seems to be missing. What in Great Britain is beginning to be termed human biology, in which biological knowledge

* Bibliography of Research Studies on Education, 1938–1939. U.S. Office of Education, Bulletin, 1940, No. 5.

is applied to individual development, family and social life, is a subject scarcely touched upon. The psychological problem of the relation between knowledge acquired at school and its application in personal living, and the deeper psychological problem of the relation between the inculcation of cultural standards and their expression in personal conduct, are fields almost untilled.

In the United States, where the impact of science has changed social and cultural standards more extensively than elsewhere, and where the rate of change shows every sign of both increasing and continuing indefinitely, altering in its train the environmental framework of man, insufficient attention has as yet been given to science as an educational force, so that the influences affecting man's destiny might be understood, and in that measure brought under control.

HYPERFREQUENCY ELECTROMAGNETIC WAVES AND THEIR PRACTICAL USE

IN a paper by Dr. Léon Brillouin presented at a meeting of the Franklin Institute held on April 6, 1939, and reprinted in the *Journal* of the Institute of June 1941, the author begins by discussing the meaning attached to the word hyperfrequency. It has commonly been used for frequencies higher than 10^9 c./s. (1000 Mc./s.) which correspond to electromagnetic waves the wave-lengths of which are shorter than 30 cm. Brillouin has studied the behaviour of electromagnetic waves of which the lengths are comprised between approximately 1 cm. and a few decimetres.

At the present time, this region of the electromagnetic spectrum is of great interest in many practical fields. The radio engineer is specially anxious to study wave-lengths of the order of one centimetre or less. Very little is known of this region until we reach wave-lengths of 0·1 mm., which correspond to the extreme infra-red. Emission and absorption spectra have still to be measured, together with optical properties of chemical compounds. Some very remarkable results have already been obtained, such as an absorption spectrum for ammonia and a strong change in the dielectric properties of water. These researches will become still more interesting when wave-lengths of a few millimetres, or fractions of a millimetre, can be produced with sufficient energy. It is to be foreseen that all chemical compounds which have an electric dipole should show a typical variation of their electric properties in this region. These waves should enable us to build up new methods of making investigations on molecular structures.

The physicist is waiting for the gap between radio and optics to be filled up. He is still very anxious to link these two different fields together. Experiments have already been tried with damped waves, but so far precise measurements have only been made with undamped and continuous waves, and precise measurements are what the physicist is anxious to obtain. The problem presents as much interest to the radio engineer as it does to the physicist. For the last twenty years or so the tendency in radio is to push in the direction of measuring even shorter wave-lengths. We do not yet know where the practical limit of measuring short waves precisely will be reached. But it has already been demonstrated that wave-lengths some centimetres long may prove of great value for radio-communication, television, signalling (radio-beacon), obstacle detection, not forgetting the use of dielectric cables. All this is more than sufficient to arouse keen interest and promote very active technical research in engineering and technical industries.

Wave-lengths some decimetres long were first used by Hertz to repeat optical experiments, such as prismatic deflexion or diffraction; and this similarity of short radio-waves to optical waves has been emphasized by a great many experimenters. Optical lenses, mirrors, parabolic reflectors are very effective as soon as they can be built with dimensions of a few wave-lengths. Another and more recently discovered point is the analogy between hyperfrequency radio-waves and acoustics. Since the wave-lengths are of the same order of magnitude in both cases, we may now note the very important use of electrical apparatus curiously similar to acoustical instruments: hollow pipes, like organ pipes; hollow resonators reminiscent of Helmholtz's acoustical resonators, and dielectric cables, which show a marked relationship with pipes as used in acoustics. Hollow tank resonators have been suggested by several physicists, mostly on the basis that they give very slight damping. As commonly expressed by radio engineers, these hollow resonators show very high Q factors; a high Q means that the resonator oscillates freely a great many times before the amplitude of the oscillations is reduced to a small value. There is another aspect of the question which seems worth noticing; this is the possibility of first storing up energy in the resonator, and afterwards radiating this energy.

The question arises: How far can we increase the fields? If air is at atmospheric pressure, its disruptive potential is about 30,000 volts per cm., that is, 100 C.G.S. electrostatic units. This upper limit will never be reached in practice. If one wishes to accumulate electromagnetic energy in a given volume, it can only be done by producing high electrical and magnetic fields inside this volume. Making certain assumptions, Brillouin calculates that the average field attains perhaps 15 E.S. units. This means that it contains 1 joule of energy per cubic metre. For short radio-waves, ordinary inductance capacity circuits cannot be used. The technical practice is to use parallel lines or coaxial lines as resonators. These lines can only be built if the distance between the two parallel wires is small with respect to the wave-length. This can no longer be done with hyperfrequency waves, and we are thus forced to work with tank resonators.

The Laboratoires L.M.T. (laboratories of Le Matériel Téléphonique in Paris) have been very active for a good many years in the field of hyperfrequencies. The researches were conducted by MM. Clavier, Darbord and various co-workers and resulted in radio transmission across the English Channel, using a wave-length of 18 cm. Photographs are given of the apparatus employed. The reflectors

produce a linear beam of very small aperture, directed from the transmitting to the receiving station. The reflectors must be in direct sight. In the cross-Channel communications, for example, one of the stations was at St. Inglevert on the French side, the other at Lympne in England, the distance between being about 50 kilometres. The electro-optical equipments were installed on suitable steel towers at St. Inglevert and Lympne. The results of operation were very good on this link, which represents the shortest wavelength circuit in commercial use. The link was used for two-way teleprinter messages as well as duplex telephony. Atmospherics are never heard on the circuits. No interference whatever is caused either by thunderstorms or motor-cars; the background noise in the receiver exactly resembles normal tube noise.

A very important step was taken when Southworth, Carson, Mead and Schelkunoff, of the Bell Laboratories, first began investigating short-wave propagation along conducting hollow tubes (so-called dielectric cables). Very similar researches were started almost at the same time by Barrow at the Massachusetts Institute of Technology. Brillouin concludes by discussing the theory of dielectric cables for various kinds of cross-sections. These high-frequency oscillations have opened up a new field of research in which are very curious theoretical and technical problems, and good prospects for important practical applications.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

MONDAY, NOVEMBER 10

FARMERS' CLUB (at the Royal Empire Society, Craven Street, London, W.C.2), at 3 p.m.—Mr. Thomas Peacock: "Farming's Great War Effort".

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 3 p.m.—Lieut. A. R. Glen: "Recent Changes in the Spitsbergen Glaciers".

SOCIETY OF CHEMICAL INDUSTRY (under the auspices of the Institute of Chemistry in the General Lecture Theatre of the University of Leeds), at 6.30 p.m.—Dr. Dorothy Jordan Lloyd: "Application of X-Rays to Leather Manufacture".

TUESDAY, NOVEMBER 11

CHADWICK PUBLIC LECTURE (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 2.30 p.m.—Mr. Fredk. R. Hiorns: "Hygiene Technique in Building, or the Economic, Psychological and Health Aspects of Surface Treatment".*

WEDNESDAY, NOVEMBER 12

SOCIETY OF CHEMICAL INDUSTRY (FOOD GROUP) (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. A. J. Amos: "Microbiology and Baking".

THURSDAY, NOVEMBER 13

PHARMACEUTICAL SOCIETY (at 17 Bloomsbury Square, London, W.C.1), at 2.30 p.m.—Dr. Harold King, F.R.S.: "Chemistry and Pharmacy".

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 3.30 p.m.—Dr. W. E. Gye, F.R.S.: "Filterable Tumours" (Imperial Cancer Research Fund Lecture).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

HEAD OF THE MATHEMATICS DEPARTMENT—The Secretary, The Technical College, Sunderland (November 15).

CHIEF ASSISTANT ENGINEER—The Engineer to the Witham and Steeping Rivers Catchment Board, 50 Wide Bargate, Boston, Lincs. (November 17).

LECTURER IN ELECTRICAL ENGINEERING—The Principal, County Technical College, Worksop, Notts. (November 18).

PROFESSOR OF EDUCATION—The Bursar and Deputy Registrar, University College of North Wales, Bangor (November 22).

SENIOR PHYSICS MASTER at the Rutherford College Boys' School, Newcastle-upon-Tyne—The Director of Education, City Education Office, Newcastle-upon-Tyne, 2 (November 29).

ASSISTANT ENGINEER to the Sudan Government Railways—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, London, S.W.1 (endorsed 'Assistant Engineer').

NATURE

SATURDAY Nov. 15, 1941

SCIENTIFIC METHOD IN ECONOMIC PLANNING

SCIENTIFIC workers, whatever their attitude to planning, will read the article by Prof. F. Hayek on "Planning, Science and Freedom", which appears on p. 580, with respect and some measure of appreciation. Whether or not his point of view is accepted, he has made an important contribution to clear thinking on a difficult and urgent problem. Even those who find his attitude negative and hold that he makes no constructive proposals, may none the less be grateful for his clear indications of some of the dangers that planning holds for science and freedom, if it is not inspired by creative thought and guided by sound and wise judgment.

Prof. Hayek's article appears to be directed particularly against economic planning. He is careful to dissociate himself from any argument about planning in the general sense of a rational design of human institutions, the desirability of which, by implication, he admits. He attacks the central direction of all economic life as against its direction by competition. His support of the competitive or price system is based on the view that a controlled economy is less efficient and that it leads direct to a totalitarian system, despotic control in every sphere of life, the repression of individuality and freedom, with all that is implied for scientific work by such repression.

No scientific worker can fail to recognize that such dangers exist and that under a totalitarian regime, whether in Germany or in Russia, scientific work of one kind or another has been impeded to greater or less degree. Prof. Hayek, however, does not advance convincing reasons as to why a totalitarian system should be the only outcome of even economic planning, and his whole argument loses verisimilitude to-day when he exempts from his attack the conception of rational planning of all human institutions in their mutual relations. It is this conception of planning for freedom that dominates the field to-day, as it inspired the whole conception of the recent Conference on Science and World Order.

The planning of the twentieth century rests its case, as Dr. Lewis L. Lerwin well said at the World Social Economic Congress in 1931, on a philosophical faith in the power of man to promote orderly economic and social change through scientific research and constructive imagination. Even at that time, Dr. Lerwin distinguished clearly between economic planning itself and technical and industrial planning and rationalization. Using the concept and mechanism of social price, economic planning attempts by new methods to co-ordinate and balance production and distribution, and while Dr. Lerwin admits that planning must be a national

function in method as well as in purpose and must possess a measure of Government authority, he sees alternatives to absolute socialist planning and to the partial State socialist planning of the U.S.S.R. in a voluntary business type of planning and a social progressive type of planning.

The ideas implicit in the latter type are in fact reflected in many of the proposals or developments which in the last few years have given a further impulse to the notion of planning, whether in regard, for example, to re-planning and re-building and the location of industry under the Ministry of Works and Buildings, or to those developments proceeding under the Leith-Ross Committee and in other ways for dealing with the disposal of surpluses and for commodity control. The realization of the waste and damage to national resources through uncorrelated individual action and private interests has been forced too vividly on the attention of the nation for it to contemplate a deliberate return to the pre-war chaos when war-time controls are relaxed. The choice to-day is not between planning and not planning, but rather of the type of planning to be adopted, and the purposes to be served. The peril of economic and political chaos after the War is too serious for no attempt to be made now to provide the institutions or policy for averting, or at least minimizing, these dangers for concerted effort.

It is equally clear that, in the post-war society, the price system will not be accepted as by itself a sufficient determinant. This is not because the idea of private property is likely to be rejected or that the ideal of service rather than profit will be a sufficient motive, but because the usual concept of price has no regard to the social effects of competition. It is this limitation that has had such untoward effects in the distressed areas as has been emphasized in one study after another, from the Barlow Commission's report to the various investigations of areas carried out by the University of Liverpool and similar bodies. In the absence of social control and definite planning, the price system and unrestricted competition will assuredly have equally or even more disastrous results for the community as a whole after the War.

A further tendency, which is also ignored by Prof. Hayek, is the new conception of the function of government as the nation's instrument for planning, and for action to safeguard and develop the collective inheritance and the social and economic welfare of the nation in peace and war. The old conception of government as a regulatory, policing and taxing mechanism is recognized as inadequate. The main weaknesses of our executive machinery of government to-day admittedly follow from failure definitely to adopt such a positive conception of government in all those spheres where individuals or private associations cannot achieve equally effective results.

If, however, the Spencerian concept that there is something inherently wicked and dangerous in government, and that the least government is the best government, should be rejected decisively to-day, there is in it, as in Prof. Hayek's views, a warning we disregard at our peril. As Cobban reminds us in "The Crisis of Civilization", while free association may be a good thing, government and organization can never be more than a necessary evil. The power of government is justifiable in accordance with its utility or the degree in which it promotes the rights of the individual. All absolute sovereignty is a usurpation.

Government, Cobban maintains, is a contrivance instituted by human wisdom for the better attainment of those ends which are laid down by the ethical intuitions of mankind, and which take the form of the natural rights of the individual of self-preservation, free association, the possibility of happiness and a certain field of free activity. The end of government should be to promote the realization of the rights of its subjects. Directly government ceases to be the instrument and in the personified State becomes the end in itself, individuality and freedom are imperilled or, as in the totalitarian State, destroyed.

At a time of flux and reconstruction, when men are seeking to mould instruments of government more effectively on an international as well as on a national scale to their social purposes, this warning, so firmly underlined by the events of the past two decades, needs to be kept clearly in mind. It is significant, moreover, that an essentially similar concept of economic planning inspired its leaders fully a decade ago, as is illustrated not only by Lerwin's paper already quoted but also by that of Mary Follett on "Individualism in a Planned Society" (recently reprinted in "Dynamic Administration"). Planning is to them an instrument for collective self-control, which can and should give scope to individual initiative by showing it the way to combine effectively with other individual initiatives. Individualism is regarded not as something apart but as something contributing to the whole, and freedom is not freedom from relation but freedom through organized relation.

The dynamic conception of planning and government as a collective instrument for co-ordination, based not on coercion from above, but on conference and agreement in accordance with ascertained facts and the changing needs of society, is fundamentally different from the conception attacked by Prof. Hayek and also that which finds concrete expression in the totalitarian regimes to-day. Planning, as Mannheim points out, does not mean rule by arbitrary forces over the living body of

society, nor the dictatorial attempt to supplant creative activity. It means, on the contrary, a conscious attack on the sources of maladjustment in the social order on the basis of a thorough knowledge of the whole mechanism of society and the way in which it works. It is not the treatment of symptoms but an attack on the strategic points.

Prof. Hayek's views must not be dismissed as entirely irrelevant because the type of planning which he attacks does not meet the criteria of such thinkers as Lerwin, Follett or Mannheim. They should rather be taken as endorsing Mannheim's contention that we should deliberately plan for freedom, and as a reminder of the dangers of partial attempts taking account of economic or political factors alone. Moreover, as Mannheim points out, we have still to elaborate much of the technique of social change. We have indeed to learn even from the totalitarian States how to use planned persuasion, not for stirring up strife, but for encouraging behaviour on which all our hopes of peace, co-operation and understanding depend.

The co-ordination of activities involved in this conception of planning is not incompatible with or inimical to freedom, provided these ideals are kept in mind. The elaboration of the necessary technique and social controls requires objective scientific research as well as the retention of such established democratic principles as equality of opportunity, the selection of the fittest and respect for human personality. It is a challenge to sociology and to psychology as much as to economics, and offers, as Mannheim points out, a real chance for sociology to make a creative contribution to the reconstruction of our society. While it may well be important, as both Cobban and Mannheim urge, to diminish the number of purely political issues and dissociate the national and international organs of welfare, health, education and economic co-operation from political and military control, a new experimental attitude in social, including economic, affairs holds the best promise of creative thought and constructive proposals.

It is the magnitude of this challenge to thought that captures the imagination to-day. Only by achieving on a larger scale and in new ways the co-ordination of his activities can man hope to retain real freedom. The new forms of organization must be evolved to serve clearly ascertained needs, and be recognized as instruments and not as ends in themselves. They must be so developed as to enlist the willing co-operation of the individuals and groups whose needs they are to serve.

Undoubtedly the dangers to which Prof. Hayek refers exist, but if humanity is deterred by dangers it is already doomed. Unless society is able to evolve further controls and organized relations while maintaining the individual capacity for adjustment, hope of a new order is a delusion. Separation and local autonomy can no longer be allowed to have the last word, but unless the democratic constitution of a planned society can avoid the bureaucratic absolutism, which is the main target of Prof. Hayek's attack, disaster is equally certain. The transfer of democratic, parliamentary control to a planned or co-ordinated society is a difficult and intricate task, and destruction of that control in the effort to establish a planned society means disaster. None the less, mankind must continue to run risks and to press forward. The study of history does not warrant pessimism as to the ability of society to throw up the men for the great occasions, or to evolve the institutions to serve its increasing and changing needs, so long as the fountain heads of knowledge and creative thought flow free and untainted.

AGRICULTURAL EDUCATION

The appointment by the Minister of Agriculture of a Committee to review the position of agricultural education (see Nature of August 9, p. 161) will be welcome to many who have long regarded a national committee or commission on agricultural education as being needed.

Agricultural education in Great Britain under Government ægis dates from 1888 and the passing of the Technical Instruction Act. In that year an agricultural committee of the Privy Council was formed, and given £5,000 with which to assist agricultural institutions. Agricultural education had, however, been operative in some measure before that, and its development can most usefully be considered from about 1840. At that time the basic process of all farming and all life—the process of photosynthesis—was first universally recognized, the Royal Agricultural Society came into being with its motto, "Practice with Science", and the first Rothamsted experiments were about to begin. During the century that has followed, the conspectus of the broad problem of agricultural education has altered in one very important respect. A hundred years ago there was much skilled craftsmanship in British farming and the limiting factor was lack of scientific knowledge. Since that time the development of scientific knowledge and the output of research has out-

stripped the development of the education and scientific training of the craftsman, and the limiting factor now is the trained ability of the husbandman to use the vast amount of knowledge and understanding of his materials and processes that have accrued. The major problem now is not more knowledge, but more personal education. It is therefore gratifying to note that the Committee appointed by the Minister is to consider the work of primary and secondary schools, and the subsequent personal training of the diverse categories of agriculturists.

To those engaged in programmes of agricultural education the foundations laid in the work of schools and in immediate post-school work is obviously of primary importance. Not that agricultural educationists would necessarily advocate vocational agricultural training in schools—they have, in fact, advocated a continuation of some general education in post-school work. What is commonly called rural science can be incorporated in a scheme of general education without being agriculturally vocational. The fact that scientific principles are illustrated by processes of farm and countryside gives no improper bias. Indeed, it may be regarded as a definite disadvantage to urban schools that such illustrations of scientific principles are not easily available to them, since it is a reasonable part of the educational demands of everyone, whatever his future occupation, to be given some understanding of the scientific basis of life.

The future agriculturist must get experience of practical farm work, normally after leaving school, and the continuity of his education in the year or years of apprenticeship, involving the establishment of appropriate day or evening classes, has been the most difficult part of the whole scheme of agricultural education. The service of elementary technical education to the farming initiate is far behind its service to apprentices in urban industries. Transport difficulties in bringing a highly dispersed rural people to a teaching centre, combined with inadequate public opinion on agricultural education, made the task impossible in the early days of technical education. The small but definite measure of success in recent years among the junior post-school agriculturists is probably due more to the work of young farmers' clubs than any other single factor. This suggests that other and less formal methods than the orthodox technical classes may be necessary to establish the continuity of the education of young agriculturists from the school-leaving age, but orderly and systematic study must necessarily be the main activity, and the discipline of education must remain in agricultural education as in all education. Alternatively, compulsory continuation classes as were contemplated in the Education Act of 1918 may have to be considered. Certainly, continuity at this critical stage in agricultural education is a major problem, and once such continuity can be established many more agriculturists will come on to whole-time courses in farm institute, college or university.

The present arrangements of agricultural education, in addition to providing diverse courses of systematic instruction, also provide the farmer with free facilities for obtaining technical advice on his many problems. There seems, however, to be scope and need for the co-ordination of these facilities. Every county has its agricultural and horticultural staff, who advise on general problems of husbandry, and each of twelve groups of counties—the advisory provinces—into which England and Wales is divided for the purpose, has a specialist staff with an agricultural chemist, bacteriologist, economist, entomologist, mycologist and veterinary officer at the service of the agricultural and horticultural community. There is, however, no official connexion (except in one province) between the county and provincial services, and that is a matter that seems to require attention. It is difficult to see that advisory work can attain its maximum efficiency if those who advise on general husbandry have no administrative connexion with those who advise on special problems of infertility, disease, and so forth. A diseased turnip may be a complex problem to the farmer, but it remains an indivisible problem while those who advise the farmer on the growing of turnips and those who investigate and advise on the disease are in independent services.

Besides the need for co-ordination within the whole advisory services, the association of advisory work with the teaching function of the agricultural educationist is a matter of some moment. The creation of universal public opinion in the farming community in favour of comprehensive courses of agricultural studies has still to be achieved, and there is no doubt that those who successfully advise farmers on technical problems are, over and above their services in solving the immediate problem of the day, doing much to develop a realization of the significance of agricultural education. The identity or intimate association of those who advise farmers and those who teach their sons and daughters in the agricultural classroom is very much needed for some time to come. This association of advisory and teaching function does exist in large measure, but its significance and importance need to be very clearly kept in mind.

Whether or not it comes within the terms of reference of the Committee appointed by the Minister, the agricultural education of the non-

agriculturist is a problem of great national importance. We live in days in which a realization of the basic significance of farming to all people is forced upon us. We realize to-day, as never before since the coming of the industrial age, that farming is the basis, not merely of all the material necessities, but also of all the material amenities of life, and indeed, that it alone among the industries provides the token whereby all men in all ages and in all lands express their mutual goodwill, their loyalties, and all that discriminates human life from animal existence. There should, therefore, be a place in the education of everyone for the development of an appreciation of the farming industry, for acquiring knowledge and understanding of the manifold aspects of the farmer's life. The life and problems of the farming community are still fundamentally the life and problems of all people. The modern industrialist has not left farming as if it did not matter to him : he has delegated it to those who still work on the land, and it should not be too much to ask that all boys and girls be given instruction in the significant position of farming, and that their education will enable them, whatever their own calling, to cultivate an informed opinion about agriculture and its problems.

MODERN PHYSICAL CHEMISTRY

Text-Book of Physical Chemistry
By Dr. Samuel Glasstone. Pp. xiii+1289. (London: Macmillan and Co., Ltd., 1940.) 42s. net.

PHYSICAL chemistry is a somewhat vague but useful term which serves to indicate those parts of chemistry and physics in which the two sciences overlap. There are few subjects in which greater and more rapid advances have been made in the last thirty years: the development of atomic and molecular theory has introduced a host of new topics, and the older parts of the subject have been much clarified and extended, particularly in the treatment of thermodynamics, the theory of solutions, and electro-chemistry. There are in existence a number of monographs dealing with the newer topics, and Dr. Glasstone's two volumes of "Recent Advances" and his "Electrochemistry of Solutions" have been very helpful to chemists in approaching some parts of the subject. It has, however, been evident for some time that a book was needed which would weld the old and the new together into a consistent and comprehensive whole. This gigantic task has now been completed by Dr. Glasstone in the volume under review ; it has been carried out with the competence and clarity which characterize his earlier writings.

The book opens with chapters on atomic structure and radioactivity which are largely physical in character, and which introduce the quantum theory and the fundamentals of wave-mechanics. This is followed by an introduction to thermodynamics, using the Gibbs analytical method and the standard symbols which are now almost universally adopted for the more important thermodynamical functions. Next comes a group of chapters which treat logically a number of new and old topics under the headings of the gaseous state, the solid state, change of state, and the liquid state. The chapter on physical properties and chemical constitution is also a refreshing blend of old and new, and includes discussions of dipole moments, molecular spectra, and magnetism. The chapter on dilute solutions which follows embodies *inter alia* a clear statement of the three definitions of activity coefficient which are to be found in the literature. Phase equilibria are next discussed in a long chapter ; this is largely classical in character, and includes a treatment of three-component systems. The discussion of chemical equilibria which follows embodies an account of statistical methods of calculating entropy changes and a discussion of the third law of thermodynamics. Electrochemistry and chemical kinetics are the next topics to be considered; the chapter on chemical kinetics includes an account of the Eyring-Polanyi theory of the activated complex and a discussion of modern views on homogeneous and heterogeneous catalysis. The final chapter, on surface phenomena, completes a volume of more than 1200 pages.

The treatment in general is a judicious mingling of deduction and description. Clear and adequate accounts of experimental methods and numerous diagrams and tables of data illustrate and enrich the theoretical discussions. The more elementary theory is lucidly set out, but the author does not hesitate to say "it can be shown that" when approaching the more abstruse parts of the subject. This, in the reviewer's opinion, is the proper method to employ in a book of this character ; those who wish to delve more deeply into chemical physics rather than physical chemistry will find adequate guidance in the bibliographies which are appended to each chapter.

In his preface Dr. Glasstone modestly states that his aim is "to take a student with a very elementary knowledge of the subject . . . and to lead him by

easy stages and with the simplest mathematical methods to such an understanding of physical chemistry as will permit him to appreciate the more advanced treatises". This aim is fully achieved, and the new "Glasstone" will soon become well known to honours students in chemistry. It should, however, appeal to a wider public, for there are many chemists outside the universities who will welcome an opportunity of making themselves acquainted with the newer work and its relationship to the old.

S. SUGDEN.

DECREASE OF WILDFOWL THROUGHOUT THE WORLD

International Wildfowl Inquiry
Vol. 1: Factors affecting the General Status of Wild Geese and Wild Duck. Pp. x+123. (Cambridge: At the University Press, 1941.) 8s. 6d. net.

THE disquieting fact has to be faced that the world's stock of wild geese and wild duck is steadily decreasing. To obtain accurate information on this decrease, and to seek some method of checking it, the International Committee for Bird Preservation recently carried out an exhaustive inquiry, the results of which are recorded in the volume under notice.

The destruction of bird life has so often in the past been allowed to continue until some rare species has been exterminated—witness the fate of the sea eagle, osprey and goshawk in Scotland—that it is good to know that some at least of European countries are alive to the potential danger in this decrease of their stock of geese and duck. Sweden, for example (p. 4), has afforded protection throughout the year for five years to all wildfowl in the large province of Jamtland. Contrast this with the state of affairs in Holland (p. 4) where it is estimated that a million wild duck are taken annually in decoys. It is satisfactory to know that few duck decoys are working in Britain. At one of these decoys—Orielton in Pembrokeshire—the duck are not killed, but after being caught and ringed are released. In the year 1935, 1,350 duck were caught and ringed here, and interesting light on their migrations has been shed. It is stated that in Eire and in Denmark duck decoys are illegal, but one wonders what the result of the present War will be as regards the praiseworthy efforts of European nations to conserve their stock of birds. Will Denmark continue such protection, and will Sweden continue to keep the great province of Jamtland a sanctuary? One fears that in the present bitter warfare, birds everywhere are bound to suffer.

This book contains interesting information on the destruction of the eggs of duck and geese in the High North. Captain J. H. MacNeile (p. 23) describes the raids made by Norwegian sealing sloops on the eggs of the eiderduck, which nest in large colonies in Spitsbergen. On the low islands off the Spitsbergen coast brent geese nest in the eider colonies, and the egg hunters make no distinction between the eggs of geese and eiders. Captain MacNeile mentions that in 1935, in early July, hundreds of eggs of eiders and brent geese were taken on one island group alone. The eggs were then hard set and, it might have been thought, useless as food. Captain MacNeile writes:

"How long can the brent geese survive such treatment? It seemed more than doubtful whether one single gosling could have been reared that year on any of the Liefde Bay islands, the principal stronghold of the species in northern Spitsbergen."

In Iceland the raven sucks great numbers of duck eggs. Major W. M. Congreve writes (p. 15):

"Freme was responsible for shooting over fifty ravens on their morning and evening flights to Myvatn, from their distant mountain breeding homes. On the evening flight they were gorged with egg, and it was running from their beaks. Now one can say that this has always gone on. I suppose it has, but what has not gone on until, say, 50 years ago, is the invention of the breech-loading gun, with the everlasting shooting by every Tom, Dick and Harry all over Europe and North Africa."

Chapter 3 of the book deals with another possible cause for the diminution of wildfowl in Britain—the undoubted decrease of the wigeon grass (Zostera) during the past fifteen years. This decrease was specially noticeable in the years 1931 and 1932.

Chapter 7 gives many interesting results of wildfowl ringing. The earliest ringing of duck was by H. C. C. Mortensen in Denmark, who published reports on the teal (in 1908) and on the pintail (1914). Since then, duck have been ringed in large numbers in Iceland, Holland, Germany, Sweden, Finland, and Russia. An unusually interesting ringing record is (p. 98) of a young wigeon ringed in Kinross, and recovered far to the north-west, in Iceland, during its first winter.

INFLUENCE OF WAR UPON SURGERY*

By V. Zachary Cope

SURGERY or chirurgery is the handicraft of healing. It has always been an art, but only during the past hundred years has it become a science. In pre-historic and early historic times the craft must have been almost exclusively exercised upon the victims of inter-tribal war. The earliest crude knowledge of anatomy may have come from skulls cleft by the battle-axe, or chests or abdomens ripped open by spear or sword; and in like manner from the time of earliest combat primitive man must have learned various ways of dressing wounds, extracting arrows or spear-heads from wounds, or applying some form of crude splint to a broken limb. By the time of Hippocrates various methods of practical value had been learnt by experience and were generally taught, but for more than two thousand years little definite advance was made in the art of surgery. Garrison states that through even the sixteenth and seventeenth centuries surgical instruction was so poor that all authorities agreed that war was the only field in which surgery could be learned. The knowledge thus gained was crude, ill co-ordinated, and only advanced by the rough method of trial and error.

Scientific surgery was not possible until there was a knowledge of anatomy, physiology and pathology, and no great extension of surgery was possible before the discovery of anæsthesia. From the time of Hippocrates until Vesalius published his monumental work on anatomy, surgery made few advances. The foundation of physiology, made possible by Harvey's discovery of the circulation of the blood, brought little immediate change apart from the interesting but abortive attempts at blood transfusion by Wren and Lower. Right up to the nineteenth century there were few changes in the methods of treating wounds, apart from those necessitated by the type of missile used. When bullets were round and propelled with only low velocity they did less damage and were often allowed to remain in the body, but when the velocity became higher more damage was done and surgeons such as Larrey used to open up (débrider) the wound and if possible remove the bullet. The usual course of wounds of the limbs was, however, so serious that many surgeons used to recommend primary amputation, and as Garrison remarks, this was often done with reckless profusion by the half-instructed surgeons of the time. The middle of the nineteenth century saw light dawn upon this dark scene, and some of the light was reflected from the battlefield.

In 1846 ether was first used as an anæsthetic, and in 1847 Simpson discovered the value of chloroform for the same purpose. In the next year, 1848, occurred the civil disturbances in Paris and there were many wounded. The value of chloroform was immediately confirmed by Roux, who stated that he had employed it in all his operations with "very marked advantage and without the slightest inconvenience". Thus was shown for the first time how warfare may provide a favourable opportunity for trying out a new scientific remedy. Soon after this the relation of microbes to suppuration was shown by Pasteur, and in 1867 Lister demonstrated how the intelligent use of antiseptics could prevent suppuration in wounds. Though Lister's work was not everywhere received with an open mind, war provided the first great trial of the method. In the Franco-Prussian War of 1870–1871 the German surgeons were very ready to try any method which might give relief to the wounded, and many of them treated the wounds with antiseptics, particularly carbolic acid. But the strength of the solution used was not constant, the methods of using it in different hospitals were various, and the results so conflicting that, though its use became general before the end of the War, the conclusions as to its merit gained no general acceptance. Indeed, in the German history of that War the conclusion is reached "the campaign of 1870–1871 belongs to the pre-antiseptic era". Yet the account given in the history makes it plain that by this War the use of carbolic acid as an antiseptic for general use in operating became widely known among the rising German surgeons.

Though now largely replaced by the aseptic method, there is no doubt that the antiseptic method opened the way for the rapid and great advances which took place in general surgery during the latter half of the nineteenth century. By the beginning of this century surgery had advanced to such an extent that an almost complacent mood came over many who thought that it had attained the limit of its possibilities. To any who thought like this the last thirty years must have caused a rude awakening, for the titanic struggles of the nations—the War of 1914–18, the Spanish Civil War, and the present War—have shown the great limitations of surgery, and at the

* Substance of the Chadwick Public Lecture delivered on October 7.

same time have provided the most valuable opportunities for research.

It is true that little of surgical value came to us from the Boer War—in fact some of the deductions made from that war have been proved to be misleading. The chief result of value was the discovery of the value of inoculation against typhoid fever—a triumph with which the name of Almroth Wright will always be associated.

SURGERY IN THE WAR OF 1914-18

The war of 1914–1918 had a very great influence on surgery in all its branches, and it will be necessary to limit ourselves to some of the most striking advances either initiated or rapidly developed during the course of that War.

It has been well said that "in former wars tetanus was a calamity to be recorded and deplored ; the war of 1914–1918 has shown that it is one which can largely be prevented". At the beginning of that War the incidence of tetanus was high, but when once prophylaxis was introduced the number of cases greatly diminished and remained so during the remainder of the War.

The War of 1914–18 helped largely to make of blood-transfusion an immediately available life-saving measure. So far as can be ascertained it was not until the seventeenth century that the transferring of blood to man, either from an animal or from another man, was considered a practicable proposition. But in spite of the many investigators who experimented with blood-transfusion, there were two great obstacles to the general adoption of the method ; one was the clotting of the blood, the other the incompatability of one blood with another, leading to serious or fatal consequences. In the first decade of this century Landsteiner detected the agglutinins in blood, and Jansky and Moss were thereafter able to classify bloods into four groups and to say which were compatible. Just before the War of 1914–18 the method of preventing clotting by using paraffin-coated tubes was discovered, and actually in 1914 several observers noted that sodium citrate when added to blood prevented its coagulation and caused no harm when injected intravenously. It was after the War had already begun that the first transfusion with citrated blood was made by Agnote in Buenos Aires. There was a delay of two years before the great value of transfusion was realized by the contending armies, but when the American surgeons came across to Europe transfusion was rapidly developed and soon became a recognized measure for saving life. Banks of stored blood are available during the present War for the immediate treatment of shocked or exsanguinated patients, and a further advance has been the use of stored serum or plasma. There have indeed been some who say that there is at present too free a use of this method.

The treatment of wounds underwent great developments during the course of the War of 1914–18. At the beginning many surgeons had a blind faith in the efficacy of antiseptics to prevent or stop sepsis in a wound—a faith which they would scarcely have entertained if they had carefully studied the original writings of Lister. This simple faith was shattered by the work of Wright, Fleming and others, who showed that the antiseptics commonly used, for example, carbolic acid and perchloride of mercury, did more damage to the tissues than to the microbes hidden within them. This led to the use of other antiseptics such as flavine and the hypochlorites, which were more efficacious and did little damage to the tissues. Good results were also claimed for a mixture of bismuth, iodoform and paraffin (BIPP), using a technique introduced by Rutherford Morison. (Readers of Lister's papers will recall with interest that iodoform was the only antiseptic substance that he ever recommended to be introduced into the interior of a wound for its antiseptic effect.) But in order to apply any antiseptic the wound had to be opened up (débridement), and when it was opened up the difficulty of reaching all the damaged parts became evident. So by logical necessity surgeons were brought to see that the best method of avoiding septic wounds was thoroughly to excise the damaged tissues along the edges of the wound, and this ultimately became the routine treatment whenever possible. This excision of damaged tissues (wrongly called débridement) became standard treatment and constituted a wonderful advance in surgical technique. (It is only fair to state that this method had been advocated in the time of the Napoleonic wars by Desault and by Larrey, but they considered that it was only applicable to wounds of the soft parts of the face.)

During the War of 1914–18, thoracic surgery underwent considerable modifications and improvements, which have continued progressively to the present time. The free opening of the thorax, which before that War was a dreaded procedure, is now a daily occurrence.

A branch of surgery which may almost be said to have owed its origin to the War of 1914–18 is that of plastic work. In previous wars gunshot wounds had usually or frequently been made by bullets discharged from a distance, but in the terrible bombardments and close fighting of that War the character of the wounds by shells and bombs became more mutilating. Moreover, in trench warfare and with the wearing of metal

helmets the face was the only part left exposed and was therefore very frequently injured. Such injuries, if the patient survived and the wounds healed, produced terrible caricatures of the human face, and such revolting sights stimulated surgeons to devise methods of repair which should, so far as possible, restore parts to their original appearance. Thus arose the modern art of plastic surgery, in which patience, skill and ingenuity are more needed than in any other branch of surgery. It would take me too long to tell of the marvellous and ingenious turns of technique called into play in this art, how skin is made to travel caterpillar fashion from one part of the body to another, how noses are made from skin borrowed from one part and bone or cartilage taken from another area of the body, how large gaps in the jaw are made good by bone transferred from another bone and grafted on to the remnants of the broken jaw-bone, and many other marvels which are now of daily occurrence.

At the beginning of the War of 1914–18 gunshot injuries of joints were usually treated by incision into the joint, irrigation by antiseptic solutions and drainage by rubber tubes inserted into the cavity of the joint. As the War proceeded, however, it was found that to put a drain into a joint was bad technique, that incision of the infected parts of the wound and removal of foreign bodies with closure or almost complete closure of the joint-cavity led to much better results. After three years of war the improvement was so great that more than four-fifths of joint-wounds were healing by first intention without suppuration, and the amputation-rate at the base hospitals was down to 7 per cent. This was indeed a notable surgical advance directly due to the War.

The loss of a limb is not uncommon in peacetime, but in war it is a very frequent occurrence and it would not be surprising if the great experience of war-time should lead to improvements in the technique of amputation. As a matter of fact during the War of 1914–18 the terrible injuries and the frequent occurrence of gas gangrene frequently made formal amputation inadvisable, so that little technical advance was made in that direction. Ingenious advances were, however, made in the prosthetic apparatus to replace those limbs which were removed, for as the late Mr. Elmslie remarked, "progress in the design and manufacture of artificial limbs has usually occurred as a direct result of great wars".

Though the War of 1914–18 advanced surgery it did not greatly help surgical education. War surgery is very different from civil surgery. In that War, by force of circumstances or by the absence of proper grading, many men of little experience were compelled to do much operating. After the War it was soon evident that such operative experience did not constitute a full or adequate surgical training to cope with the great variety of civilian surgical work. In the present War a much better system has been used for choosing and grading surgeons for responsible work, and the benefit of this has already been observed.

SURGERY IN THE SPANISH CIVIL WAR

The statement that war provides the opportunity of trying out any new method of treatment needs to be qualified by the remark that the opportunity furnished is not always seized. During the Spanish Civil War, however, we had an example of man and opportunity meeting at the appropriate time. I have mentioned that in the War of 1914–18 excision of contaminated wounds proved the best treatment, but with very extensive wounds complicated by fractures and injury to joints, suppuration often could not be prevented, and the consequent frequent after-dressing, either by Carrell-Dakin technique or other means, proved very tedious and prolonged. Similar prolonged and inconvenient treatment had been necessary at one time in those cases of inflammation of bone in which the bone had been widely opened to let out the pus. Twenty years ago, Winnett-Orr proposed that it would be a better proceeding to give complete rest to the part by immobilizing it in plaster of Paris casing and letting the wound heal underneath the plaster. Though, *a priori*, this appeared a dirty and unsurgical method, yet it proved an unqualified success and saved much time and trouble to the surgeon and much discomfort and pain to the patient. It is quite possible that this method may have been applied to gunshot wounds of the limbs before the Spanish War—in fact a similar method is stated to have been used by some surgeons in the last century—but there is no manner of doubt that the credit for making this technique applicable to severe gunshot wounds of the limbs attended by fractures mainly belongs to Trueta.

Trueta practised excision of the damaged tissues of the wound and immediate encasement of the affected limb in plaster of Paris which, unless some complication became evident, was left on for five or six weeks before being changed. It was found that severe infection seldom ensued, that what infection was present usually subsided within a few days, that virulent streptococci which were often present at the beginning gradually disappeared, and the wound took on a healthy appearance so that when the plaster was removed it revealed a granulating surface and a uniting or united fracture. This simple method, which perhaps largely depends upon the perfect rest to the part,

has proved efficient in this present War and must be accounted one of the most remarkable advances in wound treatment of late years.

SURGERY IN THE PRESENT WAR

The present War has been raging for more than two years. Realizing the need and opportunities for research on certain problems the authorities have already arranged for special research units, and some useful information has resulted.

The bugbear of the surgeon is the streptococcus, deadly to human beings, often persistent and latent in wounds and sinuses and difficult to dislodge. A few years ago mankind was blessed by the discovery of a drug which, given internally, was able to diminish and often destroy the streptococcus wherever it might be in the body, except on the surface of wounds. Recently Colebrook has found that this drug, sulphonilamide, when put on to the surface of an infected wound, has a direct inhibitory or destructive effect on the streptococcus, and this discovery is full of promise.

The other discovery deals with the effect of blast upon the human body. Everyone is now aware of the terrible effect of the blast due to the bursting of a large high-explosive bomb. A person may be killed by this blast without any external mark of injury being apparent. How this lethal effect is produced and how it may be prevented has been the subject of a research by Zuckerman and by others who have already obtained results which are full of promise for the successful prevention of injury from the terrible injuring force.

INDIRECT RESULTS OF WAR UPON SURGERY

War affects a nation otherwise than by direct physical damage. Food-supplies are often diminished to a level which is incompatible with health, and various diseases may find a chance to flourish which could not gain a footing in normal times. This was shown by the statistics of surgical diseases as they occurred in one of the large Russian hospitals during the time of the War of 1914–18 and the subsequent revolution. The whole social framework of the country was broken for a time and disease of every kind was rife. Starvation and undernourishment were prevalent. In these circumstances it was noteworthy that the number of cases of appendicitis and cholecystitis diminished almost to vanishing point, while ulceration of the stomach and duodenum increased altogether out of proportion. It is certainly significant that the most common surgical disease of the abdomen should almost disappear when war compelled drastic reduction in the diet scheme. It may well be that many other factors were concerned in this reduction, but on the face of it there may be some indication as to the pathology of appendicitis.

Every wise practitioner is taught by time and experience that to prevent is better than to cure, or to speak paradoxically, prophylaxis is the better part of treatment. The best cure of wounds is to prevent them. So we may hope that future generations may profit by the terrible experiences of the present time and there may develop the perfect prophylaxis of the war disease—that for which all of us are longing—peace.

PLANNING, SCIENCE AND FREEDOM

By PROF. F. A. HAYEK
LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE

THE last ten years have witnessed in Great Britain a strong revival of a movement that for at least three generations has been a decisive force in the formation of opinion and the trend of social affairs in Europe: the movement for 'economic planning'. As in other countries—first in France and then particularly in Germany—this movement has been strongly supported and even led by men of science and engineers. It has now so far succeeded in capturing public opinion that what little opposition there is comes almost solely from a small group of economists. To these economists this movement seems not only to propose unsuitable means for the ends at which it aims; it also appears to them as the main cause of that destruction of individual liberty and spiritual freedom which is the great threat of our age. If these economists are right, a large number of men of science are unwittingly striving to create a state of affairs which they have most reason to fear. It is the purpose of the following sketch to outline the argument on which that view is based.

Any brief discussion of 'economic planning' is handicapped by the necessity of first explaining what precisely is meant by 'planning'. If the term were taken in its most general sense of a rational design of human institutions, there could be no room for argument about its desirability. But

although the popularity of 'planning' is at least partly due to this wider connotation of the word, it is now generally used in a narrower, more specific sense. It describes one only among the different principles which might be deliberately chosen for the organization of economic life: that of central direction of all economic effort as against its direction by competition. Planning, in other words, now means that not only the kind of economic system which we want to adopt should be rationally chosen, but that we should chose one that rests on 'conscious' or central control of all economic activity. It is evidently in this sense that, for example, Professor P. M. S. Blackett uses the term when he explains that "the object of planning is largely to overcome the results of competition"[1]. This narrow use of the term is of course meant to suggest that only this kind of economic organization is rational, and that therefore it alone deserves to be called planning. It is this contention which economists deny.

The full argument which leads to the conclusion that planning in the sense of central direction is in fact an inefficient system cannot be reproduced in a few sentences. But the gist of it is simple enough. It is that the competitive or price system makes possible the utilization of an amount of concrete knowledge which could never be achieved or approached without it. It is true, of course, that the director of any centrally planned system is likely to know more than any single entrepreneur under competition. But the former could not possibly use in his single plan all the combined knowledge of all the individual entrepreneurs that is used under competition. The knowledge which is significant here is not so much knowledge of general laws, but knowledge of particular facts and the ever-changing circumstances of the moment—a knowledge which only the man on the spot can possess. The problem of the maximum utilization of knowledge can therefore be solved only by some system which decentralizes the decisions. There is no possibility of a division between the general outline of the plan and the detail of the execution—or at least no way for such a division has yet been shown. The reason for this is that the general features are just the result of an infinity of detail, and there are no principles which, without harm, can be laid down irrespective of the detail. Yet, in order that in a decentralized system the individual decisions should be mutually adjusted to each other, it is of course essential that the individual entrepreneur should learn as promptly as possible about any relevant change in the conditions affecting the factors of production and the commodities with which he is concerned. Now this is precisely what the price system brings about *if* competition is functioning. It is in effect a system under which every change in conditions and opportunities is promptly and automatically registered so that the individual entrepreneur can read off, as it were, from a few gauges and in simple figures, the relevant results of everything which happens anywhere in the system with respect to the factors and commodities with which he is concerned.

This method of solving by an automatic decentralization a task which, if it had to be solved consciously, would exceed the powers of any human mind, would have been hailed as one of the most marvellous inventions—if it has been invented deliberately. Compared with it the more obvious method of solving the problem by central direction appears incredibly clumsy, primitive, and limited in scope. It is very significant that those socialist economists who have most carefully studied the practical problems of a socialist economy have more than once re-discovered competition and the price system as the best solution—only that unfortunately this system cannot work without private property[2]. For the general attitude towards the price system it has, however, been most unfortunate that it has not been deliberately invented, but that it has spontaneously grown up long before we had learnt to understand its operation. It seems to offend a deep instinct of the man of science and particularly the engineer to be asked to believe that anything which has not been deliberately constructed but is the result of a more or less accidental historical growth should be the best method for a human end. Yet the contention is of course not that by some miracle just that system has spontaneously developed which is best suited to modern civilization, but rather that the division of labour, which forms the basis of modern civilization, has been able to develop on a large scale only because man happened to tumble on the method which made this possible.

It is now sometimes argued—often by the same type of people who by their propaganda against competition have contributed largely towards its progressive suppression—that although all this is quite true, and although it would be desirable to have competition if it were still possible, technological facts prevent this, and that therefore central planning has become inevitable. This, however, is just one of the many myths which, like that of the 'potential plenty', are taken over by one propagandist work from another until they come to be regarded as established facts, although they have little relation to reality. There is no space here to discuss this point at any length, and it must suffice to quote the conclusion at which the most comprehensive recent investigaton of the facts has arrived. This is what the final report of

the investigation on the "Concentration of Economic Power", by the American Temporary National Economic Committee, has to say on the point: "It is sometimes asserted, or assumed, that large scale production, under the conditions of modern technology, is so much more efficient than small-scale production that competition must inevitably give way to monopoly as large establishments drive their smaller rivals from the field. But such generalization finds scant support in any evidence that is now at hand"[3]. Indeed few people who have watched economic development during the last twenty years or so can have much doubt that the progressive tendency towards monopoly is not the result of any spontaneous or inevitable force, but the effect of a deliberate policy of the Governments, inspired by the ideology of 'planning'. The really remarkable fact is the vitality of competition, which in spite of the persistent attempts towards its suppression is ever again raising its head—only to encounter new measures designed to stifle it.

It is a serious thing that in this situation men of science and engineers should so frequently be found leading a movement which in effect merely serves to support the unholy alliance between the monopolistic organizations of capital and labour, and that for a hundred men of science who attack competition and 'capitalism' scarcely one can be found who criticizes the restrictionist and protectionist policies which masquerade as 'planning' and which are the true cause of the 'frustration of science'. That this attitude should be so common among natural scientists can scarcely be fully explained by that characteristic bias for anything consciously constructed and against anything which has merely grown up, to which I have already alluded. It is at least as much due to the antagonism of so many natural scientists towards the teaching of economics, whose methods appear to them unfamiliar and strange, and whose results they often either disregard or, like Prof. L. Hogben, even violently attack as "the medieval rubbish taught as economics at our Universities"[4]. This conflict over the methods proper to the pursuit of the study of society is an old one and raises exceedingly complex and difficult problems. But as the prestige which the natural scientists enjoy with the public is so often used to discredit the results of the only systematic and sustained effort to increase our understanding of social phenomena, this dispute is a matter of sufficient importance to make in this context a few words of comment necessary.

If there were reason to suspect that the economists persist in their ways merely from the force of habit and in ignorance of the methods and techniques which in other fields have proved so eminently successful, there could indeed be grave doubt about the validity of their arguments. But attempts to advance the social sciences by a more or less close imitation of the methods of the natural sciences, far from being new, have been a constant feature for more than a century. The same objections against 'deductive' economics, the same proposals to make it at last 'scientific', and, it must be added, the same characteristic errors and primitive mistakes to which natural scientists approaching this field seem to be prone, have been repeated and discussed over and over again by successive generations of economists and sociologists and have led precisely nowhere. All the progress in the understanding of the phenomena which has been achieved has come from the economists patiently developing the technique which has grown out of their peculiar problems. But in their efforts they have constantly been embarrassed by famous physicists or biologists pronouncing in the name of science in favour of schemes or proposals which do not deserve serious consideration. It was expressing a common experience of all students of social problems when an American sociologist recently complained that "one of the most terrible examples of unscientific-mindedness is frequently an eminent natural, i.e., physical or biological scientist speaking on societal matters"[5].

As the dispute on central planning has become so closely connected with the dispute on the scientific validity of economics, it has been necessary briefly to refer to these matters. But this must not draw us away from our main theme. The technical inferiority or superiority of central planning over competition is not the sole or even the main problem. If the degree of economic efficiency were all that is at stake in this controversy, the dangers of a mistake would still be small compared with what they really are. But just as the alleged greater efficiency of central planning is not the only argument used in its favour, so the objections do not rest solely on its real inefficiency. It must indeed be admitted that if we wanted to make the distribution of incomes between individuals and groups conform to any predetermined absolute standard, central planning would be the only way in which this could be achieved. It could be argued—and has been argued—that it would be worth putting up with less efficiency if thereby greater distributive justice could be obtained. But unfortunately the same factors which make it possible in such a system to control the distribution of income also make it necessary to impose an arbitrary hierarchical order comprising the status of every individual and the place of practically all values of human life. In short, as is now being more and more generally recognized, economic planning inevitably leads to, and is the

cause of, the suppression of individual liberty and spiritual freedom which we know as the 'totalitarian' system. As has recently been said in Nature by two eminent American engineers, "the State founded on dictatorial authority . . .and the planned economy are essentially one and the same thing"[6].

The reasons why the adoption of a system of central planning necessarily produces a totalitarian system are fairly simple. Whoever controls the means must decide which ends they are to serve. As under modern conditions control of economic activity means control of the material means for practically all our ends, it means control over nearly all our activities. The nature of the detailed scale of values which must guide the planning makes it impossible that it should be determined by anything like democratic means. The director of the planned system would have to impose his scale of values, his hierarchy of ends, which, if it is to be sufficient to determine the plan, must include a definite order of rank in which the status of each person is laid down. If the plan is to succeed or the planner to appear successful, the people must be made to believe that the objectives chosen are the right ones. Every criticism of the plan or the ideology underlying it must be treated as sabotage. There can be no freedom of thought, no freedom of the Press, where it is necessary that everything should be governed by a single system of thought. In theory Socialism may wish to enhance freedom, but in practice every kind of collectivism consistently carried through must produce the characteristic features which Fascism, Nazism and Communism have in common. Totalitarianism is nothing but consistent collectivism, the ruthless execution of the principle that 'the whole comes before the individual' and the direction of all members of society by a single will supposed to represent the 'whole'.

It would need much more space than can be given to it here to show in detail how such a system produces a despotic control in every sphere of life, and how in particular in Germany two generations of planners have prepared the soil for Nazism. This has been demonstrated elsewhere[7]. Nor is it possible here to show why planning tends to produce intense nationalism and international conflict[8], or why, as the editors of one of the most ambitious co-operative volumes on planning discovered to his sorrow, "most 'planners' are militant nationalists"[9]. We must turn here to a more immediate danger which the present trend in Great Britain creates. It is that of a growing divergence between the economic systems here and in the United States which threatens to make impossible any real economic collaboration between the two countries after the War. In the United States the present development is well described by the programme for restoring competition developed by President Roosevelt in the message to Congress of April 1938, which, in the President's words, is based on the thesis "not that the system of free private enterprise for profit has failed in this generation, but that it has not yet been tried"[10]. Of Great Britain, on the other hand, it could be rightly said about the same time that "there are many signs that British leaders are growing accustomed to thinking in terms of national development by controlled monopolies"[11]. This means that we are following the paths on which Germany has led and which the United States is abandoning because, as states the report on the "Concentration of Economic Power" to which the President's message gave rise, "the rise of political centralism is largely the result of economic centralism"[12]. The alternative is, of course, not *laisser-faire*, as this misleading and vague term is usually understood. Much needs to be done to ensure the effectiveness of competition; and a great deal can be done *outside* the market to supplement the results. But by the attempts to supplant it we deprive ourselves not only of an instrument which we cannot replace, but also of an institution without which there can be no freedom for the individual.

Nothing in this situation deserves to be studied and pondered so much as the intellectual history of Germany during the last two generations. What has to be realized is that the features which made her what she is are largely the same as those which made her admired and which still exert their fascination; and that the corruption of the German mind came largely from the top, the intellectual and scientific leaders. Men, undoubtedly great in their way, made Germany an artificially constructed State—'organized through and through', as the Germans prided themselves. This provided the soil in which Nazism grew and in which representatives of State-organized science were found among its most enthusiastic supporters. It was the 'scientific' organization of industry which deliberately created the giant monopolies and represented them as inevitable growths fifty years before it happened in Great Britain. The very type of social doctrine which is now so popular among some British men of science began to be preached by their German counterparts in the seventies and eighties of last century. The subservience of the men of science to whatever became official doctrine began with the great development of State-organized science which is the subject of so much eulogy in Great Britain. It was the State in which everyone tended to become a State employee and in which all pursuits

for profit were held in contempt which produced the disregard and final destruction of liberty which we now witness.

I shall conclude with an illustration of what I have said about the role of some of the great men of science of Imperial Germany. The famous physiologist Emil du Bois-Reymond was one of the leaders of the movement anxious to extend the methods of natural sciences to social phenomena and one of the first and most effective advocates of the now so fashionable view that "the history of natural science is the real history of mankind"[13]. It was also he who uttered what is perhaps the most shameful statement ever made by a man of science on behalf of his fellows. "We, the University of Berlin," he proclaimed in 1870 in a public oration as rector of the University, "quartered opposite the King's palace, are, by the deed of our foundation, the intellectual bodyguard of the house of Hohenzollern"[14]. The allegiance of the German scientist-politicians has since changed, but their respect for freedom has not increased. And the phenomenon is not confined to Germany. Has not Mr. J. G. Crowther recently, in a book which develops views so similar to du Bois-Reymond's, undertaken to defend even inquisition because, in his view, it "is beneficial to science when it protects a rising class"[15]? On this view clearly all the persecutions of men of science by the Nazis after they came to power could be justified—for were not the latter then a "rising class"?

THE SCIENTIFIC APPROACH TO COLONIAL DEVELOPMENT*

BY THE RIGHT HON. LORD HAILEY, G.C.S.I., G.C.M.G., G.C.I.E.

IN discussing colonial conditions, I shall in the main limit myself to those prevailing in the British Colonies. The character of the British colonial empire was modified as a result of the expansionist policy of the latter part of the last century. The Indian Empire and Burma have, of course, never been ranked as colonies. Up to about the eighties of last century, therefore, the Colonies comprised mainly Ceylon and a small part of Malaya in the eastern hemisphere, a number of trading settlements on the coasts of Africa, and in the western hemisphere, the old British possessions in the West Indies. The period of expansion added in Africa alone an area roughly equal to that of British India, together with parts of Borneo, an extended area in Malaya, and some of the Southern Pacific islands. The new territories were largely tropical in character; but, what is more important, the majority of their populations were at a stage at which they had needs, both material and social, far greater than those of some of the older dependencies. Judged in terms of approach to our own type of civilization, they were far more backward. On the other hand, we had then available to us the result of much previous experience of colonial development; above all, we had by this time at our service an amount of knowledge regarding the employment of the applied sciences in social development which was far in advance of that possessed by our predecessors. We had another advantage. Earlier in the last century, tropical products (excluding, of course, certain of the minerals, and the precious metals) were in demand only in the luxury market of the more highly developed countries. But the rapid growth of standards of living in those countries has made the luxuries of our grandfathers the necessities of whole populations to-day. Such things as cocoa, the great range of vegetable oils, coffee or bananas are typical of the tropical products which have become essential to the general population of Europe and America, and thus can assist the tropical peoples in financing the social services needed to improve their standards of life.

We had also at our service a growing store of

* Substance of a paper read at the Conference on Science and World Order on September 27.

knowledge about the social customs of primitive peoples. It may be that the existing customs of these people in such matters as the holding of property, the regulation of conduct by tribal or community ties, and the like, has had its analogy in the past history of our own and other highly organized peoples. But we are now divided from the primitive peoples by a gulf which makes the process of their adjustment to modern civilization far more difficult than that of many of the Eastern peoples. Our anthropological study may, at the period of which I am speaking, have been interested in the form rather than in the function of custom. But we had the means of appreciating the fact that the gulf could not be suddenly closed by a hasty substitution of our own social conceptions and practices, but must be bridged by a studied adaptation of existing custom to modern uses.

I can best illustrate the character of the problem with which I have set out to deal, if I ask how far we have actually availed ourselves of these opportunities in planning the development of the new areas which the events of the latter half of the last century brought into our possession. We need not concern ourselves here with the preliminary stage through which all colonial development must pass, I mean the introduction of law and order, and the provision of those more elementary requirements, in the form of communications and the like, which will enable the population to begin building up its material existence. We are concerned here with the secondary stage, of which the chief feature is, or should be, the conscious planning of the improvement of its standards of life.

We can afford to avoid at this point any discussion as to the nature of the ultimate objective of this development—whether, for example, we desire to Europeanize the dependent peoples, or what is the nature of the synthesis between the indigenous culture and our own culture which we seek to attain. These are no doubt questions which must have their answer at some stage, but the answer is one which is in the end more likely to be provided by the dependent peoples themselves than by us. I confine myself here to matters which we cannot doubt to be within our grasp, given a due attention to careful planning and systematic execution.

We must see that the colonial peoples have that type of nutrition which will establish the necessary measure of resistance to disease. We must secure for them a subsistence adequate to provide the strength necessary for sustained effort in cultivation or industry. They must have access to medical facilities for dealing with physical disorders, epidemic or otherwise; and access to such measure of popular instruction as will enable the mass of people to adjust themselves to the needs of new economic and cultural conditions. These are fundamentals, and precondition all further social progress.

But planning, even at this early stage, cannot halt there. We interpret economics to-day in terms of welfare, not of wealth; but it is a condition of welfare that the Government should itself have the means of raising finance for capital works or for the provision of social services, and that the population should be furnished with the means of acquiring articles which a non-industrialized country must necessarily import. All the exportable assets of the territory, whether in the form of metals or of exportable crops, must therefore be turned to the best account. But this must at the same time be effected on terms which will avoid prejudice to the primary claims of subsistence production or undue disturbance to a social economy not yet adjusted to the needs of industrial life.

How far have we planned scientifically for development on the lines which I have just described? For I take it that the use of science in colonial development means just this, that we start by surveying the whole field in order to get the problems which it presents into proper alignment, and afterwards proceed systematically to their solution, using the most expert agencies available for advice as to the methods to be employed, and expending the resources at our command in the order which the relative importance of our problems indicates.

It is doubtless unduly idealistic to suggest that we could ever have proceeded on lines involving so much prevision and systematic procedure as this involves. It is at all events clear that we did not do so. We have, for example, in many instances allowed concentration on the cultivation of export crops to outweigh the needs of subsistence production, with results no doubt less disastrous than those which at one time attended the use of the culture system in the Netherlands East Indies, but sufficiently grave to require legislation compelling a minimum subsistence cultivation, in order to prevent famine. It is only in the last few years that we have inaugurated a general survey of nutritional conditions in the Colonies. It required the revelations regarding the ravages of sleeping sickness in the neighbourhood of Lake Victoria during the years 1901–1905, where we owed much to inquiries initiated by the Royal Society, to bring home to our administrations the deplorable health conditions prevailing in many parts of Africa, and there are still many areas in which no general survey of these conditions has yet been made. The extent of popular education was for long dependent on missionary initiative, and the State did not control

the curriculum. It is only of very recent years that we have realized the widespread menace of soil erosion and the need for special measures for conserving soil fertility.

Passing to another field, there are many territories where geological survey has been very superficial, and the discovery of mineral deposits has been left to the initiative of individual prospectors, who have been primarily interested only in the precious metals. Land survey has in some cases been so exiguous that railways have had to be re-aligned at great cost owing to the lack of accurate maps. Or take yet another field. Native land tenure systems have in Africa still to come under comprehensive survey, though agricultural progress must largely depend on the evolution of a definite and easily recognizable system of land rights. Recruitment of labour for industrial enterprises has not until lately been regulated by any programme based on the capacity of different areas to provide man-power without undue social disturbance or interference with subsistence cultivation. It has been left to the management of these enterprises to investigate the most suitable dietary for labour and to apply it at their own discretion.

We must readily admit the obstacles which have stood in the way of a systematic planning of development. No one can justly overlook these, just as no one should underestimate the vast improvement which we have actually made in the life of the dependent peoples, or the services which the high sense of duty of the administrative staff has rendered to them. Nor must one overlook the many contributions which have been made, especially of late years, by our scientific bodies and the labours of individual men of science. It is sometimes said, that if we have failed to be more systematic in our policy of development, it is because we are not ourselves either a very logical or a scientifically minded people. In our own national life we prefer to act on a sense of expedience rather than on principle ; we trust to improvisation rather than to logical scheming, holding that this is more flexible and more readily adjustable to the complexities of actual situations than are the results of more abstract thinking.

Our colonial policy has in the past been dominated by certain traditions derived from our own political instincts, and by the conditions in which we originally acquired jurisdiction over our dependent peoples. We saw our first duty in protecting them from exploitation and misrule and in fitting them to maintain, in a political sense, their own position in the world. That tradition was far from unworthy, but it may be that it unduly diverted our attention from the need of pursuing a constructive policy of improvement in the physical conditions and the standards of life of these people. In the second place, we have in the past tended in our own domestic life to look on the State chiefly as a political organization, and not as one of which the primary function is the promotion of the social welfare, the health and the standards of life of its citizens. This generation has seen a radical change in our conception of the functions of the State, and with it has come a new and more constructive outlook on the activities which should engage the attention of a colonial administration.

This changed conception of the functions of the State has had a marked influence on the attitude of the British public itself towards its colonial obligations. It was in the past usual to make an appeal to a sense of trusteeship, a trusteeship which, in a well-known phrase, ought to be exercised alike in the interests of dependent peoples and those of civilization. But that form of appeal had its limitations. It was capable of a great variety of interpretations, and it supplied no standard for action. It left it open to the public to feel that it could satisfy its sense of obligation by the maintenance of a humane system of administration and by taking a liberal view of the political future of its dependants. But the new conception of the functions of the State puts our colonial obligations on a concrete plane, and one with which the public is not unfamiliar.

It is the general acceptance of this new conception of the State in relation to the provision of social services which rendered it relatively easy to secure the liberal provision of funds guaranteed by the Colonial Welfare Act passed in 1940. We started at the outset with the feeling that a Colony should be self-supporting. We advanced a further stage when the Colonial Development Fund Act of 1929 made it possible to spend up to a million pounds a year on assistance to certain of the social services, or on types of inquiry which the Colonies were not able to finance. The Act of 1940, however, is a final recognition that further development cannot be achieved without more far-reaching and more consistent assistance.

It is now the task of the administrator to make a full use, and at the same time a more scientific use, of this position. Let me indicate some of the directions which the more scientific use of the opportunities now presented might profitably take. I will begin with some of our more fundamental needs. In the first place, we need to place our demographic information on a more satisfactory basis. Even the total population of some of our territories is a matter of assumption and dependable vital statistics are generally unobtainable. The extension of land survey is essential, at all events so far as regards geodetic triangulation, in order to

provide the network within which cadastral survey can be conducted as it becomes necessary. We must not repeat the experience of South Africa, which paid heavily for its delay in carrying out the scheme of triangulation put forward by Sir David Gill in the seventies of last century. Again, the fuller knowledge of our colonial assets demands an expanded service of geological survey; the discoveries made by the Government geological staff in the Gold Coast and Sierra Leone, show how ample a return the Government revenues can secure for the small outlay involved. To-day much of the energy of our small geological staff is diverted in some areas to the provision of water supplies or the regulation of mining licences. I have referred to the inauguration of a nutrition survey, a movement largely stimulated by the work of Sir John Orr and his colleagues in Kenya, but the specialist staff engaged is relatively small, and in only one or two cases has the survey been associated with the sociological survey which must be an essential part of a study of this nature. It is not enough to know if a dietary is inadequate or ill-balanced; we must know also the social habit which determines its selection or hinders the use of available substitutes.

As regards health work I have already pointed out the absence in many territories of a complete survey of health conditions. There have been studies carried out of particular localities which have proved of the highest value, but much has still to be done in this direction. Thus, to take an example from Africa, we know as yet very little about the exact range of the 'dormant' or 'silent' stage of yellow fever, and we should indeed know less but for the aid given by the Rockefeller Foundation. The incidence of tuberculosis is still unexplored, and there is reason for believing that previous assumptions on the incidence of leprosy are largely incorrect. It is essential again that we should have a more precise knowledge of the effects of tropical and particularly equatorial climates on the physical condition of Europeans. It is equally necessary that we should know whether there are any such fundamental differences in the physical constitution of tropical peoples as will effect the application to them of the European system of curative medicine.

Our work of survey must necessarily include also studies on the social side. One such is that into land tenures, to which I have already referred. Another is the study of the procedure of native marketing, on the improvement of which depends the expansion of the internal economy of the Colonies. A third is the investigation of the extent to which indigenous customary law affords a basis for the formulation of a uniform legal system which will adjust the procedure of European law to the requirements of the more primitive populations.

It is to be hoped that much of this work will become practicable when the special fund for research provided by the Act of 1940 becomes available after the War. The provision which Parliament has thus made for colonial research is in itself significant of the new order of ideas, and I know of no parallel to such a measure in other countries. But survey, though essential to systematic planning, is only part of a scientific approach to colonial development. There still remains the need for research into the wide range of specific problems arising in the field both of the applied and social sciences, which require local investigation either because they are peculiar to colonial conditions or because, though more general in character, they present features which can only be studied within the Colonies themselves.

Here I suggest that there are certain guiding considerations. It is advisable that the facilities afforded by our great imperial institutions of research should be utilized to the fullest extent and that the energies of colonial research workers should be strictly limited to problems requiring local inquiry. One is struck by the limitations imposed on the research worker by isolation alike from the assistance and the criticism of professional colleagues. The well-known study into the alleged mental deficiency of Africans made a few years ago at Nairobi would have taken a very different form if it had been made in the more critical atmosphere of a European intellectual centre. Secondly, we should seek to group colonial research workers into suitable centres and to bring their work under some form of professional direction. At present the staff engaged in research is liable to have its energies diverted to routine work, and when it undertakes longer range inquiries the subject is often dictated by its own choice or pressed on it by the local interests which are in a position to influence its services.

There arises a further problem for which I have some difficulty in suggesting a solution. It is possible to envisage group centres for agricultural, medical or similar research, each under its own professional direction. But how are the efforts of these different departments of inquiry to be co-ordinated? Few of the major problems of the Colonies can be solved by specialists in one branch of inquiry alone. What agency is there which can exercise joint direction over these different interests in research, or at all events decide the relative importance of their application in practice? That is a question to which the lay administrator would certainly welcome an answer.

Let me add one final consideration. I have purposely refrained from instituting comparisons which might suggest that other colonial powers have given either greater or less attention to

scientific planning than we have ourselves. I have therefore made no reference to the extensive study of the economics of production made by the Dutch in their East Indies, or the use made in the French Colonies of their metropolitan research institutions, such as the Pasteur Institute, of the scientific approach made by the Belgians to certain aspects of medical work and to the problems of labour supply, or the unusually extensive programme of scientific inquiries with which Italy inaugurated its regime in Ethiopia. But if any lesson would seem likely to emerge from such a comparison it is this. Admitting a certain difference in policy and ideals, there is a very striking resemblance in our concrete problems. That we should seek for every means of co-operation in solving them is so obvious as to be commonplace. But how far does this co-operation extend at present ? In one sense, of course, all scientific inquiry is co-operative in so far as its published results are the common possession of all men of science. We have again had instances, though not as many as might be expected, of international conferences on scientific subjects which have a bearing on colonial development. But there are not many instances of combined planning for dealing with specific problems in the field of the applied or social sciences. An outstanding instance to the contrary is that of anti-locust research, which has become largely international in character. There are perhaps other instances, but they must be few. Their restricted scope justifies, at all events, the suggestion that a modern world which can combine to control the production of tea or rubber, or tin, or copper, in the interests of an investing public, might well find the means of exhibiting a greater solidarity in dealing with issues vital to the welfare of the colonial peoples.

OBITUARIES

Prof. N. K. Koltzov

ON December 2, 1940, science suffered a severe loss in the death of Nicolai K. Koltzov, the great Russian biologist. Born in Moscow in 1872 and educated at the University of Moscow, Koltzov began research as a comparative anatomist and his first paper was on the development of the amphibian pelvis. Other early work of his was in the direction of the development of the head, especially in cyclostomes.

When Koltzov turned his attention, however, to the structure of spermatozoa, beginning with those of the decapod Crustacea, which are extremely elaborate, he found himself entering a line of work which was to continue throughout his life. From 1905 onwards he was more and more fascinated by the structures in cells which seem to maintain their morphological shape. While others arrived at the conception of fibre-molecules, anisometric polymerized particles, etc., from the study of mammalian muscle fibres, Koltzov approached it from the study of cells such as crustacean spermatozoa and contractile fibres such as the stalks of Vorticella. Already in 1912, long before any X-ray analysis had been applied to fibres of biological origin, Koltzov proposed in *Priroda* that much of the morphology of cells is due to the actual shape of the molecules within them. Even in 1928, when he elaborated these views in a classical paper in the *Biologisches Centralblatt*, he had little more to go upon than the polypeptide chain conceptions of Emil Fischer. The establishment of the anisometric character of myosin particles by optical and viscosimetric methods did not come to confirm him until after 1930. In Russia the view that the shape of cells is determined largely by "solid" protoplasmic "skeletal" elements immersed in more liquid or semi-liquid protoplasm, is known as "Koltzov's Principle", and as time goes on this term may come to be more widely used. In 1928, too, Koltzov suggested that the chromosome might perhaps be regarded as a protein giant-molecule, of which genes might be side-chains ; a conception which has since been found stimulating and fruitful.

Koltzov's papers, not very numerous, but all on fundamental problems, were collected into a book "Organisatsia Kletke" ("The Organization of the Cell" ; Moscow, 1936) but he also published two excellent monographs, "Physiologie du Développement et Génétique" (Paris, 1935) and "Les Molécules Héréditaires" (Paris, 1939). Besides his researches, he founded in 1917 in Moscow the first Institute of Experimental Biology in Russia, of which for the rest of his life he was the loved and respected leader. He also founded and edited, until his death, the *Biologicheskij Zhurnal*, known to many British biologists. Among his students and colleagues were names so well known internationally as Zavadovsky, Serebrovsky, Efimov, Astaurov, Dubinin, Epstein, Filatov, Lopaschov and Manuilova.

I had the great pleasure of visiting Prof. Koltzov and his wife (also a research worker) in their laboratory and institute in 1935, and of appreciating the admirable atmosphere of collaborative work which reigned there among all its members. On November 27, 1940, Koltzov was interrupted in his work by a sudden heart attack. He was preparing a lecture which he would have delivered at the February, 1941, meeting of the Moscow Society of Naturalists. Its title was "Morphology and Chemistry". It was typical of him, this choice of a fundamental subject,

and it summarized the aim to which his whole life had been devoted. Had it not been for the fact that he remained primarily a biologist to the end, thus lessening somewhat the parallelism between their lives, we might well have come to think of him as the Russian W. B. Hardy. JOSEPH NEEDHAM.

Mr. I. O. Griffith

By the sudden death of Mr. I. O. Griffith on September 22, the day before his sixty-first birthday, the University of Oxford, and especially the science faculties, have lost more than can be easily measured. As member of the Hebdomadal Council, vice-chairman of the General Board, chairman of the Board of Faculty, treasurer of the Natural Science Club, he held a key position in the scientific administration in the University. Whatever the branch of science and however remote from his own special loves, mathematics and physics, he could always be counted upon to make every effort to help to bring a project to fruition. He will be indeed difficult to replace in the councils of the University.

After his distinguished flying work, mainly on the navigational side, in the R.A.F., during 1914–18, which earned him the Air Force Cross, he returned to Oxford as senior demonstrator in the Clarendon Laboratory. Always keenly interested in teaching he was mainly responsible for building up the advanced course and organizing the expansion of the Department which trebled or quadrupled its activities during his period of office. His work on the measurement of temperature in the high-pressure arc led on to the well-known monograph on photographic photometry published by himself and Dr. Dobson. But his conscientious devotion to his students' interest left him scant time for research, and it is in their activities and records that his main contributions to physics will be discerned.

The departure of many of his younger colleagues since the outbreak of war left him with more teaching than ever to do. Always ready to help, he had one task after another thrust upon him. True to his old service, he accepted the important and onerous duty of looking after the Air Force cadets in the University and organizing their teaching. No better choice could have been made, and the immediate success of the scheme is evidence of his tireless work and administrative ability.

It is impossible to describe Griffith's peculiar personal charm in words. Invariably cheerful and friendly, he could be relied on to face an acrimonious debate on the Board of Faculty or a critical situation in a crucial golf match with equal adequacy. Free from any thought of self, he devoted all his efforts to the advantage of his pupils and his colleagues. A keen member of his College, he never allowed parochial patriotism to over-ride his devotion to the interests of the University. His balanced judgment confuted those who delight to paint the average don as a creature of moods and foibles with an outlook bounded by curricula and examinations. Void of the glitter and clash of more metallic personalities he did great work for his University and his country which will bear fruit long after the more strident voices, which so easily gain popular acclaim, have died away.

Prof. R. B. Wild

It is with regret that we record the death on October 7 of Prof. R. B. Wild, emeritus professor of materia medica and therapeutics in the University of Manchester.

Educated at Owens College, Prof. Wild was associated with Manchester throughout his active career. After serving for a time as an assistant lecturer in the Department of Pathology he transferred his affection to the subjects of pharmacology and therapeutics and joined the staff of the late Prof. D. J. Leech. The two men developed an active Department in which important work in experimental pharmacology was done, the most significant being a study of the effects of the nitrites upon the circulatory system. One of the results of their researches was the recognition of amyl nitrite as an official preparation.

On the death of Leech in 1900, Wild was elected to the chair and in 1919 became the first whole-time Leech professor of materia medica and therapeutics. When in consulting practice, Wild was recognized as an authority on dermatology and he wrote a number of papers on diseases of the skin. For many years he was intimately associated with the Christie Cancer Pavilion and Home; he was responsible for the medical side of the work and played a leading part in the administration of the institution. Throughout his teaching career he was untiring in his efforts to develop and improve the Faculty of Medicine and his contributions to medical education were of the greatest value. For a time he was dean of the Medical School and the representative of the University on the General Medical Council. As a member of Senate he took a prominent part in general University affairs and acted for a period as one of the pro-vice-chancellors. He retired in 1927, when he ceased to live in Manchester, but still kept in touch with the University and city which he served so conscientiously and well. J. S. B. STOPFORD.

We regret to announce the following deaths:

Mr. W. A. Bailey, chief conservator of forests, Indian Forest Service, on July 14.

Mr. Norman de Garis Davies, the well-known Egyptologist, on November 5, aged seventy-six.

Dr. Walter Granger, curator of fossil mammals in the American Museum of Natural History, on September 6, aged sixty-eight.

Prof. C. M. Sparrow, professor of physics in the University of Virginia, on August 30, aged sixty-one.

Prof. T. H. Taliaferro, professor of mathematics in the University of Maryland, on September 25, aged seventy.

NEWS AND VIEWS

Science Clubs of America

A NATIONAL science activity, Science Clubs of America, is being sponsored by Science Service, the American science news service. In every locality throughout the country there will be groups active in various fields of science. Science clubs in high schools will be encouraged and given the opportunity of joining in the national movement and entering into national activities. Groups of enthusiastic amateurs in science—grinding telescope mirrors, collecting insects, breeding new plants, collecting minerals, or pursuing scores of other interesting avocations—will join in this important development. As the nucleus of Science Clubs of America, there are more than eight hundred junior clubs which have been organized during the past fourteen years by the American Institute of the City of New York. These clubs exist not only in the United States but also in Puerto Rico, Hawaii, the Philippines, British West Indies, Alaska, Canada, and even Portugal. An advisory committee on Science Clubs of America, representing jointly the American Institute and Science Service, is being formed.

Excavations in Alaska

Dr. H. L. Shapiro and Dr. F. G. Rainey, of the American Museum of Natural History, have been excavating five hundred arctic tombs at Point Hope, Alaska. The five hundred skeletons are said to form one of the largest collections of the sort ever found at a site in America. The two anthropologists sought remains of an ancient and unknown people, whom Dr. Rainey first discovered in expeditions of 1939 and 1940. Also they sought later Eskimo burials which would aid in showing what relationship the lost ancients had to the later Eskimos. The mysterious unknown people had a remarkably big town with well-planned streets, more than a hundred miles north of the Arctic Circle; and about two thousand years ago they abandoned this settlement. They are looked upon as a lost race, because their ivory arts are unlike those of known Alaskan Eskimos, ancient or modern. Also, it is explained, they lacked many typical Eskimo implements, and were more dependent on land than on the sea for their resources.

Dr. Shapiro plans to examine the physical traits of the forgotten northerners, to place them more definitely in the story of prehistoric America. The Ipiutaks, as they are now called from the Eskimo name of a spit of land near their old home, may have come from as far away in Asia as north China, according to one suggestion. A new glimpse into curious burial customs of the Ipiutaks is revealed by a carved ivory mask with staring inset ivory eyes, which was found covering the body of a little child. The child lay resting on the knees of a man, and a woman also accompanies it. Masks with ivory eyes have been found before in the graves of these mystery people, but what their significance was for a future life remains one of the unsolved puzzles of the arctic.

Koalas in Australia

A CENSUS of koalas on Phillip Island, Victoria, was taken this year with the aid of school-children, and, we are informed by Sir James Barrett, the count shows a record population of 590, a natural increase of thirty-nine over the number shown after the census of July 1939. Many *Eucalyptus viminalis* and red gum, on which the animals feed, are being planted. The koalas are now confined to the eastern fringe of the Australian mainland, from southern Queensland to Victoria. They used to be present in South Australia, but, apart from some imported from Victoria and maintained in sanctuaries, it is doubtful if there are any there now. According to *Wild Life*, the Australian nature magazine, the combined Victorian population is somewhere between 900 and 1,100 individuals. This compares very unfavourably with the number of koala pelts marketed during 1920 and 1921, namely, 205,679.

The koala fur is remarkably warm and is practically indestructible, a jacket made of it often being passed down from father to son for several generations. This, no doubt, accounts for the dwindling of the koala. Other factors have been deforestation, disease, and, above all, bush fires. The last-named is the prevalent danger. Steps are being taken to combat this, expecially on Phillip Island, where efforts are also being made to supply an abundance of natural food and shelter in open sanctuary conditions. Two large areas have been set aside for the purpose, one of 256 acres and the other of 160 acres. Money is still required for this conservation. It is estimated that a preliminary grant in Victoria of £500 a year would enable the work to be carried on satisfactorily; and it is to be hoped that such a comparatively small sum will soon be assured, preferably from the various Australian Governments, or from the natural history societies or private individuals.

Trees and their Care

IN the July–September issue of *Trees*, the journal of the Men of the Trees, it is stated that the money already received in connexion with the Million Shilling Fund has enabled about 90,000 trees, hardwoods and softwoods, to be planted in Great Britain. Exception appears to have been taken to the fact that some of these trees have been presented to landowners who have already been paid for timber supplied for war purposes. It is said in defence that since these people have trained foresters and planters, the trees will be better looked after; but surely the man who can afford to maintain a trained forester can afford the mere price of the plants necessary to replant felled areas. It is difficult to

see any justification in supplying him from a fund of small subscriptions given, presumably, by a tree-loving public.

In a brief note elsewhere "To Intending Planters", by H. E. Seaton, the sound advice is given, in deciding upon planting schemes, to remember that "pure woods of alien trees are not modern practice; but that mixed woods of trees which do well locally are likely to succeed and are fairly fool-proof". How often has this been forgotten, even by those professing forestry knowledge. "Tree Shelter for Cattle", by S. F. B. Lane, is a much-needed reminder to farmers of the dangers being introduced in many parts of Britain by the indiscriminate tree felling which is taking place. Not only cattle, but also crops will suffer from the resultant exposure. An interesting article by H. E. Seaton on "Sewage and Civilization" (reprinted from the Rotary Service, Nov. 1940) sums up research work carried out by, among others, Dr. McCarrison and Sir Albert Howard in connexion with obtaining the present food for man and beast by a future suitable treatment of soils.

The British Empire Naturalists' Association

THE twentieth issue of the quarterly bulletin of the British Empire Naturalists' Association contains its usual summary of current field records and also the interesting announcement of the revival in octavo form, as in the War of 1914–18, of its well-known journal *Country-Side*, which had to be suspended at the outbreak of war. This decision is made possible with the very considerable—perhaps unexpected—interest in field natural history that has been maintained in Great Britain despite the War, and often in the most heavily raided centres like London and Merseyside. The first issue of the new abbreviated form of this journal is expected in December.

Among botanical records in the autumn issue of the bulletin are creeping bellflower (*C. ranunculoides*) and willow-leaved spiræa (*S. salicifolia*) in the Cotswolds, thorn-apple (Datura) spreading over bomb craters in Kent and greater spearwort at Chippenham, Wiltshire. Entomological records show a very wide distribution of the clouded yellow butterfly during its immigration from the Continent this summer, records extending into Scotland. The pale clouded yellow is recorded from Cheshire, several white admirals from the Borough Green area of Kent and the Ruislip area of Middlesex, high brown fritillaries from the west Lancashire dunes, and the marbled white at Chippenham, Wiltshire. Ornithological reports include the black-necked grebe, white wagtail and shoveler nesting in Cheshire, and little gull, spotted redshank, greenshank, and sandwich tern on migration; grasshopper warbler nesting in Lancashire, and the little gull and red-necked phalarope on migration.

Future of Telecommunications

IN an address before the London Students' Section of the Institution of Electrical Engineers on October 15, Dr. W. G. Radley, of the Post Office Research Station at Dollis Hill, spoke on Telecommunications of the future. He pointed out that in 1914, although wire telephony had been in use for about forty years and had become an important factor in the social and business life of urban communities, the loss in speech power during transmission imposed definite limits to long-distance conversations. These limits disappeared as a result of the general introduction of thermionic valve amplifiers. Later on, the long-distance circuits which became possible were made cheaper by the development of systems of carrier-current telephony, culminating in a standard system providing twelve speech channels over one pair of wires. A novel form of co-axial cable followed. This was capable of transmitting television or providing several hundred speech channels over two conductors. In the meantime, the transmission of speech by radio had made world-wide telephony possible. Each of these developments was the result of a long period of experimental work.

From the position of research work in 1939, it is possible to hazard a guess at the nature of the telephone system during the post-war period. The disappearance of metallic conductors, and the development of long-distance speech transmission by means of what is virtually guided radio waves, is a future possibility. Research into the nature of speech sounds has made it possible recently to construct a machine which will speak under the control of an operator at a keyboard. An extension of this idea suggests the possibility of analysing speech in a local circuit, transmitting signals over the long-distance line corresponding to the results of the analysis and at the distant end automatically reconstructing the speech. The frequency band necessary for transmission of the signals over the long-distance line is very much narrower than that necessary for ordinary telephony, and this would enable more circuits to be obtained from long expensive submarine telephone cables. Improvements during the post-war period would probably lead eventually to the disappearance of telephone operators, except for special services. Improved fidelity of response of microphones and telephone receivers was foreshadowed, but no immediate change in principle.

The Royal Observatory, Cape of Good Hope

THE report for 1940 of H.M. Astronomer at the Cape of Good Hope illustrates how astronomical work in the belligerent countries is being affected even though they may be far removed from the present scene of hostilities. Half the observing staff at the Cape is now engaged on non-astronomical duties, this at a time when so many observatories in Europe have perforce suspended work. Nevertheless the depleted staff is doing its best to secure such observations as cannot be replaced by any made at a later date. Meridian observations of the moon have been started in view of the possible loss of European observations, and volunteers have come to the rescue in observing occultations. Photographic work has been somewhat precarious owing to delays in the delivery of plates, but few photographs have been lost, and the position has been eased by a modification of the programme of routine

solar observations which supplements that still being carried on at Greenwich. Work on the Reversible Transit Circle continues on a somewhat reduced scale, and the photometric observations are now sufficiently far advanced to make possible the construction of a framework of stars of magnitudes between 7 and 10 to which the magnitudes of the zone stars can be referred. With the 1940 batch of parallaxes the Observatory now enters the very restricted list of stations at which the distances of more than a thousand stars have been determined trigonometrically.

The section of the report which will be read with perhaps the greatest interest concerns the total solar eclipse of October 1, 1940. The main part of the programme was to measure the gravitational deflexion of light in the sun's field—the Einstein effect. The Greenwich expedition which was to have co-operated in this work was cancelled at the outbreak of war, and the entire programme was carried through, as planned, by the Cape staff. It is disappointing to have to record total failure in this part of the work. The field of stars close to the eclipsed sun was known beforehand to be a poor one; but eclipses are so few and far between that the attempt seemed justified. In fact, the lessened exposure time and reduced aperture necessary to prevent fogging of the plates by the rather bright sky, combined with the poor daytime 'seeing' on the Karroo to prevent any stars showing on the negatives at all. Astronomers all over the world will sympathize with H.M. Astronomer and his staff in this disappointment, particularly as observing conditions were otherwise good. Their sole compensation was in securing the only large-scale photographs of the corona obtained during this eclipse—photographs which, though interesting and indeed important, represent a most inadequate reward for months of work.

Prevention of Blindness

IN its annual report for 1940 the United States National Society for the Prevention of Blindness stresses the increase in eye accidents brought about by extension of industrial production made necessary by national defence. Many firms are now using the industrial film known as "The Eyes Have It", which has been made available to the Society without cost by the Pullman Society. The Society is now planning an evaluation of vision-testing procedure used with school children and pre-school children in the hope of establishing a uniform procedure. During 1940 the National League for Nursing Education began a study of nursing education in sight conservation in co-operation with the Society. The Society has also arranged to co-operate with similar organizations in Latin America, has prepared an exhibition on glaucoma, and has continued its campaign to reduce blindness caused by venereal disease and fireworks.

Earthquake in the Argentine

THE United States Coast and Geodetic Survey, in co-operation with Science Service and the Jesuit Seismological Association, has determined the provisional epicentre of the earthquake of July 3 at 7h. 11·7m. U.T. as being at lat. 33° S., long. 68° W. The calculations have been based on reports from eleven seismograph stations. The epicentre is situated near the railway line about midway between Mendoza and San Luis. Activity in this region has been much less severe and more infrequent than between 1750 and 1910. There was a strong earthquake at Mendoza on May 22, 1782, though this was surpassed by the terrific shock in the same area which caused widespread destruction on March 20, 1861. Prior to this latter shock, San Luis was destroyed on April 9, 1849. Further intense shocks were experienced in both places up to about 1910. It may be that, following the catastrophic shock of January 24, 1939, at Chillan in Chile (NATURE, Feb. 11, 1939, p. 230), the centre of activity has moved eastwards. The earthquake of July 11, 1941, at 1h. 16·6m. U.T. had its epicentre in the Pacific Ocean between the Galapagos Islands and the Isthmus of Panama.

University of Cambridge

UNDER the will of Mr. Alfred Corner, of Staverton Road, Brondesbury Park, London, who died in 1934, the University has received £1,440 for the sole purposes of the Cambridge University Biochemical Laboratory. The full value of the bequest of which this is an instalment may approach £1,800.

The professorship of animal pathology will be vacated on December 31 by the resignation of Prof. T. Dalling.

Announcements

SIR HENRY DALE, president of the Royal Society, has been awarded the Gold Medal for 1941 of the Royal Society of Medicine. The Medal is given triennially for "valuable contributions to the science and art of medicine".

THE RIGHT HON. LORD CHATFIELD, recently Minister for the Co-ordination of Defence, has been elected president of the Institution of Naval Architects in succession to the late Lord Stonehaven.

MR. R. A. WATSON WATT, scientific adviser on telecommunications to the Air Ministry, has been elected president of the Association of Scientific Workers in succession to Prof. F. G. Donnan.

IN connexion with the fiftieth anniversary of the University of Chicago which was celebrated a short time ago, the sum of 9,200,000 dollars has already been subscribed by the citizens of Chicago towards an anniversary fund of 12,000,000 dollars. It is planned to raise the balance over a period of five years.

DR. P. C. Koller and C. Auerbach, of the Institute of Animal Genetics, University of Edinburgh, writing with reference to their letter "Chromosome Breakage and Sterility in the Mouse" which appeared in NATURE of October 25, p. 501, wish to withdraw the last two sentences in the first paragraph of column 2 beginning with "We can confirm . . ."

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

Non-precipitating Protein Antigens

WHEN some protein antigens are heated with serologically unspecific proteins they cease to be precipitated by their antisera, and their behaviour *in vitro* approximates to that of non-precipitating haptens[1]. Evidence from different sources suggests that this change in behaviour is brought about by the antigens combining with the other protein during the early stages of heat denaturation to form complexes, which after combination with antibodies still remain soluble.

We have now studied such complexes *in vivo* and find that they differ from haptens in being active as producers of antibodies. The antigens we used were tomato bushy stunt virus and whole globulin from human serum. These were turned into non-precipitating complexes by heating them in the presence of rabbit serum albumin in physiological saline at pH 7·0. 0·1 per cent solutions of bushy stunt virus were heated for 10 minutes at 83° C. in the presence of 0·5 per cent rabbit albumin, and 0·1 per cent solutions of human globulin were heated for 5 minutes at 100° C. in the presence of 0·2 per cent rabbit albumin. None of the sera produced by injecting rabbits with solutions of these complexes precipitated the materials used for immunization. The serum produced against the virus-albumin complex, however, precipitated solutions of both unheated virus and virus heated in the absence of rabbit albumin; indeed, no differences have been detected between this serum and those produced by injecting rabbits with virus only. The serum produced against the globulin-albumin complex precipitated solutions of the globulin heated in the absence of the albumin. In other words, although the immunizing systems were active in producing precipitating antibodies, these could be demonstrated only when one component of the system free from the other was used as a test antigen.

It is possible that these complexes are split in the rabbit before acting immunologically, so that the antigenic component is liberated and acts alone in the production of antibodies. Whether this is so or not, it should be realized that failure to obtain a positive precipitin test between an antiserum and the material used for its preparation cannot be regarded as proof that no precipitating antibodies have been formed, for complexes behaving like those we have produced by heating may occur naturally.

Complement fixation provides a suitable test for the antigenicity of such non-precipitating complexes. With antisera prepared against either the virus or against the virus-albumin complex, solutions of the virus-albumin complex fix complement as strongly as solutions of the virus alone. Similarly, the globulin-albumin complex fixes complement with antisera to the unheated globulin and with those prepared against the complex itself. This fixation of complement equally by an antiserum with antigens with which precipitation does and does not occur is evidence for the independence of the two reactions, and strongly supports the view that complement is fixed by the union of antigen and antibody and not by the formation of a precipitate.

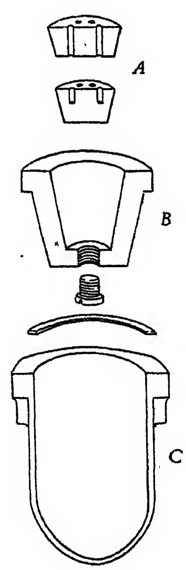
A New Capillary Cell for Measuring the Rate of Sedimentation of Virus Particles in a Centrifugal Field

ELFORD[1] has developed a method of particle size determination by centrifuging solutions in inverted capillaries. The sedimentation within the capillaries fulfils Stokes's law, that is, there is a uniform movement of the particles until the boundary approaches the lower open end of the capillary. At this point the boundary comes in contact with disturbing effects such as vibrations and heat convection currents in the outer fluid. These effects tend to reduce the true rate of sedimentation.

In order to eliminate these disturbing effects on the sedimentation in the capillaries I have constructed a new type of capillary cell as illustrated in the accompanying figure.



× ½

A is a cone made of M.V.C. alloy in which a series of capillaries are drilled in such a way that those of the upper section coincide accurately with those of the lower section, into which they extend a few millimetres. The two sections of the cone fit in a conical cup B made of the same metal. The cup is provided with a screw at the bottom which enables the cone to be forced out without disturbance after centrifugation. Four vertical grooves are cut into the inner surface of the cups. The cup, together with the conical cell, is supported by means of a rubber washer on the rim of the centrifuge cup.

The method of using this cell is as follows:

The surface between the two sections of the cone is smeared with a thin layer of a paste made of a mixture of beeswax and wool grease, and the two sections pushed together. Care should be taken to ensure that the capillaries of the two sections coincide accurately. Some of the fluid to be centrifuged is then placed in the cup, and the cone with

the capillaries carefully dropped in to replace this fluid. The thin layer of fluid between the conical cup and the cone and in the grooves counteracts the hydrostatic pressure inside the capillaries. This effect eliminates the movement of the fluid during centrifugation. At this stage the capillaries are filled with the help of a fine pipette with the solution to be centrifuged, and the open ends are sealed off with molten paraffin wax.

After centrifugation for the required length of time the cone in the metal cup is removed by pressing it out from below by means of a metal rod. The capillaries in the top section are then cut off from those in the lower section by turning the two sections in opposite directions. This enables the fluid in the capillaries to be removed by means of a fine pipette and analysed.

Test runs with horse sickness virus (diameter 46 mμ. Polson, in press) have shown that the titre can be reduced from 10,000 m.i.d. to almost zero in the required length of time. The remaining trace of virus is probably left behind through adsorption on the sides of the capillaries, or due to the capillaries not being sector shaped. However, when virus solutions low in titre, that is, 100 m.i.d., were centrifuged, the titres were reduced to zero, which proves that the disturbing effects occurring in Elford's inverted capillary method were eliminated.

This method of centrifugation has also been applied to a study of blue tongue virus. The size determined for the virus of blue tongue, 87–105*m*μ, compared well with that determined by ultrafiltration through Elford's gradacol membranes, namely, 100–132*m*μ.

Rapid Determination of Water in Animals and Plants

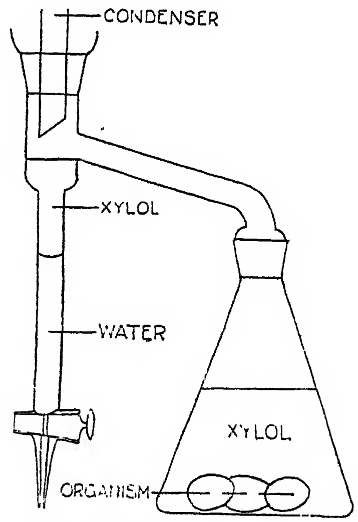
THE quickest and also the most accurate method of determining the percentage of water in animals or plants or tissues in general is a simple modification of the recognized method of determining the percentage of water in oils by means of a Dean and Stark's tube.

The animal or plant is placed in the distilling flask and covered with several times its own volume of xylol and heated over an electric heater. The xylol boils at about 135° C. and hence steam and xylol vapour distil off and are condensed. The water and xylol fall into the graduated tube and since the water is heavier than the xylol and is not miscible with it, it sinks to the bottom of the tube and for ordinary purposes its volume can be read off directly.

The same thing can be accomplished with an ordinary Soxhlet extractor provided with an outlet tap, and thus much larger quantities of water can be dealt with. The siphon tube is blocked with a little mercury. Steam and xylol are driven off as before and the water collects under the xylol.

After distillation, and when the apparatus is cold, the mercury, water and xylol are run off through the tap into a suitable graduated cylinder and the volume of water read as so many grams, but for really accurate work the height of the water is read and then the water and xylol are thrown away but the mercury is dried and returned to the same cylinder after it is clean and dry. A little xylol is added and distilled water is run in from a standard burette to the proper graduation mark. Then the same volume of distilled water is run in from the same burette into a flask and weighed. Distillation is complete when clear xylol settles in the extractor, for so long as water is coming off the xylol is cloudy.

The percentage error, which should certainly be below 0·5, is easily ascertained by distilling a known weight of distilled water under xylol and ascertaining the weight of water recovered. Paraffin cannot be substituted for xylol as its boiling point steadily rises. The percentage of distilled water in the Plymouth sea-water has been determined in this way and found to be 96·8 per cent (actually 96·796 per cent).



The great advantage of this method is its quickness and accuracy. Recently I determined the percentage of water in an ordinary hen's egg by this method and found it to be 65·4 per cent, which agrees closely with the figure given by Lebbin (65·16 per cent)[1]. The distillation took just an hour.

The alternative method of driving off the water in an oven has many disadvantages. If the material is not heated up to 110° C. all the water will not be driven off, while if it is, a good deal besides water will be driven off.

In the distillation method volatile products other than water are absorbed by the xylol; thus no difference is made to the result and so one can heat up to 135° C. without danger of decomposing the tissues. Cane sugar is charred at this temperature with prolonged distillation, but so far as I have been able to ascertain nothing else is affected. The method has been used at Plymouth for the last two years for determining the percentage of water in marine animals after they have been weighed by the displacement method[2].

Glass-ground jointing is essential and the complete apparatus with interchangeable parts is supplied by W. and J. George, Ltd., Birmingham. Fish livers are investigated as follows. They are weighed and

placed in a Soxhlet extraction thimble. This is placed in the distillation flask and the water estimated. Then the thimble with the residue is transferred to a clean extractor and the xylol removed by extraction with acetone. The remaining extract is dried and weighed and ashed if necessary. Thus at practically one distillation one can get the water, non-soluble residue, and the fat by difference. The percentage of water in mice has been found by this method. Of course it varies slightly but is always very close to 64 per cent.

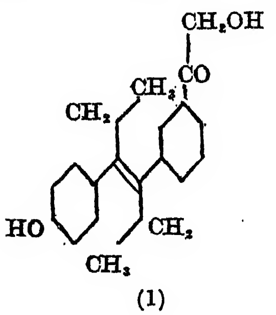
Synthetic Compounds Possessing Biological Activity Similar to that of Deoxycorticosterone

IN 1938, Dodds, Goldberg, Lawson, and Robinson[1] compared the carbon skeleton of 4 : 4′-dihydroxy-α : β-diethylstilbene (stilbœstrol) with those of œstrone and chrysene. The similarities in molecular architecture may be significant. If this be so, the possibility arises that the α : β-diethylstilbene molecule might have a similar significance in the realm of synthetic, as the condensed ring system has in the natural, sex hormones.

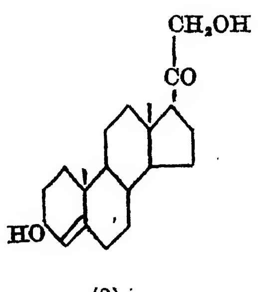
Three years ago it was decided to test the validity of this contention by applying it to the production of substances which might exhibit a similar action to deoxycorticosterone. It was first necessary to establish the importance of the -$CO.CH_2OH$ radical, and hence a series of substances possessing the general formula $R.CO.CH_2OH$ was prepared[2]. When R was aliphatic (CH_3 to C_6H_{13}), the compounds yielded osazones with 2 : 4-dinitrophenylhydrazine, but when R was cyclic (phenyl, *p*-hydroxyphenyl, cyclohexyl), hydrazones alone were formed. All the compounds reduced ammoniacal silver nitrate solution and Fehling's solution in the cold. Preliminary trials showed that of all the compounds prepared, benzoyl carbinol alone showed the desired biological activity.

The activity of this simple molecule stimulated endeavours to obtain a stilbene derivative (1) which showed a similar relationship to deoxycorticosterone (2) as stilbœstrol does to œstradiol.

Compound (1) has been obtained in the following way: *m*-nitrophenylacetyl chloride was condensed



(1)



(2)

with anisol to yield 3-nitro-4′-methoxydeoxybenzoin, which was converted into the 3-carboxy derivative *via* the amine and cyanide. Ethylation of this acid, followed by treatment of the product with ethyl magnesium iodide, gave a product that lost water on warming with iodine, yielding 3-carboxy-4′-methoxy-α : β-diethylstilbene. This compound was demethylated and the acid chloride of the acetate was converted into (1) by treatment with diazomethane followed by hydrolysis.

3′(Hydroxyaceto) 4 - hydroxy - α : β - diethylstilbene was obtained as a white solid melting at 65-67° C. It possessed chemical properties similar to the other examples of $R.CO.CH_2OH$. We are indebted to Prof. J. H. Gaddum (vice Dr. K. Coward) for the biological tests of these substances. The substances were examined for their ability to increase the survival time of young adrenalectomized rats. Comparison was made with the effect of deoxycorticosterone acetate and also with a group of negative control rats which received a daily injection of the diluent, arachis oil. Of the compounds examined, only benzoyl carbinol and 3′-hydroxyaceto-4-hydroxy-α : β-diethylstilbene showed activity, the former possessing 1/2500 and the latter something less than 1/200 of that of deoxycorticosterone. The figure obtained for benzoyl carbinol was obtained on more than one occasion, but that for the stilbene derivative is less definite. We believe that this is the first instance of purely synthetic substances showing activity similar to deoxycorticosterone. It is interesting to note that *p*-hydroxybenzoyl carbinol and cyclohexyl carbinol were inactive.

The possession of 3′-carboxy-4-hydroxy-α : β-diethylstilbene, a necessary intermediate in this work, afforded the opportunity of preparing 3′-aceto-4-hydroxy-α : β-diethylstilbene—a substance which may be regarded as the diethylstilbene analogue of progesterone. This substance has been obtained, but the reports on its examination for progesterone-like activity are not yet to hand.

An Iron-Copper-Nucleoprotein Complex in Animal Tissue

IN the course of investigations on the availability of iron in fish and other animal tissues, it appears that a more correct figure for the nutritionally available iron would be obtained if the tissue is treated with 10 per cent acetic acid or digested with pepsin before the material is assayed by Hill's dipyridyl method. Further work has shown that 30–40 per cent of the total non-hæmin iron of several animal tissues consists of an iron-copper-nucleoprotein complex, which has been obtained in a fairly pure state. The copper seems to be loosely combined; it

is easily split off by trichloroacetic acid and also by alkali. The iron is also split off by alkali. Controlled experiments with anæmic rats on hæmoglobin-building indicate that this complex (or rather its breakdown products, after absorption) may be a precursor for the formation of hæmoglobin. Previous elimination of copper from this complex has been found to diminish its hæmopoietic power. Quantities of iron and copper corresponding to a given quantity of the complex, when fed to animals, have considerably less potency regarding hæmoglobin formation than the original complex, which would indicate the importance of the organic moiety for hæmoglobin building.

Further work is in progress and the results are being published in the *Annals of Biochemistry and Experimental Medicine*.

Decreased Ovarian Response to Chorionic Gonadotropin following Hysterectomy in the Mouse

MANY attempts have been made to demonstrate a possible endocrine influence of the uterus upon the ovaries of animals. The most recent report dealing with this subject[1] describes degenerative changes in the ovaries of hysterectomized rabbits. An extract of rabbit endometrium appeared to retard the process of ovarian atrophy in another group of hysterectomized rabbits. The authors suggest that a protective influence upon the ovary is exerted by the uterus. Some clinical reports support the observation that conservation of some endometrium at the time of hysterectomy in the human lessens the severity of the menopausal syndrome following such an operation[2]. Other investigators leave the subject an open question.

That ovarian activity may be influenced by the uterus is suggested by the results of the following experiment in mice. Six 21-day-old female albino mice (litter mates) were hysterectomized through a small supra-pubic incision. Both cervices were carefully removed. No intra-abdominal clamping or tying was done save for a single black silk ligature placed about the top of the vaginal stump. The incision was closed with a single skin clip. Four female mice from another litter of the same age were used as controls. At 22 days of age each mouse was injected subcutaneously with 0·5 c.c. (5 I.U.) of an aqueous solution of chorionic gonadotropin. The solution was prepared from the international standard preparation of this hormone, to contain 1·0 mgm. per c.c.

The animals were sacrificed 96 hours after injection. Vaginal introitus had been established in all the controls and all but one of the hysterectomized animals. Œstrous and metœstrous smears were present in the controls and mucus and leukocytes only were seen in the smears from the hysterectomized mice the vaginæ of which were open. The ovaries from three of the four control animals contained corpora lutea while those from the hysterectomized animals contained none.

The experiment was repeated using ten more mice (five controls and five hysterectomized) of the same age. The amount of chorionic gonadotropin was doubled, that is, each mouse received 0·5 c.c. of an aqueous solution containing 2 mgm. of the standard hormone per c.c., or 10 I.U. The animals were sacrificed 96 hours after injection. Again, vaginal introitus had been established in all the controls and all but one of the hysterectomized mice. The controls exhibited œstrous and diœstrous vaginal smears and marked uterine growth and circulatory congestion. The vaginal smear from one of the hysterectomized animals was œstrous but the others contained leukocytes. Corpora lutea were present in all the ovaries of the controls but none was found in the ovaries of the hysterectomized animals. The ovaries of the hysterectomized mouse exhibiting full œstrus were enclosed in hæmorrhagic capsules. The ovarian tissue itself, however, appeared quite normal and contained no corpora lutea upon histological examination. With this exception none of the ovaries of the hysterectomized mice in either group showed any evidence of surgical trauma or degeneration.

The mouse unit of chorionic gonadotropin in this laboratory has been found to be approximately equivalent to 4 I.U. The experiment described above was carried out according to the bio-assay procedure by which our mouse unit of chorionic gonadotropin was ascertained: namely, a single subcutaneous injection of 0·5 c.c. of aqueous solution. The results of the experiment suggest that the absence of the uterus decreases the gonadotropic effect of threshold doses of chorionic gonadotropin on the ovaries of 20-day-old mice.

This study was made possible by the Christine Breon Fund for Medical Research.

Evolution of the Fleece of the Sheep

RECENT comparative studies of fibre-type arrays, mostly in the New Zealand Romney, have thrown new light on the probable course of evolution in the coat of the sheep from wild type to the most 'improved' domesticated fleece. Fibre type arrays[1] are distinguished essentially by differences attributed to the lesser or greater power of the pre-natal check. The effect of this check stands out most clearly when, as in Ravine and Valley arrays, among fibres beginning their development before birth, it causes some starting to grow earlier to be finer than some starting to grow later. Fibre-type array is strongly inherited[2] and this fact gives confidence in the soundness of this new approach to the evolution of the fleece.

Although I am now finding great interest in a study of the coat of wild lambs, the present communication deals with more advanced stages in the evolution of the fleece. The course of evolution has run, I am satisfied, from Plateau, through Saddle and Ravine, to Valley and Plain. Within a given fibre-type array there are mostly quantitative differences which make it possible to arrange arrays in a

graded series according to their 'toughness', and between the several arrays, which differ from one another qualitatively rather than quantitatively, there are links.

The series of arrays named reveal the increasing power of the pre-natal check of Dry, which is responsible for the fineness of fine sickle-fibres and checked curly-tip fibres. This check it seems convenient to call the 'head check' to distinguish it from a check occurring a little later, recognized by Dr. Nancy Galpin[3], which may be called the 'tail check'. 'Tail' has reference, of course, not to the caudal appendage of the animal, but to fibres starting to grow comparatively late. These fibres are well removed in position in the array from pre-curly-tip fibres, and so constitute the tail of the array.

Fibre types are classified in three groups, namely, pre-curly-tip, curly-tip and post-curly-tip. The first comprises halo-hairs, super-sickle-fibres and sickle-fibres; the second hairy-tip-curly-tip fibres and ordinary curly-tip fibres; the last histerotrichs. The first two groups constitute the birth-coat; the first fibres of the third pierce the skin about the time of birth. From the evidence in hand it is concluded that halo-hairs in the pre-curly-tip group, hairy-tip-curly-tip fibres in the curly-tip group, and histerotrichs in the post-curly-tip group are phylogenetically the oldest fibre types. In the course of evolution halo-hairs have undergone a series of changes, becoming transformed step by step to super-sickle-fibres[2] of, successively, the three types, A, A^1 and B, to chalky sickle-fibres, and eventually to fine sickle-fibres. The table serves to illustrate what has happened. Apart from an exceptional situation, to be mentioned later, the percentage of pre-curly-tip fibres (computed on total fibres in an array) is similar in all arrays.

RELATIVE ABUNDANCE OF THE SEVERAL FIBRE-TYPES IN DIFFERENT ARRAYS.

(Based on six regions of seventeen lambs. Means expressed as percentage of total pre-curly-tip group. The last two columns computed on total sickle-fibres.)

Array	Halo-hairs %	Super-sickle a %	Super-sickle a¹ %	Super-sickle b %	Sickles %	Sickles: Chalky %	Sickles: Fine %
Plateau	31·7	41·5	11·1	15·0	0·7	100·0	0·0
Saddle	0·2	4·0	8·3	26·5	61·0	100·0	0·0
Ravine	0·9	1·9	4·0	14·4	78·8	57·9	42·1
Valley	0·2	0·5	1·2	13·0	85·1	10·6	89·7
Plain	0·0	0·0	0·0	0·0	100·0	0·0	100·0

As evolution has proceeded the centre of gravity in the pre-curly-tip group has been shifted from halo-hairs and super-sickle A in Plateau to fine sickle-fibres in Plain. Hairy-tip-curly-tip fibres are abundant in Plateau, rare in other arrays, and I would elevate them to a position of high ancestral importance. Indeed, in the curly-tip group of non-Plateau I conclude that four-fifths of the curly-tip fibres have evolved from hairy-tip-curly-tip fibres.

In the evolution of histerotrichs I would emphasize what I believe to be the 'promotion' of the earliest histerotrichs to become the latest curly-tip fibres. In Plateau about half of the fibres are histerotrichs, in Valley and Plain about one fifth. The trend of evolution is seen to be towards the goal of a coat composed entirely of curly-tip fibres. In very 'improved' fleeces of Plain array the reduction of both pre- and post-curly-tip groups is very marked indeed. In a plain array, it is to be noted, the effects of the head and tail checks overlap. In arrays lacking hairy pre-curly-tip fibres, with all the fibres of this group fine sickle-fibres, the numbers of the pre-curly-tip fibres may be reduced, and quite frequently in Wensleydale arrays[4] and once in a Romney array, no sickle-fibres at all have been found. To my thinking, the pre-curly-tip fibres have undergone, not loss, but extreme change.

The covering of the wild sheep has long been recognized as consisting of a hairy outer coat and an inner coat that is fine and not hairy. In Plateau I take the outer coat to be represented by the pre-curly-tip group and many fibres of the curly-tip group. In the course of evolution the trend has been for both outer coat fibres and inner coat fibres to become non-hairy curly-tip fibres. It may be added that there is a correlation between the percentage of hairiness determined by the medullometer (McMahon[5]) and the array. The contrast is most marked between extreme arrays, Plateau being grossly hairy, whereas Plain shows scarcely any trace of hairiness. The same relation holds for the average abundance of secondary kemp.

In the Romney the Plateau array is common on the britch, but N-type having the Plateau array on all or most of the main area of the body is rare, save in Dry's experimental stocks. The fleece characterization of N-type—whatever be the genetic basis—is atavistic, and links the Romney with some other breeds of sheep situated lower on the ladder of evolution, notably Blackface Mountain sheep. On the other hand, Valley and Plain arrays were found not only in the Romney but also in the Ryeland, Southdown[3], Wensleydale and Merino[4]. Thus we deal with a transitional series of arrays, from Plateau through Saddle and Ravine to Valley and Plain. In this series we trace the path of the evolution of the fleece. The genetic basis of these evolutionary changes probably resides in small mutations.

This note is based on a thesis recently presented to the University of New Zealand. It is hoped shortly to publish a full account of this investigation.

Aphid Transmission of Strawberry Viruses

BRITISH workers with strawberry viruses have so far failed to obtain transmission of Fragaria virus 1 (yellow edge) or Fragaria virus 2 (crinkle) by aphides other than the 'delicate strawberry aphis', *Pentatrichopus* (*Capitophorus*) *fragariæ* Theob., a species possibly identical with the American vector *Capitophorus fragæfolii* Ckll.

In experiments at this College the following species of aphides, recorded on strawberries in North Wales, consistently failed to transmit any virus from severely diseased plants of the variety Royal Sovereign: *Macrosiphum solanifolii* Ashm., *Aula-*

corthum solani Kalt (= *Myzus pseudosolani* Theob.), *Myzus persicæ* Sulz., *Myzus circumflexus* Buckt. (a single specimen only—possibly a stray from a glass-house—was taken on strawberry), *Myzus ornatus* Laing (tested only in the case of crinkle).

Other aphides tested as possible vectors of crinkle included *Pentatrichopus potentillæ* Walk. and *Pentatrichopus tetrarhodus* Walk. All attempts to achieve transmission by means of the former species were unsuccessful, but transmission from Royal Sovereign to *Fragaria vesca* L. was obtained with *P. tetrarhodus* both in 1940 and 1941, the resultant symptoms being indistinguishable from those induced by means of *P. fragariæ*. This discovery is of academic interest in that it suggests a specificity of relationship between strawberry viruses and the genus Pentatrichopus. The host-ranges of British members of this genus were described in a recent paper by Thomas and Jacob[1], who stated that *P. potentillæ* appears to occur only on *Potentilla anserina* L., and fails to survive on strawberries; while *P. tetrarhodus*, although capable of living for a rather longer period on strawberries under glass, occurs naturally only on species of Rosa. Further work is contemplated to discover if *P. potentillæ* is invariably a non-vector of crinkle and, if so, whether this is due to some metabolic cause operating within the insect or to the feeble extent to which the species is able to feed on strawberry.

Frequency of Occurrence of Wars and other Fatal Quarrels

IN order to investigate the causes of wars by counting occurrences, let the magnitude of any war be defined to be the logarithm, to the base ten, of the number of persons who died because of that quarrel. This definition has the advantage that it applies, not only to what are ordinarily called wars, but also to all kinds of fatal quarrels, including insurrections, frontier incidents, riots and murders.

The numbers of wars of various magnitudes, which ended from 1820 to 1929 A.D. inclusive, have been counted, after laborious search in works on history. The number of murders is an estimate from the statistics of crime. Between the wars and the murders, in the range between magnitudes 2·5 and 0·5, there were certainly many fatal quarrels; but statistics of them are scanty, presumably because such incidents are mostly too small to be history and too large to be crime. The results are:

Ends of range of magnitude	$7\pm\frac{1}{2}$	$6\pm\frac{1}{2}$	$5\pm\frac{1}{2}$	$4\pm\frac{1}{2}$	· · · ·	$0\pm\frac{1}{2}$
Observed number of fatal quarrels	1	3	16	62	· · · ·	10^7

It is seen that the numbers of wars in successive equal ranges of magnitude are nearly in agreement with the geometrical progression 1, 4, 16, 64; but that when this progression is continued, it gives 16,384 for the number of murders instead of the observed 10^7.

These remarkable relations call for explanation. A full account of this and cognate matters is nearly ready for publication elsewhere.

Science in the U.S.S.R.

IN NATURE of October 25, p. 497, M. Maisky's statement that "there is no place in the U.S.S.R. for pure science" is described as "rather unfortunate". In 1646 Robert Boyle stated that he was studying natural philosophy "according to the principles of our new philosophical college, that values no knowledge, but as it hath a tendency to use". I think the two statements are equivalent. Sprat, the first historian of the Royal Society, into which the Invisible College metamorphosed, went even farther towards the theory held in the Soviet Union, in postulating a class basis for science. "Their mechanics and artificers (for whom the true natural philosophy should be principally intended)", he wrote, "were so far from being assisted by those abstruse doctrines, that perhaps scarce any one of these professions, and trades, has well understood Aristotle's *Principles of Bodies*, from his own time down to ours." I think these quotations will show that the Soviet practice and theory on this important matter, whether or not we approve of them, are in the great tradition of British science.

J. B. S. HALDANE.
Department of Biometry,
University College, London;
at Rothamsted Experimental Station,
Harpenden, Herts.

TAKING the above quotations from two British men of science of three hundred years ago on their face value, one must allow that the Soviet practice and theory are compatible with their views, though it is possible that the *general* views of Boyle and of Sprat may be considered to be not quite so dogmatic as these single quotations would imply. In any event, we cannot agree that the views of these two men alone thus put the present-day Soviet practice and theory in the great tradition of British Science.

More important still, the main point at issue, surely, is the attitude of the general body of *present-day* British men of science. It is to be hoped that the time will never come when it can truthfully be said that there is no place in Great Britain for pure science. Prof. Haldane should, we think, have concluded the sentence in quoting from NATURE, which ran as follows: "since we do not believe that pure science has been altogether taboo in the U.S.S.R."

There seems to be a dangerous tendency to make too prominent a distinction between pure and applied science, for it may easily involve the risk that the protagonists for a *planned* scientific policy will be accused of wishing to oust pure science altogether. This is far from the truth. Scientific planning involves pure as well as applied science, especially when taking the long view; and that is why we consider M. Maisky's statement unfortunate, because we have no doubt that though there may be more *conscious* planning of science in the U.S.S.R., that country has not expunged pure science from its programmes merely because it is pure.—EDITORS.

CEREALS AS FOOD

THE fourth of the series of symposia on the nation's food arranged by the Society of Chemical Industry took place on October 29. The subject was "Cereals as Food".

The first paper, contributed by R. G. Booth, R. H. Carter, C. R. Jones and T. Moran, dealt with the "Chemistry of Wheat and Wheat Products". It consisted of a review of the literature, supplemented by estimations carried out by the authors on analyses of the wheat 'berry' as a whole and its separate constituents. The paper showed the wide variations that exist, depending upon the variety and cultural conditions of the wheat, but it is equally clear that many of the figures quoted in the literature are based on unsatisfactory analytical methods. Figures were given for the phytin and vitamin contents of wheat and flours of different extraction, and a large section of the paper dealt with the separation of the different fractions of wheat during milling.

This led logically to an analysis of high-extraction flours including National Wheatmeal. According to the authors, wheatmeal can be classified as rational or irrational meals depending upon how far the proportions of the different offal stocks in the meal are equal to, or are in excess of, the amounts present in whole wheat. National Wheatmeal is a rational meal, but the authors showed that, provided white flour continues to be milled, an 85 per cent extraction meal superior to National Wheatmeal could be produced. This is clearly a question to be considered after the War.

A. L. Bacharach and D. W. Kent-Jones followed with a paper on "The Nutrient Analysis of Bread". They first pointed out that flour as bread alone contributes something like 20 per cent of our total intake of calories and 20 per cent of our intake of proteins; in all forms, including cakes, puddings, etc., these figures are increased to about 35 per cent. Incidentally, they showed that, in terms of calories and protein combined, bread is far and away the cheapest foodstuff. The authors then considered the effects of phytin in immobilizing calcium, and attempted a calculation of the available calcium in white flour and National Wheatmeal, on the basis that the salts formed are either the tri- or hexa-calcium phytates. They pointed out, however, that this at best could only be a rough guide because of the complicating effects of magnesium on the precipitation of phytate. Their figures gave a quantitative justification for the 7 oz. and 14 oz. of calcium carbonate per sack of white flour and National Wheatmeal that the Medical Research Council recently recommended. It should be pointed out, however, that recent work has shown that most of the phytin can be hydrolysed by suitable conditions of baking, so that the higher amount for National Wheatmeal may not be necessary.

The authors also outlined the proposals in the United States for the fortification of white flour which would make B_1, nicotinic acid, riboflavin and iron compulsory, with calcium and vitamin D optional. The maximum amounts proposed for the first four factors would make the flour the equivalent of wholemeal bread. Mr. Bacharach and Dr. Kent-Jones suggested that the fortification of white flour should be extended to include iron as well as B_1 and calcium.

H. C. Moir had a difficult task in his paper on "The Composition and Nutritive Value of Oats and Oatmeal". The literature on this particular cereal is scattered and scanty, but the author succeeded in assembling data which should be of great value as a source of reference; there would, however, appear to be many anomalies; for example, the fact that the contents of tryptophase, lysine and histidine are greater in flaked oats as against whole oats. Mr. Moir emphasized that in view of the high protein, fat, iron and B_1 of oats, it is clearly an important human food. In the preparation of porridge the loss of B_1 is only 5–10 per cent, but with oatcakes the loss is 35 per cent, due presumably to the added sodium bicarbonate reducing the acidity. The question of phytin in oatmeal was also discussed, and it was pointed out that when porridge is properly prepared, that is, by soaking overnight, the inorganic phosphorus would be increased. The suggestion that oatmeal aggravates gout and rheumatic conditions was summarily dismissed.

The final paper, by W. P. Ford, "The Composition and Nutritive Value of Cereals other than Wheat and Oats", dealt with the remaining cereals—maize, rice, rye and barley. Maize contains 8–10 per cent of germ with a fat content in the germ of about 30 per cent. It is deficient in calcium, magnesium, iron and phosphorus as compared with wheat, but the protein contents of whole-maize and wheat are apparently equal.

The author described the changes in vitamin B_1 consequent upon de-husking, winnowing and polishing rice and showed why, except as a source of easily digestible carbohydrate, polished rice is the least valuable of all the cereals. He also mentioned the interesting fact that in the middle of the eighteenth century up to 42 per cent of rye was included in bread flour in Great Britain. German rye often contains 20–30 per cent of white flour, while American bread of the same name never contains less than 66 per cent.

In the discussion that followed, Dr. Green emphasized the importance, in cereal research, particularly in its nutritional aspects, of using material of known history and origin. This was supported by Mr. Bacharach, who, after pointing out the wide variations in individual chemical characteristics found in cereals, suggested that after the War at least, an organized attack should be made on all food stuffs, in order to collect precise and comprehensive analytical data.

Mr. Bacharach also stressed the need for further work on the availability of the different elements including calcium and iron, and went so far as to suggest that instead of protein figures for foods the individual amino-acids might be estimated.

In the papers and the discussion two points stood out: (1) the frequent references made to the analytical tables of McCance and Widdowson; (2) the unanimous view that much work has still to be carried out before we have anything like a factual picture of the chemistry of cereals, even wheat. Perhaps for this reason the excursions into the nutritional field were generally extremely tentative. The chemist does not dogmatize without the facts. This alone is a guarantee of the value of these discussions on the nation's food.

MODERN CAST IRON

FEW metallurgical products have shown such a marked improvement in quality during the last two decades as have the cast irons. So rapid has this advance been, that few, except those in immediate contact with the industry, can have kept abreast of the work done; and the engineer user has perforce lagged behind in his knowledge of the new materials thus placed at his disposal. It was presumably in appreciation of this fact that the Institution of Mechanical Engineers formed a Research Committee on High Duty Cast Irons for General Engineering Purposes, the first report of which was published in 1938. This was concerned with a general outline of the development of both the "high-duty" irons used on account of their enhanced strength, and of the special-duty irons employed in the main as a result of their possession of unusual physical or chemical properties.

On the outbreak of war, the attentions of the Committee were necessarily somewhat diverted to those matters within their province which would most immediately assist in the national effort. Of these, one of the most important was the question of making the fullest use of Great Britain's own iron ores, the most abundant of which are phosphoric. From these ores, irons containing up to around 1·5 per cent are produced, and the second report of the Committee, recently published by the Institution, is an excellent account, prepared by J. G. Pearce, director of the British Cast Iron Research Association, of the phosphoric grey irons used by the foundryman and engineer. The mechanical properties of these materials, both at ordinary and at elevated temperatures, are discussed, and curves are provided showing what type of properties may be expected from an iron of given carbon, silicon and phosphorus contents.

A third report, also prepared by Mr. Pearce, is devoted to a consideration of the newest forms of alloyed irons. As a consequence of the War, a demand has arisen among engineers for fuller information regarding the special irons which are being used, both for their own sakes and as substitutes for other materials in urgent demand.

This report is divided into separate sections dealing respectively with the austenitic and the martensitic irons, and well fulfils its purpose. The former type of iron bears to ordinary ones a relationship not dissimilar from that borne by the stainless steels to plain carbon material. Their characteristic properties include softness, ductility, and high resistance to wear, erosion, corrosion and heat. In addition, they are non-magnetic, of high electrical resistance and thermal expansion and low thermal conductivity. These materials have passed far beyond the field of research, and an appendix contains a list of many scores of examples of typical applications of such irons in actual engineering practice.

Where resistance to wear or erosion is the factor of prime importance, the martensitic irons, on account of their great hardness, find many important uses, some sixty or seventy specific examples of which are cited.

These reports, of which others are promised, contain select but adequate references to original sources of information, and should be of great value to makers and users alike. The author, the Committee and the Institution, in preparing and publishing this information, are performing a service of immediate national importance. F. C. T.

FORTHCOMING EVENTS

MONDAY, NOVEMBER 17

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 3 p.m.—Miss L. E. Cheesman: "The Border Mountains and Torricelli Range of Northern New Guinea".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. A. J. Curtin Cosbie: "Brewing, the Story of a National Industry" 1: Brewing Materials. (Cantor Lectures, I).

WEDNESDAY, NOVEMBER 19

SOCIETY OF GLASS TECHNOLOGY (at Elmfield, Northumberland Road, Sheffield, 10). Twenty-fifth Anniversary Meeting. 10 a.m.—Symposium on Glass Furnace Problems, I. 2.35 p.m.—Symposium on Glass Furnace Problems, II.

THURSDAY, NOVEMBER 20

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. W. T. Astbury, F.R.S.: "X-Rays and the Stoichiochemistry of the Proteins".

ROYAL INSTITUTION OF GREAT BRITAIN (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Sir James Jeans, O.M., F.R.S.: "Is there Life on Other Worlds ?"

FRIDAY, NOVEMBER 21

INSTITUTION OF MECHANICAL ENGINEERS (at Storey's Gate, St. James's Park, London, S.W.1), at 2.30 p.m.—Mr. W. T. Halcrow: "A Century of Tunnelling" (Thomas Hawksley Lecture).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DIRECTOR OF EDUCATION—The Town Clerk and Clerk to the Local Education Authority, Town Hall, Brighouse, Yorks. (endorsed 'Director of Education') (November 19).

BOROUGH ANALYST—The Town Clerk, Town Hall, Burnley (November 24).

SENIOR ASSISTANT to the Principal of the Barrow-in-Furness Technical College and Junior Technical School (will be required to take Evening Classes in MECHANICAL ENGINEERING)—The Director of Education, Town Hall, Barrow-in-Furness (November 29).

REPORTS AND OTHER PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

THE CIVIL SERVICE IN GOVERNMENT

BEHIND the less restrained and sometimes unfair criticism which has been levelled at the Civil Service as the War has continued, there has lain a vague, unformulated feeling that the Civil Service as a whole is slightly out of touch with the times, and neither in calibre nor technique quite so competent to handle the tasks with which it is confronted as was the Civil Service of a generation ago.

It is the great merit of a recent broadsheet, "The Machinery of Government", issued by Political and Economic Planning, that it brings such uneasiness into the light of day, probes its causes, and, setting the Civil Service in its proper perspective in relation to the task of government, makes constructive proposals for removal of many of the defects revealed.

In the first place, as the broadsheet points out, there is no peculiar 'democratic virtue' in incompetent administration; modern government is increasingly a matter of determining the right priorities in the broadest sense, of educating public opinion to those priorities, and of adjusting organization and methods to give them the fullest and most immediate effect. The failure of our executive machinery of government to plan ahead, its failure continuously to adjust its working structure and technique to the problems with which it is called upon to deal, its continued domination by financial and accounting aspects, its neglect of scientific and technical advances and its timidity in accepting responsibility, all flow from a failure to renounce the old conception of government as a regulatory, policing and taxing mechanism ; and openly to adopt the conception of government as the nation's common instrument for expanding its social and economic welfare in all those spheres where individuals or private associations cannot achieve equally effective results.

Although some improvement is being effected through the creation of new organizations and the elimination of weak spots, apart from the important exception of Mr. Eden's proposed reforms at the Foreign Office and in the Diplomatic Service, there has been little sign of the radical change of outlook involved in this new conception of government. Moreover, in reviewing the complex machinery of central government, as the broadsheet points out, it is important to consider Parliament, Ministers and the Civil Service, not in isolation but in their mutual actions and reactions. The Minister, for example, is to a very great degree dependent on the advice of the full-time professional officers of his Department for the policies which he submits to his colleagues in the Cabinet. In the execution of these policies

he can do little to secure more vigorous or effective action if the machine of which he is temporarily in charge is rusty or otherwise defective. No individual Civil Servant should be blamed for the consequences where advice he has given has been ignored by the Minister or by the Cabinet, but the Civil Service as a body must bear a fair share of the responsibility if the techniques for obtaining information and for shaping and presenting policy are such that too high a proportion of decisions prove to be ill-advised. The Civil Service, as a body, given the knowledge and the will to do so, is in a position to alter those techniques: generally speaking, the individual Minister is not.

The P E P broadsheet, leaving for a later statement the political and ministerial elements in the problem, discusses the main weaknesses of the Civil Service and how they might be corrected. It carries into constructive detail the ideas to some extent outlined by Dr. W. A. Robson in his introductory essay in "The British Civil Servant" some four years ago, and forms an admirable complement to the study of the growth of the British Civil Service, 1780–1939, by Emmeline W. Cohen*. There is indeed no simple or magic remedy. The solution lies partly in the change in the basic attitude to the task already emphasized, partly in some changes and developments of organization, partly in the modernization of methods and the use of available resources and techniques which have hitherto been neglected. Behind it all lies the problem of choosing the right men and using their abilities to the full.

It will readily be conceded that in present circumstances it would be impossible and highly dangerous to attempt a complete reorganization of the Civil Service. Modification of the recruitment, training and development of a great professional body is a long-period undertaking, which can only take effect over several decades. Fortunately, however, the measures which are immediately possible do not appear to conflict with the long-range measures required to equip the country to face the tasks which will meet it at the end of the War.

The analysis of the Civil Service in this broadsheet points once more to the weakness of the Service in knowledge of social and natural science, and in grasp of scientific method or technique. Training is in general political and administrative rather than executive. There is little knowledge of the new techniques of large-scale organization and management which have been developed in the last forty years, and an imperfect appreciation of the fact-finding method of approach to problems of administration on which these techniques are based. Even less than in industry the distinction of staff from line functions is not properly recognized, and there is no conception of holding any of the strength in reserve for emergencies—a criticism which equally applies to a large part of industry.

*The Growth of the British Civil Service, 1780-1939. By Emmeline W. Cohen. Pp. 222. (London: George Allen and Unwin, Ltd., 1941.) 10s. 6d. net.

These severe criticisms find support in a recent important study of the advisory bodies, on which the Haldane Report laid such stress; indeed the analysis reiterates not a few of the criticisms contained in that Machinery of Government Committee's report of twenty-three years ago. The emphasis laid there on the need for further provision for the continuous acquisition of knowledge and the prosecution of research, and on the desirability of establishment departments keeping themselves acquainted with what is being done in the business world are at once recalled by comments in the present broadsheet.

At the same time, it should be remembered that the adoption of a fact-finding technique by the Civil Service has sometimes been checked or discouraged rather than welcomed. The rebuke administered in the *Times Educational Supplement* to the Board of Education regarding a memorandum compiled by officers of the Board as a basis for discussion on the nation's next moves in educational planning is a recent example. If responsible opinion is to stigmatize such initiative as a grave constitutional novelty it is unlikely, to say the least, that the type of administrator now so urgently needed will be forthcoming.

The truth is that the weaknesses of the Civil Service are due, not to incapacity, but to a group of inhibitions and an absolute conception of government, which must be overthrown by the force of public opinion. That is the first step to securing that the Civil Service recognizes its function in safeguarding and developing the collective inheritance and the social and economic welfare of the nation, as well as that of preserving and assisting to enrich the individual liberties of its citizens. Only public opinion can secure the change from an agenda of public business, determined by external pressures, to one determined by the needs and facts of the situation, based upon thorough intelligence, careful forecasting and continuous analysis of the problems affecting the particular branch of government, and of the best ways of meeting them within the limits of general policy decided by Ministers and approved by Parliament. That change involves a radical alteration in the criteria applied in public administration—a shift in emphasis away from reliance on precedent, consistency and the avoidance of trouble from minority groups, towards action based on a thorough survey of the situation, a sound judgment of its implications and a clear perception of both in the minds of all the officers and departments concerned.

The first main conclusion of the P E P survey, then, is that this new conception of the function of government, with all that it implies for the Civil Service in changes in outlook, organization and methods, and in its relation to Ministers, should be fully and frankly faced. This conception was in fact equally implicit at the recent Conference on Science and World Order, not merely in the session devoted specifically to science and government, but also in those devoted to the relation of science to human needs and to post-war relief. The speeches of Mr. Eden and Mr. Morrison in connexion with the Conference indicate that the Government in Great Britain is now alive to these implications, and scientific workers may well be encouraged by the Conference to further efforts towards the formation of the public opinion essential for Parliamentary support.

From this it follows that the Cabinet secretariat must somehow be permanently strengthened in powers and personnel in co-operation with the departments concerned, to exercise the three functions of planning, personnel management and budgetary control, which are of decisive importance in determining the scope and efficiency of the machinery of government. This involves keeping continuously under review the main strategic conditions affecting government in the economic and social fields, presenting and examining the possible alternative courses, and putting them up for decision in order to elicit from Ministers the necessary directives on policy and priorities affecting groups of departments. The organization would also be responsible for working out with departmental officers the application of such directives to particular circumstances, for seeing that action is taken and for recording and circulating suitably digested information regarding it. Such an organization would not only supply the machinery for central planning and co-ordination; it would also supply the equally important mechanism for following up and seeing that approved policies are effectively and promptly put into operation.

The same fundamental conclusion regarding the Treasury is reached by the P E P broadsheet as in the Haldane Report. The recommendation that this should become purely the Department of Public Finance and the Budget, with a modernized outlook and methods, is the reflexion of criticism of the traditional attitude of antagonism between the Treasury and other departments. It is a reminder of the comment in the Haldane Report that the obligation of spending departments to formulate a full and reasoned statement of their proposals places upon the Treasury a corresponding obligation not to assume a negative attitude in the first instance towards suggestions for improving the quality of a service or the efficiency of the staff which administers it.

In the same train of thought follows the recommendation that the management and control of personnel matters should be delivered from finance, but the P E P broadsheet goes far beyond the Haldane Committee in recommending the formation of a central personnel office by transfer to a reconstituted Civil Service Commission with a suitably qualified membership, not limited to Civil Servants, of the establishment and office organization function of the Treasury. In political matters this Commission should be directly responsible to the Prime Minister. This step should be taken immediately, even if some of its long-term implications cannot be worked out until after the War.

This and other recommendations, like those for the establishment of a staff college for the higher training of men and women destined for high administrative or executive responsibilities, and the introduction into each department of the organization and techniques necessary for effective forecasting and planning ahead, or again the modification of methods of recruitment, training and grading so as to bring the ablest men rapidly to the top and eliminate the waste of good material, are in harmony with modern scientific administration and the best practice of large-scale industry. So, too, is the suggestion that the scope normally assigned to scientific workers and to technical experts should be enlarged. The broadsheet in fact reflects the essential criticism contained in many recent discussions of the Civil Service.

There can be no doubt that this searching analysis goes to the root of the troubles which have prompted much recent criticism of the Civil Service, fair or unfair. If it seems disappointing to find so little effect has been given to authoritative recommendations formulated more than two decades ago, Emmeline Cohen's book provides an admirable corrective. For all its weaknesses, the British Civil Service is a growing service, adapting itself continuously to changed conditions. The rate of change may lag behind what is desirable, but that can be accelerated by the pressure of public opinion. The suggestions in the P E P broadsheet would go far to secure the greater flexibility required within the Service, the increased mobility between it and the external world, the new conception of the task confronting the Service and the dissemination throughout the Service of a new outlook and new methods. What is required to secure the adoption of such methods and the placing of new men in key positions is the steady pressure of public opinion, in the formation of which scientific workers themselves have an important part to play.

PSYCHOLOGY OF WAR AND CRIME

War and Crime

By Hermann Mannheim. Pp. ix+208. (London: Watts and Co., Ltd., 1941.) 10*s*. 6*d*. net.

The Education of Exceptional Children

Its Challenge to Teachers, Parents and Laymen. By Prof. Arch. O. Heck. (McGraw-Hill Series in Education.) Pp. xviii+536. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 26*s*.

Genius in the Making

By Herbert A. Carroll. (McGraw-Hill Series in Education.) Pp. xi+307. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 19*s*.

IN his latest book, Dr. Mannheim has amplified the course of lectures which he was recently invited to give at the London School of Economics on the relations between war and crime. Formerly professor of criminal law in Berlin and a judge in the German Court of Criminal Appeal, later Leon research fellow and lecturer in criminology in the University of London, he is almost uniquely equipped to discuss the problems he has taken up.

War, as is well known, commonly increases the frequency of certain types of crime, but Dr. Mannheim shows that it may also diminish the frequency of other types, thus in some measure acting as a substitute. This in turn suggests that, from a psychological point of view, war may be regarded as itself a form of crime. He is thus led to examine the various analogies between an unjust war as an anti-social action committed by nations, and an illegal offence as an anti-social action committed by an individual.

Writers who have discussed the origins of war or crime have often advanced, seemingly without recognizing the parallel, much the same causal theories. Lombroso and his followers have put forward a biological explanation of crime; similarly Steinmetz and others have put forward a biological explanation of war, attributing it to the innate aggressiveness possessed by the more vigorous nations that have been brought to the fore in the struggle for survival. Other criminologists have argued that, not heredity but environment, not inborn degeneracy but external poverty, is the main factor in crime; similarly sociologists have argued that the main causes of war are not biological but economic. Finally, psychiatrists have sought to explain both war and crime in terms of whatever psycho-analytic doctrine happened to be in fashion at the moment: the followers of Freud attribute them to the social repression of the common human instincts; in their view, the Œdipus complex, with the love-hatred situations, the consequent defence-mechanisms, and the curious symbolic processes that it involves, will account for the behaviour alike of belligerent nations and of the individual offender; Adler's disciples prefer to trace both war and crime to an inferiority complex, leading, in nations as in individuals, to over-compensation and a morbid desire for power.

Dr. Mannheim has no difficulty in criticizing these one-sided and somewhat speculative theories. As he points out, they are the views of amateurs who have strayed into psychology from other fields of work rather than conclusions reached by scientific psychologists themselves. Those who have investigated the causes of delinquency at first hand have almost unanimously agreed that crime in the individual is due "not to a single universal cause, but to a multiplicity of converging factors, the nature of the factors and of their varying combinations differing widely from one individual to another". In much the same way, Dr. Mannheim concludes that, in war as in crime, not one cause but a number of causes are operative, the causes being different in different cases. From the numerous analogies in respect of causation he draws a practical corollary in regard to remedies: the psychological methods that have proved so successful in the treatment of crime might profitably be adopted to prevent war and to secure peace.

The inferences, as Dr. Mannheim develops them, prove most suggestive. But one principle he perhaps does not sufficiently stress. Recent investigations into the after-careers of criminals treated at psychological clinics and elsewhere, indicate that by far the most hopeful method of reducing crime is to deal, not with the hardened adult, but with the younger generation: the education of the young is at once easier and more effective than the re-education of the old. Moreover, to be successful, methods of education must be adapted more closely to the needs of the individual. Dr. Mannheim himself has shown that it is the exceptional individuals—the highly intelligent, the highly excitable, the relatively phlegmatic and most of all the relatively dull—who most frequently succumb to crime. This suggests that one of the most important items in post-war reconstruction should be an improvement of educational methods, in catering more particularly for the exceptional child.

Dr. Heck's book provides an admirable survey of this problem as it arises in the United States. He describes in turn the special needs of those who are handicapped socially, physically and mentally, and of those who are intellectually gifted; and his chapters summarize in considerable detail the existing provision for these children in the cities and States of North America, and reviews the basic principles that emerge from psychological inquiries on the various questions involved.

In Great Britain a long series of psychological researches has been carried out on the mental characteristics and the educational requirements of the mentally subnormal; but little has been done in regard to the intellectually gifted. We have a scholarship system; and the efficiency of scholarship examinations has been subjected to critical investigation. But few British psychologists have attempted a systematic study of the gifted child as such.

Prof. Carroll's book brings together in compact and readable form the results of the work carried out upon this subject, chiefly in the United States. Many of the conclusions that he cites as fairly well established are still insufficiently appreciated in Great Britain. Prof. Carroll shows, for example, that high ability is nearly always recognizable in childhood: the exceptions so commonly cited are not enough to invalidate the rule. At the same time, eminence in later life is not determined by intelligence alone. Among the intrinsic factors, he lays most stress on temperamental qualities: "ambition" (in the sense of a determination to become eminent), "drive" (in the sense of emotional energy), "singleness of purpose", "fluency" (especially in speaking or writing), and finally emotional and moral stability. Physical factors, such as appearance, size and health, often play a contributory and sometimes an undue part. The popular notion that the genius is an unhealthy weakling, an unsociable recluse, a misfit who cannot get on with others, and so ill-balanced in character as to verge on actual insanity—all this, though widely held, is shown to be derived from an unfair selection of rare but sensational cases. Among extrinsic factors, Prof. Carroll lays greatest stress on the economic status of the child's family, on the competition which the budding genius meets as he grows older, and finally on a congenial marriage. But here it is necessary to remember that social and environmental conditions may operate very differently in Great Britain and in the United States.

On all these problems there is an urgent need for further psychological research; and such investigations should unquestionably form part of present preparations for post-war reconstruction.

A DICTIONARY OF PHOTOGRAPHY

Wall's Dictionary of Photography: and Reference Book for Amateur and Professional Photographers.

Edited by F. J. Mortimer. Sixteenth edition, revised and largely re-written by A. L. M. Sowerby. Pp. v+701. (London: Iliffe and Sons, Ltd., 1941.) 12*s*. 6*d*. net.

THE first edition of this book was published in 1889, since when a great deal has happened in the world of photography, and the size of the "Dictionary of Photography" has increased accordingly. The sixteenth edition, as mentioned in the preface, has been published largely because of the unexpectedly rapid exhaustion of the previous edition; but the opportunity has been taken to correct errors and generally bring the subject matter up to date, though relatively little advance has been made during the interval.

The book is essentially a reference book for the amateur and professional photographer, and is confined mainly to the theoretical principles and practical details of all generally used photographic processes. Sufficient details are in most cases given to enable the photographically minded reader to grasp the mechanism of processes, such as those of colour photography, and sufficient working details, including formulæ, to enable anyone experienced in the technique of general photography to carry them out. The physicist or chemist interested in photography will find the book extremely useful from the practical point of view, but will naturally be disappointed in many cases in the superficiality of the theoretical treatment.

It is not possible to mention all the alterations and additions that have been made since the previous edition, but the following are the most striking examples. The section on "Aerial Photography" includes an account, chiefly of topical interest, of the present technique used by the Royal Air Force. The section on "Photoelectric Exposure Meters" has been improved considerably by including a sub-section on the use of the meter, relating to the method of directing the meter towards the subject and thereby assessing the value of the 'subject' and 'light intensity' factors. It is unfortunate that no mention is made of the

Smethurst high-light meter, which has certain advantages over the more usual type of meter, especially when dealing with reversal processes, and most particularly reversal colour processes, where accuracy of exposure is of first importance. The section on "Latent Image" has been re-written to include a very brief account of the Gurney-Mott theory. It is, of course, impossible to convey even an impression of the scope of the theory in the ten lines devoted to it, and it is interesting to note that in the first edition of the Dictionary nearly a page was devoted to the theory current at the time based on the formation of a sub-halide.

As a reference book the "Dictionary of Photography" will be found extremely valuable to the general photographer, though its value might be further increased by the inclusion of more references to fuller accounts of processes and theories which, owing to limitation of space, cannot be dealt with adequately in a volume of this size. It is always difficult to discover omissions, but there appear to be few, with the exception of 'reciprocity' and 'intermittency' failure, which do not seem even to be mentioned. Surely reciprocity failure, which can manifest itself under certain conditions in ordinary photography, is worthy of mention!

APPLICATIONS OF ELASTICITY IN ENGINEERING

Theory of Plates and Shells

By Prof. S. Timoshenko. (Engineering Societies Monographs.) Pp. xii+492. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 42*s*.

PROF. TIMOSHENKO is one of the outstanding exponents of the mathematical theory of elasticity and of the application of this theory to a variety of practical problems. He has written on these topics for thirty years, and his books have become indispensable to every engineer who has to apply mathematical principles and methods to such problems.

As is so often the case, mathematical theory becomes very much simplified when approximation becomes possible, and as indicated by the title of the present book, Prof. Timoshenko discusses here the theory of elasticity as applied to problems of two dimensions, that is, to problems in which the thickness of a plate or shell can be neglected in comparison with the other dimensions.

The importance of this type of problem in practical application is too obvious to need elaboration. The hulls of ships, the walls of tanks, the domes of buildings, the boilers in engines of all kinds, and above all the vitally important light structures that can withstand great pressures necessary for the development of modern transport, particularly in aeronautics and especially in air-fighting—all these topics represent problems that come within the purview of the present book.

The development of the topics discussed in the book is in itself an interesting picture of the evolution of an engineering structure. The author begins by dealing with the bending of plates into cylindrical forms and the symmetrical bending of circular plates. The boiler or container or aeroplane fuselage begins to appear. The study of supported rectangular plates with various edge conditions portrays the placing of a structure into position. Finally, the study of shells as cylinders and as surfaces of revolution takes us into the more detailed applications to daily needs.

The author devotes only moderate attention to general theory, but deals in considerable detail with a number of definite problems which are of special importance. The mathematical treatment is very full and exhaustive, but is always clear and easy to follow. What adds greatly to the value of the book is the fact that the mathematical solutions obtained are not left in their general form, but are discussed both graphically and numerically, so that the engineer who is not a professional mathematician is shown exactly how to use the mathematical methods practically and how to get the results that he needs for his professional purposes.

At a time when the main attention of humanity is directed towards the epic struggle which is taking place in Russia, it is naturally of interest to see how Russian thought and research have contributed to general human progress. The thick and high wall of prejudice and hostility, due to mistakes and intolerance on both sides, that was set up after the War of 1914–18 between the Soviet Republics and the Western democracies, had the effect of blocking the current of scientific influence between the Russians and the world outside. But Russian science and technology, as well as Russian thought and literature, have meanwhile made great strides, and the breaking down of the wall by recent events can lead to results of great advantage to all. Prof. Timoshenko has been working in the United States for many years, but he began his important contributions to the literature of mathematical methods applied to mechanics and engineering in the Russian language nearly thirty years ago. It is a pleasure to welcome his latest book in English as a further contribution from his competent pen to this important subject.

S. BRODETSKY.

RELATIVE NUTRITIVE VALUE OF DIFFERENT FORMS OF MILK

By Dr. S. K. Kon

National Institute for Research in Dairying, University of Reading

Recent Government pronouncements make it clear that during the forthcoming winter there may not be enough fresh milk to go round in Great Britain, and that priority for this milk will be given to certain classes of the population, such as expectant mothers and infants. Adult consumers will receive as part of their national basic share, in addition to liquid, also some concentrated form of milk.

A brief account of the relative nutritive properties of milk in its different forms may hence be timely.

It should be realized at the outset that, from the point of view of nutritive value, milk is a variable food. Though its 'major' constituents, protein, fat, carbohydrate and ash, change but little throughout the year, some of its vitamins are subject to marked fluctuations according to the season and the nutrition of the cow. Unless this is understood, any comparison of separate types of milk of different origin would be clearly misleading, especially as concentrated forms of milk are manufacted mostly in summer and early autumn.

The importance of milk in human nutrition rests primarily on its content of first-class animal protein of high biological value, its exceptional richness in calcium, and its valuable contribution of vitamin A and of riboflavin and other water-soluble vitamins. It is generally agreed that even in peace-time, when all foods are plentiful, it is difficult to plan an adequate diet without the use of milk or milk products, and with war-time limitations this is an admitted impossibility. The unique value of milk for children, adolescents, pregnant and lactating women is now universally recognized.

With the development of our knowledge of vitamins and of methods for their accurate estimation much work has been done on the effects of commercial processing on the food value of milk, and it may be said broadly that these have proved much less drastic than was formerly believed. The idea that raw cow's milk possesses unique nutritive properties which are lost if it is exposed to any form of heat treatment is certainly not supported by the bulk of modern evidence. Losses undoubtedly occur; some are avoidable and should be prevented, others can be made good by intelligent planning of the diet.

Of the milk constituents the proteins and certain vitamins are most liable to heat injury and the extent to which this takes place can best be judged by taking raw fresh liquid milk as a base line. Typical analytical figures are given in the accompanying table, and little comment is needed on the 'major' constituents. It is probably superfluous to remind the reader that the quantity of fat varies markedly according to breed, and that the Channel Island breeds produce milk especially rich in this respect. The proteins of milk consist of casein, lactalbumin and lactoglobulin, which are almost completely digestible, and have a high biological

Composition of Different Forms of Milk[1]

[1] The composition varies from sample to sample; the figures given in the table may be taken as representative.
[2] Varies according to season.
[3] Varies according to the handling of the liquid milk.
[4] Product hitherto made in Great Britain in accordance with 1923 Condensed Milk Regulations.
[5] Suggested composition for product manufactured in accordance with the recently reduced standards (Condensed Milk Order, 1940) and corresponding with U.S.A. Standards.

value, that is, they can be efficiently utilized to build or replace body protein. As judged by animal experiments, this efficiency may reach some 90 per cent for raw milk.

Regarding the so-called 'minor' (on a weight basis) constituents, milk is a rich source of vitamin A, which is partly present as the provitamin, β-carotene. It is well known that milk produced on pasture is much yellower and also contains more vitamin A than milk of stall-fed cows. Under south of England conditions milk is high in vitamin A from May until November or December, when it contains some 150–200 I.U. per 100 ml., and low during the rest of the year, when the concentration drops to about half this quantity. Vitamin D, of which there is little in milk, also varies with the season, but normally it depends not on the feed, but on the direct action of the sun on the cow. There is a steep peak, therefore, around the summer solstice, which drops away sharply on either side. In May, June, July and August there are about 2·5 I.U. of vitamin D in 100 ml. of milk; during the rest of the year the content falls to one half to one fourth or even less of this figure.

Of the water-soluble vitamins riboflavin is richly represented in milk, which contains some 100 μgm. per 100 ml. during the stall-feeding period, and 150–200 μgm. when the cows are on pasture.

The vitamin C content of milk varies but little throughout the year, and is independent of the feed of the cow. The amount present in milk as it leaves the udder is appreciable, 2·0–2·5 mgm. (40–50 I.U.) per 100 ml.; one pint of such milk would supply one quarter to one third of the daily requirements of a child. Vitamin C is, however, easily destroyed in milk by exposure to light; it is at first converted into a labile form, dehydroascorbic acid, which in turn decomposes spontaneously or under the action of heat. For this reason commercial milk generally contains only a fraction of the vitamin C originally present. In any event, care should be exercised not to expose bottled milk unnecessarily to bright light.

The level of vitamin B_1 in milk is also independent of the feed, and remains constant during the year at about 12–15 I.U. per 100 ml.

Several other vitamins belonging to the vitamin B complex are also present in milk. Some of them, like nicotinic acid and vitamin B_6 are heat-stable, and are not likely to be affected by processing; the fate of others has not yet been sufficiently studied.

Milk should not be consumed raw unless it is established that it is bacteriologically safe. Rapidly brought to the boil to ensure freedom from infection, it loses little or nothing of its nutritive properties. A large part of the commercial supply of milk in Great Britain is now pasteurized by the holder method. It has been satisfactorily established that the only nutritive effects of this treatment are a loss of some 20 per cent in the vitamin C content (and this due, rather, to previous exposure to light than to heating in the course of pasteurization), and a 10 per cent decrease in the vitamin B_1 value.

In certain towns in the Midlands, such as Birmingham, and also in London, there is a demand for yet another form of liquid milk—sterilized milk. Though there is no legal definition of what sterilized milk is, it is customary to apply this term to milk which has been heated to at least 212° F. (and generally higher) for varying lengths of time. This product, usually sold in swing-stoppered bottles, has the advantage of keeping for long periods of time, and is also liked because of its 'richer' taste. Before the War it was being increasingly used in infant feeding. The drastic heat treatment to which the milk is exposed in the process of sterilization brings about a loss of some 50 per cent of the vitamin C and of about 30 per cent of the vitamin B_1 originally present. The biological value of the proteins is also slightly decreased—by about 6 per cent. There is no evidence of nutritive impairment of other constituents. Sterilized milk remains, therefore, a most valuable foodstuff, though it is not the equivalent of raw or pasteurized milk, and its shortcomings for infants and children must be recognized and repaired by the addition of necessary supplements.

The stable, concentrated forms of milk are, broadly speaking, prepared in three different ways. The moisture may be removed as completely as possible, giving dried milk powder; or it is only partly removed, and the condensed milk is either sterilized by heat treatment to ensure bacteriological purity or enough sugar is added in the process of manufacture to inhibit bacterial growth. All three methods in various modifications are applied to separated as well as to full-cream milk.

Most of the 'major' and some of the important 'minor' constituents of milk are relatively stable, and these are not affected by the various commercial processes. Thus, vitamin A and carotene, vitamin D and riboflavin survive the various methods of preservation of milk without appreciable loss. Other more labile factors suffer to a greater or lesser extent, according to the severity of the treatments.

Of these treatments drying by modern methods is generally quite mild in its effects. Spray-drying consists in principle in forcing an exceedingly fine spray of milk into a heated chamber, where it dries almost instantaneously. Spray-dried milk is nearly completely soluble in water, and 'reconstitutes' readily. In drying, it loses about 20 per cent of the vitamin C present in the raw milk and one tenth of the vitamin B_1. The proteins are only

very slightly affected, and the 'biological value' is decreased by probably not more than 5 per cent. The significance of such loss may be trivial, as in a mixed diet the various proteins supplement each other, and the biological value of the mixture need not necessarily change. The availability of the minerals of milk, and especially of the valuable calcium it contains, is not affected by the heat treatment. It is clear, therefore, that spray-dried milk retains to a remarkable extent the nutritive qualities of the fresh product.

Another method of drying consists in rapidly dehydrating a thin film of milk on steam-heated revolving metal cylinders, from which it is removed by means of a stationary scraper. First-quality roller-dried milk is, from a nutritional point of view, only slightly inferior to the best spray-dried product, though its solubility in water is generally lower. As a rule, the loss in vitamin C is slightly higher, nearer 30 per cent, and the deterioration of the proteins is rather more noticeable. In some less satisfactory samples up to one third of the vitamin B_1 may be lost. Occasionally spray- or roller-dried milk is encountered in which the losses in vitamin C are much more severe than those just quoted. This is largely due to the practice obtaining in some factories of mixing the bulked milk before drying by bubbling air through it. Full-dream dried milks keep quite well when properly packed in hermetically sealed containers. They ceteriorate, however, on exposure to the air.

Cream has proverbially been considered as the most valuable part of milk, and milk from which the fat had been removed has borne a stigma of inferiority. Even now, when the full food value of milk is much better understood, there is still widespread prejudice against the use of skim milk in human nutrition. In the liquid state it was seldom used for this purpose in Great Britain before the War. Dried, it went into consumption concealed in bakery goods, ice cream, confectioneries and breakfast cereals. Even in the United States, where its use as human food is much more widespread than in Great Britain, some 40 per cent of the dry skim milk was used as animal fodder. Yet, when its limitations are properly understood, it is a most valuable food. The absence of fat and of vitamins A and D make it totally unsuitable as a food for babies, and in Great Britain it must be clearly labelled to this effect. All the other important constituents of milk remain, however, unimpaired, and for that matter, proportionally increased at the expense of the missing fat. The high content of animal protein, calcium and riboflavin makes skim milk a most valuable addition to war-time dietaries. Vitamin C and vitamin B_1 are higher than in full-cream milk, and the important, though less well-defined other members of the vitamin B complex are also there in relatively increased amounts. If protected from moisture, dried skim milk keeps almost indefinitely and without need for special packing. Relative cheapness and ease of transport emphasize its value in war-time, and it is to be hoped that as much of it as possible will be made available for general consumption.

Of the milk products from which water is only partly removed, unsweetened condensed milk, generally known as evaporated, is exposed to the more drastic heat treatment. The concentration itself is carried out *in vacuo* at low temperature, but the milk is then placed in tins which are sealed and sterilized by heat at a temperature of 240° F. This exerts noticeable effects on the more labile components. Some 60 per cent of the vitamin C, and 30–50 per cent of the vitamin B_1, are lost. The digestibility and biological value of the proteins decrease slightly but unmistakably. Other factors, so far as is known, remain unimpaired, and the good record of evaporated milk in the feeding of infants and children shows that when its known defects are remedied it remains a food of outstanding value.

Sweetened condensed milk is not exposed to temperatures above the boiling-point of water, and frequently the maximum temperature is well below this. Sugar, which is added before condensing, reaches a final concentration of about 40 per cent and effectively prevents the growth of micro-organisms. In up-to-date sweetened condensed milk the losses of nutrients are quite small. Thus, a good specimen may contain only 15 per cent less vitamin C, and 5–10 per cent less vitamin B_1 than were originally present in an equivalent quantity of the fresh milk before manufacture.

In assessing the food value of different types of milk it should be remembered that dried milks are concentrated about $7\frac{1}{2}$–$7\frac{3}{4}$ times in comparison with fresh milk, and unsweetened condensed milk about $2\frac{3}{4}$ times. Hence, the amount of milk solids varies in the different products, but the composition of these solids remains the same. It is altered, however, in sweetened condensed milk by the presence of large amounts of sugar, and this type of milk is richer in total solids than evaporated (unsweetened condensed) milk, though the concentration of the milk solids is roughly the same in both. Such assessments show that the alternative forms of milk which may be offered to the adult population will be perfectly satisfactory from a nutritional point of view, even though their use may entail some readjustment of established food habits. The essential point is to ensure the maximum possible supply of milk in any form for adults, and to reserve a full quota of liquid milk for children and expectant and lactating mothers.

J. A. KOMENSKÝ (COMENIUS), 1592-1670

BY DR. GERALD DRUCE

THREE hundred years ago there arrived in England a Czech exile, Jan Amos Komenský, better known by the Latinized form of his name, Comenius. This refugee from an earlier persecution of his nation came at the invitation of Parliament in order to lay before contemporary men of learning his views on education and the organization of science in the service of mankind. It was, therefore, appropriate that the tercentenary of Comenius's visit was commemorated at Cambridge on October 24.

Convened by Dr. Joseph Needham and under the presidency of the vice-chancellor, Dr. J. A. Venn, the meeting was attended by representatives of the U.S.S.R., Holland, Poland and Sweden, as well as by Czechoslovak and British men of science and learning. Papers were read by President Beneš ("Comenius' Plans for Peace Leagues and his Place in History as a Great European"), Mr. J.L. Paton ("Comenius as an Educational Pioneer"), Prof. J. D. Bernal ("Comenius' 'Pansophic College' and the Rise of Scientific Societies in the 17th Century") and Prof. E. Barker ("The Debt of Europe to Czechoslovakia and to Comenius"). Others present also paid tribute to the personality and achievements of the great Czechoslovak pioneer (see NATURE of November 1, p. 518).

Born of Protestant parents at Uherský Brod, Moravia, in 1592, Comenius had a local schooling which was followed by residence at Herborn, a Calvinist academy in Nassau. Before returning home he visited Amsterdam and Heidelberg. He became a teacher in 1614 and in 1618–19 he was headmaster of a school at Fulnek in north Moravia. These were critical years in Czech history, parallel with 1938–39. Disaster followed, Bohemia lost its independence and persecution set in. Comenius first moved to the estates of Charles of Žerotín, in east Bohemia, not far from the frontier over which he escaped to Leszno, in Poland, in 1627. Here he started a very successful secondary school for the Czech colony in this part of Poland.

He was also able to print tracts and works that he had written earlier. In 1622 he had completed the first accurate map of Moravia. Then came his "Labyrint Světa a Raj Srdce" (Labyrinth of the World and the Paradise of the Heart), an allegory written in an endeavour to escape from mental depression during anxious years. It describes a pilgrimage to an imaginary city, a method that the author adopted to direct attention to the social injustices, cruelty and dishonesty of his time. Remedies are suggested, and the consequences likely to follow, if the evils are allowed to continue, are foreshadowed.

At Leszno Comenius produced a new type of Latin grammar, "Janua Linguarum Reserata" (1631). Its plan was to impart, as well as Latin, useful general knowledge concerning everyday life and simple science. Instead of giving grammatical rules and exceptions, Comenius's method was to begin with simple phrases and gradually progress to complex sentences. The method was very successful and the "Janua" was translated into twelve European and four Asiatic languages. Some thirty of its sections are devoted to natural history, sixteen to arts and crafts (gardening included), twenty to learning and culture, five to social affairs, ten to ethics, eleven to politics and six to religion.

Comenius began to formulate his pansophic plans as a student at Herborn under the influence of J. H. Alsted. He printed the first part of his "Great Didactic" at Leszno in 1627 under the title, "Didaktika čili umění umělého vyučovaní" (Didactics or the Art of Teaching), with a supplement relating to the establishment of schools in Bohemia when victory came. Though Comenius probably obtained some of his ideas from Alsted and from J. V. Andreæ (whom he met at Heidelberg) and was also influenced by the works of Francis Bacon, the comprehensive conception of this educational scheme was his own and shows how much he was in advance of the times. That he possessed modern notions of the purpose and methods of education, to develop intelligence and to impart real knowledge and to maintain a progress from the known to the unknown, is apparent from the earliest edition of this work, which reached its final form and appeared in Latin as "Didactica Opera Omnia" (Amsterdam, 1657).

Comenius divided schooling into four grades: (1) In the family up to six years of age. (2) In the mother-tongue (primary) school from six to twelve. (3) In the higher (grammar) school from twelve to eighteen. (4) At the university after eighteen.

This system of education was to be available to all children without regard to station or sex, but higher education was to be based only upon merit. At school Comenius had been taught one subject, Latin, and that badly. He lamented that much useful knowledge was never taught or new discoveries (for example, those of Copernicus) even mentioned. Therefore, in his mother-school

curriculum he included observations on common objects and phenomena in most of the sciences. He claimed that in his first six years even, a boy can be brought to know something of water, earth, air, fire, rain, snow, frost, stone, metals, trees, plants, birds, fishes, etc. He can learn something of his own body and so be ready for systematic science at the grammar school. Comenius applies the same reasoning to his method of introducing the pupil to optics, astronomy, geography, history and mathematics and mechanics.

According to Comenius, the training to be completed at the university should be really universal and include every branch of knowledge. Positions of honour should be given only to those who have completed their university course and shown themselves fit to be entrusted with the management of affairs. For this final stage of education Comenius aimed at a compilation of all established facts from every branch of the sciences. The first part was published at Leipzig in 1633 under the title, "Physicæ at lumen divinum reformatæ synopsis". It included contemporary alchemy, cosmology, astronomy and anthropology, while current superstitions were not excluded. This work, in which Comenius emphasized the unity of all knowledge, was eventually translated into English by John Dury (1651). But the pansophic plans of Comenius became known here much earlier through Samuel Hartlib, a Pole from Elbing, who spent much time in England. Hartlib published two tracts, "Prāeludia conatuum pansophicorum Comenii" (Oxford, 1637) and an "Essay towards Compleat Wisdom" (London, 1639), so that the ground was prepared for Comenius to come to England. He was now widely known in Europe—and indeed in the New World, for there is a legend that he was invited to Harvard, and certainly his advice was sought concerning the education of American Indians, a matter in which Robert Boyle also was interested.

Comenius arrived in England in September 1641, and became acquainted with the leading men of learning, including Bishop Williams of Lincoln (later Archbishop of York and a great patron of science), Lord Brooke, John Pell, Theodor Haak, Sir Cheney Culpeper, Robert Boyle and John Selden, all of whom showed an interest in his plans. They discussed schemes for establishing an international academy or pansophic college (three sites were considered) which was to be "a living laboratory supplying sap, vitality and strength to all". The work of compiling a comprehensive encyclopædia of science was to be conducted by a number of specialists and assistants working under Comenius's direction.

At first there seemed every prospect of success, but the outbreak of the Civil War in 1642 caused the scheme to be abandoned, and Comenius returned to the Continent. It would, however, be incorrect to suppose that Comenius's visit had been in vain. His views and objects had been well received and he continued to correspond with Hartlib, Boyle, Dury and others. When the Royal Society was founded in 1662, Comenius was overjoyed and hastened to dedicate his "Via lucis" to the fellows, whom he addressed as "the torchbearers of this enlightened age", especially urging them not to neglect metaphysics. It may be pointed out that the expression "Invisible College", applied to the periodical meetings of those who later founded the Royal Society, may have originated from Comenius's reference to the projected pansophic academy as a "Collegium Lucis".

After further visits to Sweden, Poland and Hungary, Comenius eventually settled in Holland, writing alternately educational and pansophic works. Besides his country's persecutors he had philosophical adversaries. Thus, Descartes criticized his works on the ground that he mixed theology with philosophy. This refers, no doubt, to the fact that since 1631 Comenius had been a bishop of the "Unitas Fratrum", or Bohemian Brethren. Others contended that he attempted to spread Calvinism under the cloak of pansophy, while Samuel Desmarets, a Dutch contemporary, went so far as to describe him as "a mystical beggar with a commercial instinct". Comenius replied to these unfair charges by further explanations of his pansophic principles. His intention was to organize knowledge and apply it for the moral and material benefit of his fellow-Europeans.

The Thirty Years' War came to an end in 1648 when the exhausted belligerents signed the Peace of Westphalia. The terms left the kingdom of Bohemia (which included Moravia) in the hands of her enemies. For this Comenius bitterly reproached Oxenstiern, the Swedish plenipotentiary, who had promised that Bohemia would not be forgotten. But if he had lost his fatherland, Comenius found that he had become a citizen of the world. To his Czech compatriots he addressed a "Last Testament of a Dying Mother" (Kšaft umírající matky Jednoty bratrské) in which he made his famous prophecy, "I believe that, after the tempest of God's wrath . . . shall have passed, the rule of thy country will again return unto thee, O Czech people".

It was in these circumstances, too, that he wrote ("Panegersia"), "We are all fellow-citizens of one world, all of one blood, all of us human beings. Before our eyes there is only one aim—the good of humanity". The claim to regard Comenius as a great European can also be illustrated from

his "Angelus Pacis" (Amsterdam, 1667), addressed to English and Dutch plenipotentiaries, which contains a plea to all nations to abandon war and establish courts of peace for international consultations and the direction of human affairs. Whether a pansophic academy would have achieved the objects that Comenius had in view may be doubted. He was in advance of his age, and, apart from the far-seeing savants who founded the Royal Society, there were few who showed enthusiasm for his projects. No one on the Continent was prepared to do more than support the printing of his books and, indeed, it is only in modern times that international organizations have begun to function.

G. W. Leibniz (1642–1716), who was of Slav origin, showed a sympathetic interest in Comenius and assimilated his ideas regarding encyclopædic compilations and scientific societies, restating them and implementing them as completely as the unsettled state of Europe allowed.

Nor were Comenius's educational endeavours to meet with immediate success. He was a realist at a time when his contemporaries still learned their natural history from Aristotle and Pliny. Problems were 'settled' by reference to the writings of the authorities even after Comenius had asked, "Do not we ourselves dwell in the garden of Nature as well as the ancients? Why should not we use our eyes, ears and noses as well as they? Why should we need other teachers than these our own senses? Let the children touch, feel, see, hear and find out by experiment for themselves, draw the object, measure it and understand it".

To generations of his own countrymen Comenius has served as an inspiring example. They named the new University of Bratislava and also the Czechoslovak secondary school in Vienna after him. His energy and fortitude can serve to-day as a stimulus to us all to continue steadfastly working for those same ideals which we know to be true.

The papers read at the Cambridge tercentenary meeting are to be made available in a permanent form. Other recent works on the life and activities of Comenius are the following: "Comenius in England" by Dr. R. F. Young (Oxford University Press, 1932); "Comenius and the Red Indians of New England" by Dr. R. F. Young (1929); "Comenius" by W. M. Keatinge (McGraw Hill, 1931); and "Johannes Amos Comenius" by Dr. J. Jakubec (Orbis, Prague, 1928). Prof. R. J. Kerner's "Czechoslovakia" (University of California Press, 1940) also contains references to Comenius.

SCIENTIFIC KNOWLEDGE AND ACTION*

BY SIR RICHARD GREGORY, BART., F.R.S.

IN the study of man and his activities three types of cultural development may be recognized; and they are all measured by different standards. In the fine arts the imaginative qualities of the mind appeal primarily to the emotions through stimulation of the æsthetic judgment; material culture is the province of the industrial arts; and science—the domain of reason—is systematic and formulated knowledge in all fields of human understanding—natural, moral, social and political.

Natural science, or natural philosophy, is only one division of science as thus defined, yet, in general usage, the single word 'science' signifies verifiable knowledge acquired by observation and experiment. The history of civilization from this point of view is a history of intellectual development in which science has been the chief factor in changing habits of thought from superficial observation and magical theories of causation to clear concepts, rational conclusions, and progressive principles in the advancement of man and society.

It is common in these days to think of progress in terms of material development and to leave out of consideration the contacts of science with what is known as 'polite' learning—literature, religion, and other expressions of the human spirit. The noblest works of man are not, however, represented by great industrial advances, but by the search for the truths upon which they are based, and by the influence of this effort upon personal and social ethics.

In the pursuit of natural knowledge, the common object is to solve problems of life and thought; and all additions to knowledge thus gained contribute to the world's store, whether they admit of immediate practical application or are deposited in the archives of science for safe keeping. There can be scientific knowledge without action, and action without scientific knowledge; and the two are combined in applied science for practical service. There are, however, many aspects of Nature

* From the Hinchley Memorial Lecture delivered before the Institution of Chemical Engineers on October 24.

which appeal to the human mind, in addition to those in which usefulness is the measure of achievement. Purely scientific studies may claim to represent this attitude towards knowledge for its own sake and to be responses to a stimulus more exalted than that derived solely from material aims. So long as this spirit prevails, the influence of the high ideals of truth-seeking associated with scientific research will be extended : without them, science becomes a business in which the highest attributes and needs of human nature take no part.

Concepts of natural causes and phenomena must change with increased insight and inquiry, whether the interpretations represented by them are myths or scientific theories. Science asks for no faith in theories, except as reasonable explanations based upon verifiable observations, or as suggestive schemes which may or may not be found true when tested by further knowledge. Its duty is to observe with open eye and unprejudiced mind the picture presented by Nature, and to get nearer and nearer to the view. No loss of the sense of beauty need be involved in the analysis of the details which create the picture. The scientific mind is not satisfied with distant views and is critical of itself and its conclusions. It must, however, record faithfully what it perceives, knowing that the value of the record will be measured by its approach to permanent truth. True to Nature is the highest tribute that can be paid to a scientific testimony, as it is also to reflexions of Nature expressed in art and literature.

Observations carefully made and precisely recorded may be used or explained in various ways, but they are part of the permanent structure of natural knowledge. Whether undertaken with direct practical service in mind, or purely in the spirit of interest in natural objects and processes, is unimportant in comparison with the perception they afford of natural truths. In this respect, all who contribute to the store of verifiable knowledge increase the useful and the intellectual heritages of the human race.

Man is, indeed, more than an animal needing food and shelter and other essential means of existence : he seeks also to understand the nature and meaning of these things, usually with the view of deriving advantage for himself and for others from his discoveries, but often also with the desire to satisfy his curiosity in the object and operations of Nature. The common aim is to obtain information by inquiry and experience, though the motive in one type of observer is application of the knowledge gained, while in the other it is to explore the unknown and explain the mysterious. The standard of value of one is use and of the other intellectual satisfaction ; and the difference between the two is that between practical service and philosophy.

The discovery that certain natural events were repeated in orderly succession, and that their re-occurrence could be predicted, was a practical generalization from systematic observations, and revealed, therefore, a natural truth or law. If a generalization is well founded, it remains true independently of speculations as to the powers or causes which create and control the natural phenomena observed.

At all times, Nature has created wonder in the human mind as well as the desire to use and understand the proximate or ultimate causes of what is perceived by the senses. Knowledge of natural properties and effects was first acquired to supply needs of the body, and their interpretation as influences of spirits in the empyrean had mystery as its basis. The separation of the study of Nature from that of personal deities may be said to have begun with the Greeks. In the sixth century before the Christian era, Thales, Xenophanes and Pythagoras first opened up those veins of speculative philosophy which occupied afterwards so large a part of Greek intellectual energy. It is in their philosophies that the idea of an impersonal Nature was considered as a subject of study apart from mythical conceptions. They defined the scope of natural philosophy with its objective character and invariable laws, discoverable by the exercise of human intellect, and they first used the word *phusis*, signifying Nature and surviving in the words physics, physiology, physiography, and similar derivatives, to distinguish such studies from theology.

When early Greek philosophers began to speculate upon the nature of the universe and the meaning of life they introduced the spirit of liberty of thought in inquiring into all things—sacred, social or political—independent of authority, and thus established the principle of intellectual freedom essential for the advance of science, art, literature, or any other aspect of civilized culture. Many of their speculations were crude in the light of modern knowledge, but they all represented attempts to apply reason to the problems presented to human senses, and some have proved to be of fundamental significance. The particular contributions of the Greeks were not in the technical arts and crafts, or in knowledge gained by observation and experiment, but in generalized thinking about universals. Their characteristic was creative thought and theory on intellectual planes as far removed from needs of the body as mind is apart from matter. They used knowledge of natural properties and processes, acquired by observers and craftsmen before the classical period, not as useful applications of science but to construct philosophic systems which were logically sound and therefore required no other proof. It was believed

that truth in Nature could be revealed by abstract thought, without the slow and laborious process of learning by experience what things or circumstances in earth or sky could be applied to useful human service. Passive contemplation has an appearance of dignity not usually associated with the active exercise of either hands or brain.

When manual work of any kind began to be regarded as a menial occupation, and meditation became the characteristic of a higher social class, a distinction was created between useful knowledge and academic or philosophic thought. Pure science has thus come to mean natural knowledge acquired for itself alone, and studies without particular useful purposes in mind. Similarly, a pure chemist is said to be one whose active interests are confined to chemistry, while a pure biologist has physical life as his field of study. The word 'pure' used in this sense is objectionable for several reasons. Chemistry and biology, like other sciences, cannot be sharply separated from the main body of natural knowledge, but often merge into one another and lead to new productive branches, so that pure biochemists come into being, and members of the families of physics and chemistry, long separated by verbal distinctions, unite to produce the fertile line of physical chemists.

In general, however, it may be said that the main distinction between pure and applied science arises from exclusive attention to theory and practice respectively. Applied science is concerned directly with theory only as a generalization or principle which relates natural causes to consequences and enables new effects to be predicted. It is based upon observation, and its aim is the production of new agents or powers for the service of man. In most scientific societies, the passport to publication in their records is obtained by observational inquiry of a practical kind or original conceptions suggested by them. In their pursuit of natural knowledge by methods of observation and experiment, independent adventurers and practical prospectors meet on common ground, whether the purpose of inquiry is knowledge itself or its application.

In one of his aphorisms, Francis Bacon said that "All knowledge should be referred to use and action". On this narrow view, the value of scientific work is measured in terms of application to human service, without consideration of the dignity of knowledge and the intellectual aspiration to attain it. It is true that the main object of Bacon's new philosophy was to enlarge the dominion of man by increasing his knowledge and control of operations of Nature; and in this sense the standard of scientific achievement is service. Whether his philosophy was limited to this outlook is, however, unimportant in comparison with his advocacy of independent observations of natural operations and events, and legitimate inferences from them, free from prejudice and to be judged only by their faithfulness to natural truth. Whatever views may be held as to the inter relationships between science and society, civilized life is shaped by the uses to which scientific discoveries are put; and the spirit and method of scientific inquiry are now accepted as essential principles in the pursuit of truth through verifiable evidence of any kind.

Theories based upon such evidence are mental models of structures and actions for use as stepping-stones to further knowledge, and they have to be modified or discarded when they fail to satisfy crucial tests of their validity. Most natural philosophers are content to base their understanding of Nature upon the solid ground of observed facts, and to leave ultimate meanings to metaphysical minds. They are constructional engineers continually building bridges to cross into new territories and using materials of which they have discovered or created properties of practical value in the execution of the design. As the traffic of science increases, such bridges have to be replaced from time to time by others of newer designs and better materials; but the purpose is, as it is in all forms of organic life, the efficient adaptation of structure to function.

Artists and poets may use their imaginations to construct scenes and cities having no factual foundation; and without deliberate intention they sometimes anticipate designs and developments which eventually come to pass. Such conceptions of truth belong, however, to mysticism rather than to realism. The anticipations of expanding applications of scientific discoveries and their social consequences, made by Mr. H. G. Wells in many of his outlooks upon life, are of a very different character. They are similar in nature to scientific theories in which new relationships are foreseen from observed reactions, and are afterwards confirmed. They represent the products of a disciplined imagination working upon existing knowledge with the wide vision and adventurous insight by which the greatest advances have been made in both pure and applied science. It is in this spirit, and by the recognition of possibilities in opportunities presented by new contributions to knowledge, that material progress is achieved in industry and in science.

In these aspects of progress, theory and practice are complementary factors of service, each being used to reconstruct the other by relating effect to cause. This is the method of Bacon's inductive philosophy; and the achievements of modern science are due to its application. It is possible, however, to arrive at generalizations about the

nature of things and the structure of the universe by theoretical reasoning independently, or largely so, of observational or experimental evidence. With a few great exceptions, this was the method of approach of classical Greek philosophers towards problems of Nature; and it takes an important place in the history of science. They gave little consideration to the practical or useful services of science represented by chemistry, mechanics and engineering, but they take a supreme place by their philosophic and mathematical contributions. Many Greek philosophers meditated upon the nature of matter and space, each conceiving theories of primary elements or substances from which everything in the universe was formed and evolved. Abstract ideas about causes were discussed as propositions to be established or rejected by logical reasoning independently of knowledge perceptible by the senses.

Following this method of interpreting Nature by thought alone, Democritus, in the fifth century B.C., conceived the theory that the universe is made up of atoms varying in size and shape and moving in a vacuum. The atoms were indivisible particles and infinite in number; and by their motions and combinations with one another the world and all in it were produced. This atomic theory of the universe was taught a century later by Epicurus, whose philosophy was embodied by Lucretius in his great poem, "De Rerum Natura", in the first century B.C. The theory remained a philosophic conception until the beginning of the nineteenth century, when Dalton gave scientific precision to it. To Dalton, as to the Greek philosophers, an atom meant "the smallest possible quantity of any element which can combine with other substances", and the three laws formulated by him as to the structure of bodies by atoms are the foundations of modern chemical science.

These principles still hold good to explain chemical constitutions and changes, though there has been a complete revolution in conceptions of the structure of atoms themselves. In this revolution, however, theory has been used to account for observed properties and to forecast new effects from known causes. So long as the operations of the mental model thus constructed proceed according to plan it serves a useful purpose by providing points and movements of attack and defence. When opposing forces or natural obstacles reveal weaknesses in the system, adjustments have to be made to meet them. Expressed in another way, schemes of operations in the battlefield of science are not final orders to be followed without question, but working hypotheses which have continually to be modified to meet changing requirements of the front line.

In the fields of applied science, usefulness is the standard of value of both fact and theory. Natural relationships and laws represent the accumulation and collation of empirical knowledge, and nothing more is desired or claimed of them than service in action. Whether such generalizations, arrived at by theoretical and experimental research, are causally repetitional, and have no other significance, is too abstract a proposition to influence the activities of scientific workers generally in laboratory or field. When, however, the special theory of relativity, the quantum theory, the indeterminancy principle, and similar mathematical conceptions become factors which have to be taken into consideration in constructing rational schemes of structure and happenings in atoms and the universe, physical laws appear to be only convenient rule-of-thumb guides to practice and not ultimate truths.

Most scientific workers are satisfied with confirmatory experiment or observation as a test of the validity of a theory or principle. Clerk Maxwell's electromagnetic equations were of this type and were established as true by the experiments of Hertz and Lodge. Mathematical equations thus interpreted in physical phenomena often develop, however, into broader schemes and suggest that other states or conditions exist for which no objective proof may be attainable. In arriving at such equations upon purely mathematical principles, it is permissible to assume properties and relationships without reference to conscious knowledge of them. Though only a few of these revelations of the mind find contact with reality, while the rest belong to the realm of ideals, the general shape of the structure depends upon mathematical reasoning, which may be logically sound even when it does not coincide with observational knowledge.

The right of mathematicians to construct schemes of this kind, in which laws are derived from *a priori* concepts, must be conceded, however unsubstantial such flights of imagination may appear to practical minds. A physical law is not an unalterable creed, but a statement of knowledge of particular relationships of Nature derived from observation and experience. It has to be altered when cases arise which are not covered by it, and is not, therefore, a permanent statute. No scientific mind supposes that a physical law is among the eternal verities or a faith which it is sacrilege to assail.

There are other rational standards of value in Nature, in addition to those based upon scientific methods of inquiry. The inductive method is usually employed to construct theories of the nature of the universe from what has been discovered as to the constitution and distribution of

the bodies in it, but such theories can obviously be nothing more than rational pictures painted in the pigments available at the time. As they must change with the expansion of theoretical and observational knowledge, they can never be more than temporary schemes which explain what is known when they are expressed, and suggest a possible past and future history from present appearances. Mathematics and philosophy are, however, not confined to known laws of Nature or to observable phenomena : though these may be used in constructing mechanical systems of the universe, they are not essential factors in mathematical conceptions, any more than they are in poetic flights of fancy. Ideas as to the origin and construction of the universe, based on logical mathematical principles, can only be refuted, therefore, by positive evidence of their untruth, and not by the apparent lack of contact with what is known when they are put forward.

Our senses determine the range of objective phenomena, but creative thought has no such limitations. It is the source of the greatest human achievements, whether expressed in music and poetry or in scientific discovery and invention. Its exercise is determined not by what is known but by what is unknown ; and whether a pursuit is worth while must be measured by originality of intention and result rather than by direct intellectual or practical service. Here, then, is the common standard by which all scientific inquiries, and all expressions of human feelings, may be judged. It makes no distinction between pure and applied science, so long as the object is increase of knowledge and the endeavour is the discovery of truth.

When this is borne in mind, the pursuit of knowledge for its own sake becomes just as estimable an occupation as that in which the purpose is use or action. It is generally acknowledged that inquiries undertaken to solve purely scientific problems, and without thought of their proximate or ultimate usefulness, have been the starting points of most of the great achievements of modern science ; but such problems need not be excluded in planning scientific work for the benefit of the community. Science has transformed so many aspects of modern civilization that structures of society designed in earlier times have been shaken to their foundations by it. Its sources and resources, if they are wisely used, give almost unlimited powers to construct a world in which life can be made worth living to all peoples of the earth.

Systems of planning with these objects in view have to provide not only for the full use of existing knowledge but also for efficient means of extending it. Most scientific inquiries are best advanced when groups of workers concentrate attention upon them, whether intellectual interest or industrial application is the motive. It is, however, as impossible as it is undesirable to attempt to limit creative thought to a particular pattern, or to apply the criterion of usefulness to its exercise. This is as true of science as it is of other activities in which hand and brain combine to express themselves in new products. Men of science, like musical composers and other artists, may follow their occupations as a means of living, but their most original achievements are those which depend for their expression upon inborn light rather than external influences. In every walk in life, both interest and pleasure are required for contented effort, but they are not always to be hired in the market place. They are at their best when they are exercised in perfect freedom, whether in craftsmanship or in the expression of human consciousness.

STRUCTURE OF LIQUID METALS

BY DR. A. LATIN

RESEARCH DEPARTMENT, MESSRS. THOMAS BOLTON AND SONS, LTD.

THE view that the arrangement of atoms or molecules in a liquid is not entirely random may now be considered well established. In other words, the liquid possesses certain characteristics to which the term 'structure' can be properly applied. This does not mean that a liquid possesses anything so definite as a 'lattice structure', and any reference to a 'liquid lattice' may be very misleading, if not, indeed, devoid of meaning. It would perhaps be allowable to refer to the 'ghost of a lattice. Before going on to consider liquid metals themselves, it will be as well to deal first with the general question of the structure of liquids.

There are perhaps two main types of conception of liquid structure that have proved of value. These may be termed (1) group and (2) statistical conceptions. In some ways, indeed, these con-

ceptions have tended to merge into one another and perhaps their chief distinction is in the difference of mental picture that they give. Thus one view or the other may prove of the more value according to the particular case under consideration.

Theories of the first type postulate the existence in the liquid of minute groups of atoms or molecules possessing a more or less high degree of order, particularly at temperatures near the melting point. Such theories have been put forward, for example, to account for the increase in supercooling on freezing with the degree of original superheat. This implies a higher degree of order (or a greater number of 'seed crystals') in a freshly melted liquid than in one which has been superheated. There is considerable evidence, however, favouring the alternative view that the effect is due to the presence of impurities which, in one way or another, furnish nuclei for crystallization. Even in the case of the so-called 'liquid crystals', there appears to be no evidence of any very definite regularity of arrangement of the molecules, other than a common orientation. Perhaps the most elegant development of the group type of conception is Stewart's theory of 'cybotaxis'. In this the groups are considered to be of a transitory nature, continually forming and disappearing. The mental picture of the liquid is, so to speak, 'spotted' and ever-changing.

In the purely statistical type of conception, the liquid is regarded as being essentially molecularly homogeneous. There is, however, a tendency for the molecules to concentrate in certain favourable positions with respect to neighbouring molecules. In other words, there is a maximum probability of nearby molecules being situate in certain more or less well-defined positions with respect to one another. The distribution function representing the statistical radial distribution of molecules around an average molecule possesses peaks which become less marked as the distance increases. Moreover, there appears in many cases to be a distinct resemblance between the form of this function and that of the equivalent discrete function by which the structure of the crystalline solid may be represented.

A valuable insight into the nature of liquid structure can be obtained from a consideration of modern theories of fusion. These deal with fusion as a type of order–disorder process, analogous to that which takes place in certain solid alloys, but with the difference that the lattice itself, as it were, melts. In more general terms, the process of fusion may be included with the other so-called 'co-operative' processes, the statistical mechanics of which have been studied by Guggenheim and Fowler. The obvious corollary to this conception is that a certain degree of regularity must persist in the liquid. Similar considerations applied to the reverse process of freezing should be capable of giving more fundamental information into the mechanism of supercooling and nucleus formation than is obtained from either the conceptions of Miers or of Tammann, and it is obvious that much valuable work remains to be done on this side of the problem.

The most direct evidence favouring the above views of liquid structure, although there is a body of more circumstantial evidence from other sources, is that obtained by X-ray studies. The halo or haloes produced when a monochromatic beam of X-rays is passed through a liquid were early shown by Debye and Scherrer to be due to interference. Moreover, the Bragg spacing calculated from the most intense halo is in general of the same order as for the principal plane in the crystalline solid.

There is no space here to go fully into the question of the interpretation of the X-ray diagrams, but two main methods may be very briefly described: (1) a 'model' of the liquid structure, based on the influence of the thermal vibrations on the structure of the crystal, may first be proposed, the theoretical X-ray intensity diagram derived from this, and then compared with the actual diagram. (2) From what is essentially a Fourier analysis of the X-ray intensity diagram the distribution function of the liquid is obtained. Naturally, further interpretation, and even further data, are necessary for this distribution function to be made to yield a detailed picture of the liquid structure. This latter is probably the most difficult aspect of the matter.

X-ray studies have as yet been applied to only a few metals in the liquid state, but it seems already possible to draw certain tentative conclusions.

Of the close-packed metals lead, thallium and aluminium have been examined. All investigators agree that the liquids have a close-packed structure; that is to say, the atoms may be imagined as equal spheres which, while in continual motion, tend to remain always closely packed together. The inference is that there occur in the liquid, configurations bearing a relationship to those in the crystalline solid.

The body-centred cubic alkali metals have received considerable attention. Tarasov and Warren, for example, have shown that there exists a similarity between the atomic distribution of liquid and solid sodium. Their work has been followed up by Trimble and Gingrich, on the basis of whose results Wall has derived an interesting form of distribution function for liquid sodium. In his model each atom is imagined as being trapped in a spherical shell, the shells themselves being dis-

tributed in an arrangement of a 'quasi-solid' type. He shows that the chief effect of temperature is in influencing the shell radius, this being 0·60 A. at 100° C. and 0·77 A. at 400° C. One may perhaps conclude from this that a fairly high degree of regularity, related to the body-centred cubic arrangement in the solid, may be present near the freezing-point.

Coming to metals deviating more markedly from close-packing in the solid state, mercury, naturally, has been studied by many investigators. All agree in imputing to liquid mercury a close-packed structure. Solid mercury is rhombohedral, with a co-ordination number of 6, and the structure of the liquid may perhaps be most simply regarded as the result of the increased freedom given to the atoms on melting. Kratky has argued that a hexagonal close-packing fits the results best, but it seems unlikely that there can be much real difference between hexagonal and cubic close-packing in a structure so irregular as that of a liquid.

Bismuth is of particular interest in view of the large amount of work, in other connexions, of Goetz and his collaborators on this metal in the liquid state. There is some evidence of so-called 'pre-melting' in bismuth, and its melting point would appear to be not so sharp as for the close-packed metals. The results of the few X-ray investigations are conflicting. Randall and Rooksby find a band spacing identical with that for liquid lead, and consider that liquid bismuth has a close-packed structure. Solid bismuth has a structure differing widely from that of the close-packed metals, but, as Randall and Rooksby have pointed out, there are certain similarities to lead, its neighbour in the periodic system. Their view may be said to amount to the conclusion that this similarity increases on melting. They cite the changes in diamagnetism and electrical conductivity as affording more evidence in favour of this view. The results of Prins agree with the close-packed theory, but Danilov and Radtchenko consider that a 'blurred' simple cubic lattice fits their results best. The structure of solid bismuth is often considered as a slightly distorted simple cubic one.

As a result of his experiments, Goetz, particularly in connexion with his 'block' theory of the structure of crystals, has put forward the view that in liquid bismuth there persist, up to about 10° C. above the melting-point, groups of atoms, under certain conditions quite large, having a highly regular arrangement closely allied to the structure of the solid. His theory has received considerable criticism, and it would seem that more certain evidence is necessary to substantiate it. To me, it seems a possibility that the change which takes place in bismuth on melting is, from one point of view, analogous to an order–disorder change in a solid alloy, accompanied (as is not infrequent) by a change in lattice form. The possibility of cybotaxis also exists.

X-ray investigations have also been made on liquid tin, but will not be dealt with here. Of perhaps greater interest are the results on gallium, as representing a 'borderline' case, or highly abnormal metal; also because Menke has carried out an investigation on the supercooled liquid, at 18° C. (m.p. = 30° C.). The intensity diagram shows a pronounced 'ridge' near the principal maximum. A similar effect occurs with water. The structure of solid gallium is complex, and there is evidence of molecular binding. The simplest conclusion is that some degree of molecular binding and relationship to the solid, possibly with cybotaxis, occurs in the liquid. On the other hand, it also seems not unlikely that a definite change in structural characteristics occurs on melting. It is noteworthy that supercooling would seem to be more marked in those metals, for example, bismuth and gallium, in which such a change takes place, than in metals such as the close-packed ones, in which the structural characteristics of liquid and solid appear to be more closely allied.

A few alloys have also been investigated in the liquid state by X-ray methods. The results on intermetallic compounds indicate a certain degree of stability in the liquid state. Bornemann's measurements of the electrical conductivity of liquid alloys also confirm this. In view of the electron-atom ratio theory of the structure of intermetallic compounds, these results are of interest in indicating that the forces responsible for the structure of solid intermetallic compounds persist in modified form in the liquid. It seems possible also that what amounts to a form of cybotaxis is present, the compounds, as it were, continually forming and dissociating. A few eutectic alloys have also been investigated. The results would seem to indicate the possibility that there is some tendency for the eutectic components to separate in the liquid, particularly near the freezing point; that is, the structure of the solid alloy is to a certain extent 'foreshadowed' in the liquid. Again, what amounts to a form of cybotaxis, continual intermingling and separation of the eutectic components, seems possible.

It is evident that much work remains to be done. The experimental difficulties, quite apart from the difficulties of interpretation, are of course very great. Nevertheless, considering that the vast majority of metals and alloys used in industry start their existence, so to speak, in the liquid form, and that the process of freezing, as in casting, etc., is still so imperfectly understood, it would seem that there is here a useful line of fundamental research waiting to be developed.

OBITUARIES

Sir Arthur Hill, K.C.M.G., F.R.S.

THE tragic death of Sir Arthur Hill, director of the Royal Botanic Gardens, Kew, in a riding accident on November 3, is not only a disaster for the Gardens, but also a great loss to the many societies, institutions and Government departments of which he was the chief representative of official botany for Great Britain. The twenty-odd years during which he was director saw a tremendous advance in the progress of botanical science in all its branches, and it was natural that Kew should play a prominent part in many of the activities characteristic of this period.

Arthur William Hill was born on October 11, 1875, and was the only son of Daniel Hill, of Watford. He was educated at Marlborough and at King's College, Cambridge, where he obtained a first class in both Part I and Part II of the Natural Sciences Tripos, and later took the degree of Sc.D. He was elected a fellow of King's College in 1901 and became dean in 1907, and since 1932 had been an honorary fellow. He was University lecturer in botany from 1905 until 1907. During the War of 1914–18 he was placed on the special list as adviser on horticulture to the Imperial War Graves Commission and held the rank of Captain from 1917. He was elected a fellow of the Linnean Society in 1908 and a fellow of the Royal Society in 1920. In 1926 he received the honour of C.M.G., and that of K.C.M.G. in 1931.

Hill was attracted to botany by a classical master at his school, the late Edward Meyrick, F.R.S., who was also an enthusiastic naturalist. At Cambridge he came under the inspiring genius of Marshall Ward, and later had the advantage of assisting Walter Gardiner in his work on the continuity of the protoplasm between adjacent plant-cells. His admiration for Gardiner's manipulative skill comes out in the obituary notices he has so recently written (see NATURE of October 18, p. 462). Hill continued this line of research independently, and his contributions, "The Histology of the Sieve-tubes of Pinus" (1901), and "The Histology of the Sieve-tubes of the Angiosperms" (1906), were two of his most important papers and may be regarded as the classic English accounts in this line of investigation.

After taking part in the Bisiker expedition to Iceland, Hill visited the high Andes of Peru and Bolivia in 1903 and this expedition probably made a greater impression on him than all the rest of his world-wide travels. He was particularly struck by the dwarf rosette and cushion plants—a modification displayed in very many families—which are abundant on the Andes, and of these he selected after his return the members of the Malvaceæ, with their remarkable variation in leaf-form, as a subject for detailed investigation. On these he published, some years later, "An Account of the Acaulescent Species of *Malvastrum*" and "A Revision of the Genus *Nototriche*". Many new species of these curious plants have since been discovered, and Hill, who never ceased to be fascinated by them, was planning at the time of his death an entirely new revision of the genus Nototriche to be illustrated by an elaborate series of drawings.

The appointment to Kew as assistant director under Sir David Prain was made in 1907. Hill was allotted a number of routine duties including the editorship of the *Kew Bulletin*, but in spite of these he was able to continue research and he published several taxonomic revisions and other papers. He took a share in the preparation of the great African Floras published from Kew, namely "The Flora Capensis" and "The Flora of Tropical Africa". For both of these he elaborated the difficult family Santalaceæ, which entailed careful dissection of small and inconspicuous flowers, and for "The Flora Capensis" he prepared (in collaboration with Prain) the article on the Gentianaceæ.

On Sir David Prain's retirement in 1922, Hill became director. Some years after his appointment he was successful in obtaining what was to prove of immense value to Kew for the strengthening of ties and the broadening of outlook, namely additional funds and facilities for travel by members of the scientific staff. These came in the form of grants from the Empire Marketing Board. In this enterprise he was stimulated and assisted by the boundless energy of T. F. Chipp who had succeeded him as assistant director. Hill himself took full advantage of the opportunity and visited Australia, New Zealand and Malaya, and, on another occasion, South Africa and Rhodesia, after which he attended the Conference of Directors of Agriculture of East Africa held at Amani in Tanganyika and visited Kenya and Uganda. In all these tours he was able to promote the study of the native flora and vegetation and to improve the relations which Kew already had with Government departments and herbaria throughout the Empire. The result of his visits and of those of the scientific staff led, among other things, to an enormous increase in the amount of material reaching the Herbarium for identification. With the aid of grants from the Marketing Board, additional staff was recruited; but to this day a great accumulation remains to be worked out. The two wings composing the Herbarium were already crowded to excess and after repeated attempts, extending over several years, Hill succeeded in obtaining sanction for the erection of a new wing.

A very successful enterprise which he inaugurated in association with the Forestry Commission was the acquisition of about fifty acres of land at Bedgebury for the purpose of forming a national collection of conifers, especially of those genera which did not flourish at Kew. His active support of the transplant experiments and genetical work carried out at Potterne showed further his sympathy in branches of botany which were not in his own line.

The Kew tradition of providing Colonial Floras was fully maintained under Hill's directorate. The publication of the Gramineæ for the unfinished

"Flora of Tropical Africa" was continued and an entirely new work "The Flora of West Tropical Africa" was initiated and completed. His interests were, however, not confined to the continent of Africa. Of the Indian Floras, he supervised the publication of much of the "Flora of the Madras Presidency" and was recently in correspondence as to the preparation of a final part of the "Flora of the Upper Gangetic Plain". His visit to Trinidad had given him an interest in the vegetation of the West Indies and under his sponsorship also it was arranged in 1928 that the drafts of the new Flora of Trinidad and Tobago should be checked at Kew after preparation in the Colony, and he had himself during the last few years prepared the accounts of certain families—the Sapotaceæ and Convolvulaceæ among others. Repeated attempts to secure funds for a Flora of British Guiana were unsuccessful, but Hill greatly stimulated the study of the flora of this Colony by arranging for an expert systematist from the Herbarium staff to pay visits there, and a number of papers on the flora have already appeared.

Although Hill worked on systematic problems he was not attracted to taxonomy for its own sake and still less when it involved investigation into past history or the unravelling of involved nomenclature and botanical errors. Taxonomy appealed to him as the arrangement of the phenomena presented by morphology. The cushion plants of the Andes, the curious aquatic umbellifer Lilæopsis, the bulbous species of Peperomia, the trimorphism in the flowers of *Oxalis tuberosa*, or the strange development of the basal auricles or the leaves of a southern Caltha, attracted him instantly and led sooner or later to the production of papers. His researches on the living plants at Kew also concerned morphology rather than taxonomy, and considering the wealth of material in the Gardens this was a natural and indeed eminently suitable field of research for a director whose interests had to be wide and who could not spend his days in concentrated study in the Herbarium and Library. The problem of the stony endocarp, Dicotyledons with a single or unequal cotyledons and the twisting movement of flowers and leaves are recent examples of his studies. All these papers taken together form a valuable contribution to general morphology and a fitting sequel to the work of his predecessor Thiselton-Dyer. An experimental turn of mind and an interest in physiology are shown also in not a few of his writings, and during recent years he went to great trouble to initiate and supervise experiments on purifying the air in greenhouses and providing illumination to counteract the adverse effects of London fog, experiments which unfortunately had to cease on account of the War.

As president (1930) of Section K of the British Association Hill chose as the subject of his address "Present-day Problems in Taxonomic and Economic Botany". Another important public lecture was that delivered before the International Congress of Plant Sciences at Ithaca in 1926, when he spoke on "Antarctica and Problems in Geographical Distribution". His address to the first Imperial Botanical Conference in 1924 urging the need of a complete botanical survey of the Empire was opportune and noteworthy.

To the Gardens themselves Hill became deeply attached, and he carried out a number of improvements, some of them being on a considerable scale. His highly developed artistic sense was revealed in all these changes as it was also in his horticultural interests generally. He served on the Council of the Royal Horticultural Society and on many of its committees, and, since 1934, had edited the *Botanical Magazine* for the Society. In 1919 he edited the interesting memoir of that great horticulturist Canon Henry Nicholson Ellacombe, of Bitton. He worked regularly with his own hands in his private garden and was always ready to encourage the good amateur.

Riding was a relaxation he greatly enjoyed and had retained from his Cambridge days. He would often say that so long as he could have a horse and ride a bicycle he would not buy a car. He was a man of very high and rigid principles and a devout churchman. He had an intense interest in church architecture and was a generous benefactor to the church he regularly attended. A love and appreciation of art and music also found a place in his busy life, while the genial hospitality of his official residence was known to botanists and others from all parts of the world. Fastidious in his tastes and often somewhat aloof, he was truly sympathetic and kind-hearted. His intimate friends were few and these held him in the deepest regard and affection.

For Kew the loss is very great. He held the balance almost perfectly between the interests of the Gardens and those of the Herbarium, Museums and Laboratory, while the versatility of his nature made him capable of taking interest in every aspect of the Gardens' administration. A. D. COTTON.

AMONG the many activities of the late Sir Arthur Hill not the least was his interest in the botanical welfare of the Dominions and Colonies. In the early days he had made a collecting tour of the high Andean regions of Peru and Bolivia, and this seems to have stimulated his interest in travel, for in after years he visited many widely separated regions and consequently acquired a vast knowledge of tropical and subtropical flora. His first visit to the West Indies was made in 1912, when he represented Kew at the Eighth West Indian Agricultural Conference at Trinidad; afterwards he visited Barbados and the Windward and Leeward Islands. He visited botanic gardens in the various islands, and while appreciating the many fine exotic species, deplored the neglect of native plants in the collections. He was specially impressed with the early work on cacao grafting, and urged continued work on more intensive lines. Incidentally it may be remarked that this work has been developed and is one of the main items on the programme of cacao research which has been undertaken with gratifying results by the Imperial College of Tropical Agriculture.

Sir Arthur Hill was keenly interested in agricultural

education, and was one of the original governors of the Imperial College of Tropical Agriculture, being nominated by the Secretary of State for the Colonies. He visited Trinidad again in 1919 with Sir Arthur Shipley, to attend the opening ceremony of the West Indian Agricultural College at St. Augustine, Trinidad, an institution which received a Royal Charter two years later and changed its name to its present designation. He afterwards visited Jamaica, and it was during this visit that he became impressed with the seriousness of the threat to the banana industry, which was beginning to suffer severely from the ravages of disease. It was due to his proposals that the Banana Research Scheme, also centred at the Imperial College, came into being. He was firmly of the opinion that the problem could best be solved by breeding strains resistant to Panama disease.

In 1921 he visited the Cameroons to advise the Secretary of State on the Botanic Gardens at Victoria, and he afterwards toured Nigeria to study native agriculture. He attended the International Congress of Plant Sciences at Ithaca in 1926, and then visited California and British Columbia. His theme was always the necessity for preserving the native flora in suitable reservations or parks. Official tours were made during 1927–28 to Australia, New Zealand, Malaya and Ceylon, and the Botanic Gardens at Buitenzorg in Java were also visited. In all these places he was consulted on matters connected with herbaria, museums and botanic gardens, and the result of these visits was to establish closer liaison with Kew. One of the results of the tour was a scheme for the temporary exchange of botanists from Kew with those from Australia, and a somewhat similar system was devised for India and the Union of South Africa. The winter of 1930–31 was occupied in a visit to South Africa at the invitation of the Government of the Union. Here again he stressed the need for botanical reserves, especially in connexion with the preservation of the native flora. He deplored the extensive planting of the slopes of Table Mountain with exotics, and expressed the view that it should be kept sacred as a reserve for the native flora. On his return he visited East Africa and attended an agricultural conference at Amani, when he took the opportunity of reviewing the botanical work that was being undertaken by the Agricultural Research Institute.

He had been appointed a member of the Colonial Advisory Council of Agriculture and Animal Health when that body was first constituted. His unique knowledge of conditions in so many of the Colonies proved of great value, and during the period of construction that followed the end of the War of 1914–18 he served on many committees and conferences dealing with agricultural improvement in the Colonies. It is rather remarkable that the last meeting he actually attended before his death was a committee of the council which was dealing with agricultural education in the Colonies.

Sir Arthur had long wanted to visit India, and his chance came in 1938 when he visited Calcutta as an official representative of the British Association to the Indian Science Congress. It was a real *tour de force* and he received a great welcome from the Royal Botanic Gardens, Calcutta, the universities and the cinchona plantations and other gardens which were staffed by Kew-trained men. His last foreign tour was in March 1939 when he was an official representative of H.M. Government at the Eighth International Congress of Tropical and Subtropical Agriculture. The meetings were held at Tripoli, and afterwards he took the opportunity of visiting the new Fascist Colonies in Cyrenaica. In discussing the matter after his return he remarked that the work of reclaiming the desert was of great interest and value, but that the cost must prove uneconomical.

Kew has been the source of inspiration to all botanists in the Empire for the last hundred years, and Hill's many tours and his personal correspondence did much to preserve the links that tie it to so many of the botanical institutions that have sprung up overseas.

He was always particularly glad to see old Kew men when they were home on leave from their overseas stations, and his advice was valued. The advent of the present War saddened his outlook, and every bomb that fell on the Gardens was regarded more or less as an act of sacrilege. Throughout this period, however, he carried on bravely with a much depleted staff, and looked forward to the future with serenity. His private benefactions were numerous—how numerous few people can guess—but the people of Kew realize their loss. A manner which was often rather abrupt hid the kindliest nature and a heart of gold. His passing will cause a big break in the story of the Royal Botanic Gardens. He had worked there for thirty-four years either as assistant director or director, and during the last few months had spent much time in compiling a full and detailed history of the Gardens.

Geoffrey Evans.

The broad zone of common interests shared by the Royal Botanic Gardens and the Royal Horticultural Society afforded Sir Arthur Hill, as director of Kew, ample opportunity for rendering service invaluable to the Society. For many years, from 1919 onwards in fact, Sir Arthur served on the Society's Council and on several of its committees, thus he was a regular visitor to the Wisley Gardens and Laboratories.

To his unfailing generosity the fellows of the Society are largely indebted for the collection of plants in the Wisley temperate house. A more recent gift of uncommon hardy shrubs materially assisted in the planting of the newly acquired Battleston Hill.

The members of the Wisley staff will not fail to remember his kind concern with all aspects of their scientific work and also with their welfare; nor will those concerned with taxonomy and nomenclature forget his constant courtesy in so frequently assisting them by placing the facilities of the Kew Herbarium at their disposal.

Away from his administrative duties and cares, Sir Arthur thoroughly enjoyed his quiet but critical contemplation of the Society's decorative plants—

species, varieties and garden hybrids; and there is no doubt that he too appreciated an epicurean discussion of the virtues and failings of apples old and new. He frequently aroused the interest and envious admiration of professional and amateur fruit growers alike, less fortunate perhaps than he was in regard to frost damage to their trees, when he described the quality and quantity of the crops he gathered in his own garden.

When in South America, Sir Arthur noticed the three coloured forms of the oca (*Oxalis tuberosa*). He wished to study the relationship between the tuber colour and the structure of the flowers which proved very difficult to obtain in Great Britain, but by controlling the period of light we found it possible to obtain a few flowers at Wisley for comparison with other material grown at very high altitudes in central Europe.

During the last seven years Sir Arthur edited *Curtis's Botanical Magazine*, published by the Society, thereby maintaining the tradition so firmly established by Sir Joseph Hooker during his forty years editorship. It is deeply regretted that these activities have been so tragically terminated, but one records with gratitude the high value to us of his interest and work. M. A. H. TINCKER.

FOR nineteen years Sir Arthur Hill held with outstanding success an official position which developments of the science of botany have made very exacting. In the middle of last century the expansion of the Empire had confirmed the commanding position of Great Britain in systematic botany: Kew was its centre, and the Hookers its leading figures. But the study of botany in the universities was at a low ebb. The publication of the "Origin of Species" led to that revival of interest in the morphology and physiology of animals and plants which sprang up at South Kensington under Huxley and Thiselton-Dyer.

Hill did not himself participate in the change, for he was then too young. Even Gardiner, under whose guidance at Cambridge he acquired the finest microscopical technique, was a product rather than an agent in the revival of botanical study there in the 'seventies. Thus Hill passed on imbued with the 'new botany' already widely current. As assistant director of Kew he had under Prain an unrivalled opportunity for systematic study. The result was that, when appointed as director after Prain's retirement, he was able to give to the botanists of his time advice and help in both branches. His genial personality made him a friend to all inquirers. In fact, he was for many years an ever-ready adviser for students, whether in the garden, the laboratory or the herbarium.

Others are giving detailed accounts of Hill's life, and its widespread Imperial activities. Here a very old friend has pleasure in telling how fully he maintained the old systematic tradition of Kew, while promoting and expanding its adaptation in the widening scope of the science to meet the needs of a later time. F. O. BOWER.

OTHERS will have expressed their appreciation of Sir Arthur Hill's eminence as a botanist; I knew him best as a man and a gardener. What was most distinctive of him was the very wide circle of friends to whom he was "Arthur". He had a gift for friendship and as his official position at Kew brought him into contact with the lovers of gardens and trees, not only in Great Britain but also all over the English-speaking world, these acquaintances ripened easily and at once into something warmer and more intimate.

He knew plants as few men did; he appreciated their points of interest and he liked to draw others into his own appreciations; I remember him perhaps at his happiest when at certain dinners, where gardeners or men of science met to exchange experiences, he was explaining the special features of things he had brought from Kew. This ease of intercourse was of great value to him officially. As a Government Department Kew Gardens belongs to the Ministry of Agriculture, its expenditure requires the sanction of the Treasury, its buildings, glass houses and the like have to be dealt with by the Office of Works. It is easy for any of these great offices to adopt an unsympathetic attitude to a relatively small spending organization which does not lie within the great stream of public affairs, but Hill's tact and friendliness smoothed the way to many improvements in the Gardens and in the conditions of work of its extensive staff.

Hill's contacts with gardening were many and various; he was closely-associated with the Royal Horticultural Society, from the council of which he only retired to edit on their behalf *Curtis's Botanical Magazine*, that record of new plants running back for more than a century and a half. He was long a member of the council of the John Innes Horticultural Institution, in the affairs of which his quiet judgment was always of value. No record of Hill would be complete that ignored his devotion to the Church and its social work; my last business with him was concerned with the education of two boys in difficult circumstances who had been brought to his notice through the Church.

Hill was not a player of games, his recreations were conversation and riding, and if the latter did bring him down at last, his end came instantaneously in the full tide of his enjoyment—and what better end can any man desire? A. D. HALL.

ONE evening early in 1907 Arthur Hill called at my house in Cambridge to discuss the prospects of an appointment of which he had just heard. The post in question was that of assistant director of the Royal Botanic Gardens, Kew, in itself an attractive one; but Hill was much attached to Cambridge and to King's, and the thought of leaving was disturbing. I knew of these Cambridge attachments, but I knew, too, something of the prospects offered by Kew under Sir David Prain, then recently returned from India, and I had no hesitation in strongly advising Hill to accept the London post.

I have never had any doubt, nor I feel sure had he, that this advice was right. The more one saw of Hill and of Kew, the plainer it was how well man and post were assorted. Of this, visitors to Kew had much evidence in the condition of the Gardens; but it was not so much from the broad general picture as seen by the public as from minor indications that Hill's deep love of Kew and all that Kew stands for were to be gained. Watch him, for example, exult as a friend fails to detect on some smooth lawn the spot where a month or two before a bomb-crater yawned; or, again, note his pleasure over the complete recovery of some tropical plant, saved from destruction by the temporary repairs effected to badly damaged glass. Or accompany him on some Sunday afternoon to the loose boxes in which were two fine teams of Suffolk horses waiting impatiently for the carrots which clearly were expected as soon as Hill was seen. Trivial things these, but pointers to conditions that make the duties of a post not merely matters to be attended to, but a worth-while job.

In recent years my own association with Hill arose chiefly from the fact that we were both members of the Council of the John Innes Horticultural Institution. Here his Kew experience was most helpful to Hill's colleagues, and his loss will be much felt.

Thomas H. Middleton.

My first recollection of Arthur Hill is of seeing him riding through the streets of Cambridge. My next is of attending six lectures he gave on Algæ in the Easter Term of 1906 when he shared the elementary course with R. H. Biffen and A. C. Seward owing to the illness of Marshall Ward. By that time he had travelled to Iceland and the Andes and had written short accounts of their vegetation; his chief interest was, however, in histology, his work on protoplasmic connexions being of fundamental importance. The following year he left for Kew.

I do not think that Hill seriously concerned himself with the practice of systematic botany. He had no flair for herbarium work possibly because the new order in botanical ideas prevalent in his student days apparently regarded such studies as worthless. He was, however, a keen observer of growing plants and attributed his interest in natural history generally to the stimulus of his Marlborough days. He published a number of small systematic monographs but was attracted mainly by general problems of taxonomy, particularly the origin of Monocotyledons, which interested him to the end. The plants growing at Kew provided him with material for a steady flow of notes and papers on morphology and development; at the last meeting of the Linnean Society he exhibited a Streptocarpus with cleistogamous flowers.

The Royal Botanic Gardens were to Hill almost a religion. No improvement he carried out, so far as I recollect, did anything but enhance their beauty.

After the War of 1914–18 there was money available for schemes of imperial development, and Hill, always keen on travel, characteristically made full use of his opportunities. He believed in the eminence and prestige of Kew and pushed his belief to the utmost. The Kew collections benefited from the contacts he made and he himself gained a wide first-hand knowledge of botanical conditions overseas, and in the years that followed continued and extended his interests. The tragedy of his death is that it should have occurred now, for his experience would have been invaluable in the reconstructions that are inevitable when peace ensues.

Arthur Hill was very much the boy at heart. He was the kindest of men, showing an understanding sympathy not only in the written word but also in unostentatious generosity to those in need.

J. Ramsbottom.

Mr. M. Ussishkin

Palestine and the Jewish people have suffered a great loss through the death in Jerusalem at the age of seventy-eight of Menachem Ussishkin. He was known as "the grand old man of Zionism", and his influence was felt in every Jewish activity in Palestine. But he had a particular love for the soil of Palestine, and for the last eighteen years of his life devoted himself to the buying of land in Palestine as the collective property of the Jewish people.

Ussishkin was closely associated with the Hebrew University in Jerusalem, which was inaugurated by the late Lord Balfour in 1925. He was a member of its Board of Governors, and attended the meetings of this body not only in Palestine, but also in many different centres in Europe. He was also a member of the executive committee of the University in Jerusalem. His enthusiasm for every branch of university life, and in particular his close personal contacts with successive generations of students, gave him a great influence on the development of the Hebrew University, which now has 1,100 students with a staff of more than 125 professors and lecturers.

Ussishkin's early training in his native land, Russia, was as an engineer, but he very soon became a leading figure in the movement for the return of the Jews to Palestine, and later in the Zionist movement. He was particularly ardent in the support of the movement to revive Hebrew as a language of daily intercourse, and as a language of literary and scientific writing.

Ussishkin's most obvious characteristics were indomitable courage and uncompromising adherence to principles. At the same time he was the kindest and the most courteous of men. When he died, 50,000 people followed his coffin to the grave, for Palestine had lost in him its greatest figure.

We regret to announce the following deaths:

Mr. V. M. Foster, geologist in the U.S. Geological Survey, on September 2, aged thirty-seven.

Prof. A. C. Fraser, professor of plant breeding in Cornell University, on September 17, aged fifty-one.

Prof. E. E. Maar, professor of the history of medicine in the University of Copenhagen, aged sixty-eight.

Mr. J. D. Martin, assistant conservator of forests, Northern Rhodesia, on November 10, aged thirty-two.

NEWS AND VIEWS

Royal Society Medallists

HIS MAJESTY THE KING has been graciously pleased to approve the recommendations made by the Council of the Royal Society for the award of the two Royal Medals for the current year, as follows:

Prof. E. A. Milne, Rouse Ball professor of mathematics in the University of Oxford, for his researches on the atmospheres of the earth and the sun, on the internal constitution of the stars, and on the theory of relativity;

Prof. E. L. Kennaway, professor of experimental pathology in the University of London, and director of the Chester Beatty Research Institute, Royal Cancer Hospital (Free), for his investigations on production of cancer by synthetic substances.

The following awards of medals have been made by the President and Council of the Royal Society:

Copley Medal to Sir Thomas Lewis, physician-in-charge of the Department of Clinical Research, University College Hospital, London, for his experimental researches in the clinic and the laboratory, on the heart and the circulation, and their disorders.

Davy Medal to Dr. H. D. Dakin, director of the Research Laboratory, Merck Institute of Therapeutic Research, Scarborough-on-Hudson, New York, for his work as a pioneer in biochemical research and especially because of his fundamental contributions to the study of intermediate metabolism.

Hughes Medal to Prof. N. F. Mott, Melville Wills professor of theoretical physics in the University of Bristol, for his fertile application of the principles of quantum theory to many branches of physics, especially in the fields of nuclear and collision theory, in the theory of metals, and in the theory of photographic emulsions.

The Student Martyrs of Prague

NOVEMBER 17 was the second anniversary of the shooting by the Germans in Prague of ten Czechoslovak students, and was observed as an International Day of Students. On November 16 a commemoration meeting was held in the Caxton Hall, London, and was attended by students from more than twenty nations. The following stimulating declaration was made and has since been broadcast to students in all parts of the world: "We declare that November 17 shall always be for us not only the day on which free students everywhere shall pay tribute to their dead Czechoslovak fellows, and to those who are still in prison and concentration camps, but it shall also be the day when we will remember with fervent determination the ideals for which they suffered and are suffering. We free students give our solemn promise to do all that is in our power to crush this brutal Fascist violence, and to dedicate ourselves to preventing its renewal in any shape or form."

The persecution of students and intellectuals has not been confined to the Czechoslovak peoples; neither is it ended. The Yugoslav Government in London has recently announced that ruthless atrocities against the civil population have taken place in Kragujevac, in Central Serbia. The Germans are stated to have shot in that town 2,300 civilians in the last two weeks as a reprisal for the killing of 26 German soldiers. A large number of intellectuals have been taken out of their homes and shot. The Germans, not being able to find enough hostages among the adult population, have arrested hundreds of students between the ages of sixteen and eighteen, and some of these have already been executed.

Men of Science and the National War Effort

IN view of the widespread feeling that our scientific and technical resources are not being used to the best advantage in the national effort, that much valuable knowledge and experience is being wasted through sufficient responsibility not being given to scientific workers, and that a number of scientific workers have grievances, caused by irregular conditions of working, which unnecessarily discourage them from putting out their maximum effort, the Association of Scientific Workers is calling a series of regional conferences at which men of science, engineers, technicians and laboratory assistants can discuss their problems and decide on appropriate action. Much of the responsibility for improvement of the situation must be borne by all classes of scientific workers. It is therefore to be hoped that the fullest co-operation of all concerned will be obtained.

At the first of these conferences, which will be held in Birmingham on December 6 from 2.30 until 5.30 p.m., at the Royal Society of Artists, New Street, Birmingham, the discussions will be opened by Mr. D. P. Riley, who will speak on "The Responsibilities of the Scientist to the Community"; Mr. J. A. Henley, on "The Position of the Scientist in Industry"; and Mr. E. D. Swann on "The Rôle of the Scientist in the National Effort". The meeting will be open to all scientific workers.

Committee on Producer Gas Fuel

THE Secretary for Mines has asked the committee which considered low-temperature carbonization processes last year to reassemble, and to examine the sources of fuel for producer gas vehicles, to estimate the quantities that could be made available at present, and to report on the measures that would be required to increase the supplies if necessary. The committee will also inquire whether the development of the peat resources of Great Britain would make any useful contribution to the supplies of domestic fuel in the present coal situation. The constitution of the committee is: Lord Henley (chairman); Mr. Gordon Macdonald, M.P.; Dr. W. H. Mills, lately reader in

stereo-chemistry in the University of Cambridge; Mr. F. B. Richards, chairman of Woodall-Duckham Company; Mr. J. Shearman, road motor engineer, L.M.S. Railway; Mr. T. E. B. Young, general manager, Bolsover Colliery Company; Mr. W. A. Macfarlane (secretary); and Dr. F. S. Sinnatt, director of fuel research (Department of Scientific and Industrial Research), and Mr. J. A. Brook, Mines Department, assessors.

Bibliography of the British Fauna and Flora

ONE of the difficulties facing anyone wishing to study a group of British animals or plants is that of obtaining reliable information on books and papers that will be helpful in their identification. The Association for the Study of Systematics in Relation to General Biology, one of the aims of which is to encourage wider and more serious studies in systematics, therefore decided to compile a bibliography on the subject. This laborious task has been accomplished with the help of various experts, mainly of the British Museum (Natural History) and the Royal Botanic Gardens, Kew, and the book is expected to appear shortly. It contains systematically classified lists of books and papers which may be consulted when studying any given group of British animals or plants. Brief notes on the character and contents of each book and paper are given, so that an idea can be formed as to whether it answers any particular requirements. The whole forms a most useful guide for systematic studies and is certain to achieve its purpose of stimulating scientific interest in the British fauna and flora. Further information can be obtained from the Secretary of the Society at the British Museum (Natural History), Cromwell Road, South Kensington, London, S.W.7.

American Foreign Policy

UNDER the title "American Foreign Policy" Prof. D. W. Brogan has given (Oxford Pamphlets on World Affairs, No. 50. 4*d.* net) a brilliant and concise interpretation of the traditional outlook of the United States on world affairs, the policy which she has followed in recent years and the machinery by which that policy is carried out. The pamphlet should make a valuable contribution to that mutual understanding by the two peoples upon which alone effective collaboration can be based. What Prof. Brogan has to say about the United States as a missionary of freedom and of American sympathy with democracy, no less than his explanation of the machinery of American foreign policy and of the real meaning of the Monroe doctrine, should go far to remove some of the difficulties which the ordinary citizen of Great Britain experiences in understanding, and still more in reconciling, the high moral line taken in foreign affairs by American public opinion, and the much more realistic attitude of the Administration. In this lucid account, written with admirable detachment, particular attention is given to the development of policy since 1918, including the "Good-Neighbour" policy, the reactions of the rise of Nazism and the collapse of France on the Monroe doctrine and its application or interpretation and the influence of the war debts on American opinion. Prof. Brogan has rendered real service to Anglo-American collaboration and all that it involves by this admirable exposition of the 'neutrality legislation' and the factors weakening extreme isolationism and bringing the two democracies to such a declaration of common policy as that contained in the Atlantic Charter.

The Genetical Society of Great Britain

DURING the first year of the War the British Genetical Society, which has a membership of 146, held only its annual meeting. From the summer of 1941 it may be said, however, to have resumed its normal activities. Two meetings have been held, at the Rothamsted Experimental Station and at Oxford. On each occasion papers were read and members demonstrated a considerable series of exhibits. Although winter meetings are still impossible, it is hoped to commence a full programme next year with a meeting in the early spring. The present officers of the Society are: *President*, Prof. R. A. Fisher; *Vice-Presidents*, Dr. C. D. Darlington, Prof. Julian Huxley, Dr. R. N. Salaman; *Treasurer*, E. R. Saunders; *Secretaries*, Dr. K. Mather, Dr. E. B. Ford.

Announcements

ACCORDING to a Dutch correspondent of *The Times*, the German authorities in Holland have closed the University of Leyden. After November 20 no examinations are being held there, but the students will be allowed to sit for examinations at other Netherlands universities, and will be admitted to German ones. Lectures at Leyden were discontinued a long time ago (see NATURE of February 8, p. 161).

THE following appointments in the Colonial Service have recently been made: E. D. Bumpus, agricultural superintendent, Nigeria; A. E. Kerr, assistant Government chemist, Trinidad; J. E. Cousens, assistant conservator of forests, Malaya; A. P. D. Jones, assistant conservator of forests, Nigeria; J. J. Laurie, assistant conservator of forests, Gold Coast; G. H. Thompson, assistant conservator of forests, Gold Coast; R. J. Osborne, surveyor, Uganda; D. Westwood, agricultural officer, Gold Coast; Dr. A. W. R. Joachim (agricultural chemist), divisional and research staff officer, Ceylon.

A CENTRAL sales branch has been organized for all work connected with subscriptions, sales and distribution of the journals and other publications of the majority of the Imperial Agricultural Bureaux; its offices are at the Agricultural Research Building, Penglais, Aberystwyth. The only publications not dealt with by the central sales branch are those of the Imperial Institute of Entomology (Assistant Director, Imperial Institute of Entomology, 41, Queen's Gate, London, S.W.7) and the Imperial Mycological Institute (Director, Imperial Mycological Institute, Ferry Lane, Kew, Surrey), and *Nutrition Abstracts and Reviews* (Secretary, Imperial Bureau of Animal Nutrition, Rowett Institute, Bucksburn, Aberdeen).

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

Auxin Production during the Development of the Grain of Cereals

IT has been shown by Gregory and Purvis[1,2], Kostjucenko and Zarubailo[3,4] and others that the developing grain can be vernalized in the ear during the period of embryo formation. It has further been suggested by Cholodny[5,6,7] and others that auxin or a similar hormone plays an important part in the vernalization process. It appeared important therefore to undertake a direct study of the auxin relations in developing grain of both spring and winter varieties of cereals. The work was carried out with pure-line spring and winter varieties of Petkus rye. At known intervals after anthesis grains were removed from the ears and the auxin content determined by Went's coleoptile method. The hormone was obtained in two ways: (1) direct diffusion into agar, (2) extraction of the ground fresh material in water and subsequent concentration under reduced pressure. Relevant details of the methods will be published elsewhere.

It was found that no diffusible or extractable hormone appears in the developing carpel until two weeks after anthesis, but from this time forward rapid production of auxin occurs reaching a maximum at some 5–6 weeks after anthesis. The maximum is simultaneous with the stage of complete differentiation of the embryo. In the interval mentioned the auxin content has increased nearly a hundredfold. The data are presented in the accompanying table and refer to (*a*) winter rye grown in the field, (*b*) winter rye grown in sand culture with controlled nutrition, (*c*) spring rye. No consistent differences are seen between the varieties; so that the different behaviour of these types with regard to their low temperature requirements for flowering cannot be accounted for on the basis of auxin production during development.

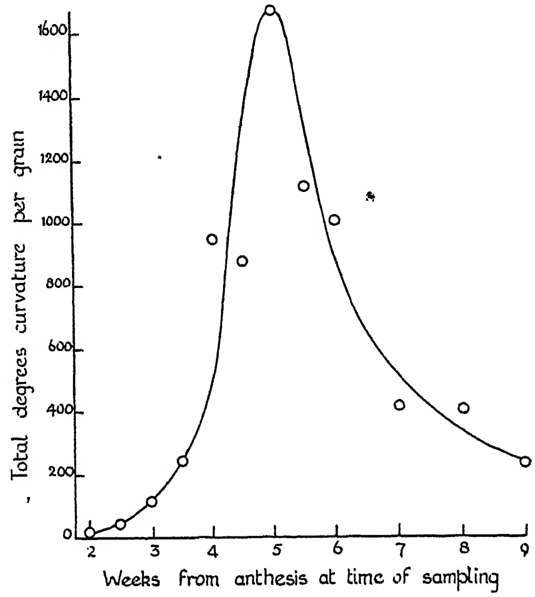
The mean values are presented graphically in the figure. It will be noted that after the maximum hormone content has been attained a rapid fall follows, so that in the completely mature grain the hormone content is so low that the diffusion method fails to detect its presence, though by extraction it can still be demonstrated. The apparent disappearance of the hormone is related closely to desiccation of the grain and has been found to be associated with its germinating capacity. It is worth noting that the hormone is confined to the endosperm and at no time

Auxin Content per Grain at Various Stated Times after Anthesis Measured by Extraction Method.

Weeks from anthesis	Winter rye in field	Winter rye in sand culture	Spring rye
2	18	—	—
2·5	—	45	35
3	96	122	116
3·5	—	240	—
4	865, 810	768	1210, 1120
4·5	—	877	—
5	1419	2301	1260
5·5	—	1113	—
6	357	789	1874
7	270	—	560
8	—	—	402
9	234	—	—

All values given in total degrees curvature per grain

$$= \frac{\text{Mean curvature} \times \text{dilution (c.c.)} \times 100}{\text{Number of grains in sample extracted}}$$



is sufficient auxin present in the embryo to detect it by the methods employed. In view of the low content of auxin in the mature endosperm of rye it may be pointed out that other cereal grains have been examined. The large hormone content of dry maize endosperm first shown by Cholodny has been confirmed. Oats is found to occupy an intermediate place, and diffusible auxin from this grain has been estimated. Wheat and barley resemble rye in that no diffusible auxin could be established.

Egg-laying of Ducks as an Enforced Relaxation Oscillation

THE formation and deposition of a bird's egg can be described as a relaxation process[1], the egg material being piled up gradually and released suddenly. The sustained production of eggs can then be regarded as a series of relaxation oscillations. In an undisturbed relaxation system discharges take place when the accumulating material (energy) reaches a certain level, but the length of period may change if the stream of material (energy) varies. If a bird were

an undisturbed relaxation system, eggs of fairly constant size would be expected at varying intervals according to the amount of food available. This is not the case in ducks, where eggs of varying size are deposited regularly in the morning on consecutive days, sometimes for months, with pauses of one, seldom two or more days, between each clutch.

Now constant period length and variable amplitude, although foreign to relaxation oscillations, are characteristic of the well-known type of sinoidal oscillation. A duck's egg-laying activity combines features of both types of oscillations. This is due to the synchronizing of an external sinoidal 24-hour rhythm on the relaxation system, as can be shown by the following facts. The eggs of a clutch decrease in weight so that the first egg is usually the heaviest and the last egg the lightest. The differences between the biggest and smallest egg laid by one duck are not great (c. 20 per cent) and extremely small eggs (35 gm.) and big eggs (double-yolked eggs more than 110 gm.) are exceptional.

Tables 1 and 2 show the decrease of egg weight from the beginning to the end of the clutch.

TABLE 1.

The mean deviation from the dam's mean egg weight of 570 eggs according to position in the clutch.

Position of egg in clutch	1	2	3	4	5	6	7
Weight of egg relative to the mean (gm.)	+3·42	+2·54	−0·09	−1·99	−2·41	−2·43	−3·12
Number of eggs	105	105	105	105	70	52	28

TABLE 2.

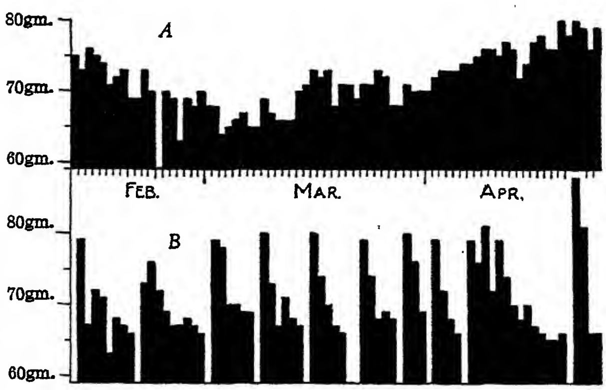
Mean weight of the last five eggs in 161 clutches of at least five eggs, laid by 24 Aylesbury × White Campbell ducks.

Position of egg in clutch	5th last	4th last	3rd last	2nd last	last
Mean weight in gm.	76·04	74·90	73·26	72·79	72·03

Some ducks lay eggs on more than two hundred consecutive days, others pause more frequently. If the egg weights of two such birds are compared, it is seen that the decrease in weight is much more rapid in the latter than in the former (see accompanying figure). It seems that the ovary or oviduct of the former cannot produce enough material completely to replace the egg laid twenty-four hours earlier, and hence the eggs decrease in weight until a limit is reached where no egg is laid at all. During the pause more material is accumulated and so the first eggs of the next clutch are again bigger.

For the occasional occurrence of pauses of two or more days only a historical explanation can be suggested. The wild duck lays two or three clutches of eggs each season, each clutch being separated by a period during which the eggs are brooded and the ducklings reared. Once the laying of a clutch ceases there seems to be some mechanism which delays the resumption of laying. In the domestic duck, which has its eggs removed and is not encouraged to brood, this blocking mechanism is eliminated, but not completely. It may be mentioned that broodiness is known to be inherited in hens[2].

The synchronizing 24-hour rhythm is probably the light rhythm, but it remains to be decided experimentally whether it produces its effect through its action on the endocrines[3,4] or by the determination of feeding periods. A diurnal rhythm of the genital tract has so far only been described for female rats[5].



WEIGHTS OF ALL EGGS LAID BETWEEN FEBRUARY 10 AND APRIL 25, 1931; *A*, BY A DUCK LAYING CONTINUOUSLY; *B*, BY A DUCK LAYING INTERMITTENTLY.

The yearly period also influences egg-laying, the weight of the ducks' eggs increasing during the laying period, as has been recently shown[6]. As can be seen in Table 3, not only heavier eggs, but more eggs are laid as the year goes on and the clutches increase in length. Probably both the stream of assimilated material and the egg-producing organs are influenced by seasonal factors.

TABLE 3.

Mean production of eggs per day, and number of days where no egg was laid. 24 Aylesbury × White Campbell ducks.

Month	Egg per day	Free days in month
October	0·04	29·60
November	0·05	28·37
December	0·09	28·13
January	0·15	26·46
February	0·50	13·58
March	0·75	7·58
April	0·70	8·38
May	0·60	12·25
June	0·37	18·79
July	0·07	28·83

The egg production of ducks as described above shows a close formal resemblance to electro-physiological phenomena, as for example, the normal or pathological action of heart and muscles[7], and to related biorhythmic processes.

I wish to thank Mr. J. M. Rendel for permission to use his data on egg weights.

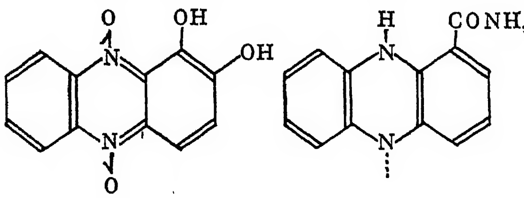
Antibacterial Action of Two Bacterial Products of Known Structure

THE importance of inhibitory compounds in normal living systems, as distinct from their artificial introduction for example, as therapeutic agents, is being increasingly realized. In particular, substances have been isolated from certain micro-organisms which inhibit the growth of other species (for detailed references see Waksman and Woodruff[1]). The structures of the majority of these compounds are not yet known, and in view of their importance as possible therapeutic agents or as models for such agents, the following results with two bacterial pigments of known composition are given.

The pigment of *Chromobacterium iodinum* was isolated and shown to be the N.N′-dioxide of a dihydroxyphenazine (probably I) in 1938.[2]



I II

In connexion with other work in this laboratory, its effect on the growth of *Bact. coli* and *Streptococcus hæmolyticus* was recently investigated. The compound was found differentially inhibitory to a marked degree, and its effect on the growth of one strain each of other organisms was briefly surveyed.

It is seen that approximately 2 µgm./ml. of the pigment prevents visible growth of *S. hæmolyticus* in liquid media; this inhibitory power is of the order of those recorded for the more active of the natural inhibitory substances. Like other substances, its action is greatest against the Gram-positive organisms investigated; the order of susceptibility of the organism is also that of increasing nutritional complexity. Inhibition was also exhibited on solid media: 2 µgm. of the pigment prevented growth of *S. hæmolyticus* within a radius of 1 cm. In growth, *Chr. iodinum* can produce 100 µgm. of pigment per sq. cm.[2].

A synthetic specimen of chlororaphin (II, formulated as a phenazyl[3]) which was prepared in 1934[4] in confirmation of the structure of Kögl and Postowsky[5] was also found inhibitory, but to a lesser degree. Pyocyanin is already known to be inhibitory to bacterial growth and metabolism[6]. Thus the three known types of naturally occurring phenazine compounds, which are all bacterial pigments, can be of functional value to the organisms producing them, by antagonizing the growth of competing organisms.

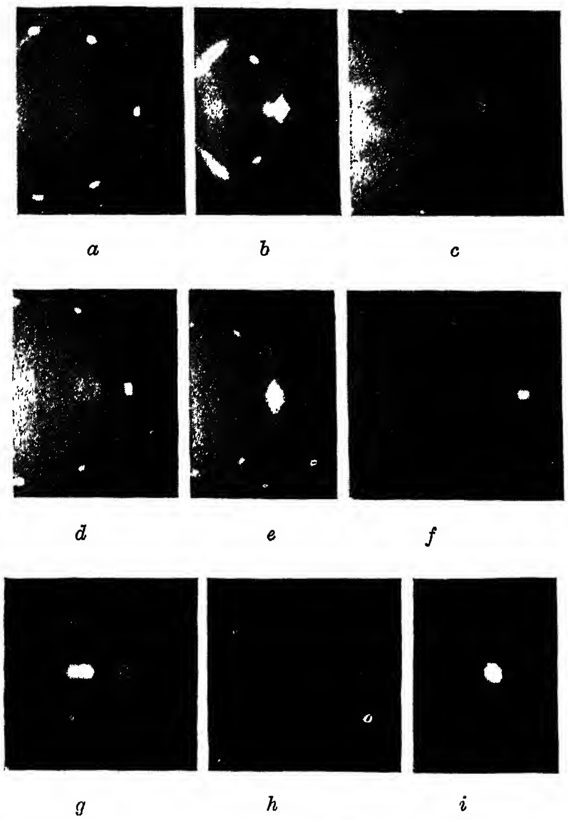
X-Ray Diffuse Reflexions from Sodium and Lithium in Relation to Elastic Anisotropy

WE have photographed the diffuse X-ray reflexions from a number of single crystals of lithium and of sodium at various temperatures. Both show beautiful and elaborate patterns of spots and streaks, which are temperature-sensitive but not structure-sensitive.

Dr. Jahn has recently[1] given an expression for the coherent diffuse scattering from a cubic crystal, based on the Faxén-Waller theory of thermal vibrations. He has applied the formula to sodium, using the known values of the elastic constants to predict the exact detail of the diffusely reflecting region around each reciprocal lattice point. One significant consequence of the theory is that for an elastically anisotropic cubic crystal (that is, when $c_{11} - c_{12} \gtrless 2c_{44}$) the *distribution of reflecting power is different for different reciprocal lattice points* while, other things being equal, the *intensity* at a given distance from any lattice point varies inversely with the absolute values of the elastic constants. A soft, elastically anisotropic substance of simple structure, such as sodium, is therefore ideal for the purpose of testing

the theory. It may be deduced from Dr. Jahn's calculations, for example, that when the $[1\bar{1}0]$ axis is vertical, the copper $K\alpha$ diffuse (110) reflexion from sodium should consist of an approximately square group of four spots when the angle of incidence is considerably less than the appropriate Bragg angle, but that this square closes up and a strong vertical streak (parallel to $[1\bar{1}0]$) appears through it as $\theta \rightleftarrows \theta_{\text{Bragg}}$. The (002) diffuse reflexion should be



(a) Na ; unfiltered, $\theta_{110} = 19{\cdot}9° = \theta_B + 5°$; 3·0 cm.
(b) Na ; unfiltered, $\theta_{110} = 14{\cdot}9° = \theta_B$; 3·0 cm.
(c) Na ; filtered, $\theta_{002} = 23{\cdot}3° = \theta_B + 2°$; 3·0 cm.
(d) Li ; unfiltered, $\theta_{110} = 21{\cdot}1° = \theta_B + 3°$; 3·0 cm.
(e) Li ; filtered, $\theta_{110} = 18{\cdot}1° = \theta_B$; 3·0 cm.
(f) Li ; unfiltered, $\theta_{002} = 28{\cdot}0° = \theta_B + 2°$; 3·0 cm.
(g) Na ; unfiltered, $\theta_{112} = 24{\cdot}4° = \theta_B - 2°$; 3·0 cm.
(h) Na ; unfiltered, $\theta_{112} = 28{\cdot}4° = \theta_B + 2°$; 3·0 cm.
(i) Na ; filtered, $\theta_{002} = 21{\cdot}3° = \theta_B$; 4·0 cm.
Radiation from copper target ; $[1\bar{1}0]$ crystal axis vertical throughout.

quite different, its shape being rather like that of a pair of scissors when $\theta \gtrless \theta_{\text{Bragg}}$, and like a flattened cross when $\theta = \theta_{\text{Bragg}}$. In particular, *the vertical streak parallel* $[1\bar{1}0]$ *should not be present for* (002). This difference is readily explained by the introduction of the elastic anisotropy ; it is a direct consequence of the relationship $c_{11} - c_{12} \ll 2c_{44}$. The disappearance or reversal of sign of the elastic anisotropy would completely change the detail of the individual diffuse spots, even for a crystal of exactly the same crystal structure and unit cell size.

The diffuse spot detail observed for the {110}, {002}, {112}, {130}, {222} planes of sodium, using filtered or unfiltered radiation from a copper target, is just that predicted by the theory. A few examples of Laue photographs taken in various orientations are shown to illustrate this, and exact measurements of the reflecting regions around different reciprocal lattice points will be published later.

The diffuse spot detail for lithium is very similar to that of sodium, and it follows therefore, from X-ray observations alone, that the elastic constants are roughly of the same order of magnitude and anisotropy for the two metals.

It has recently been suggested, on the basis of intensity measurements of powder reflexions, that lithium is not isomorphous with sodium, but crystallizes in a unit cell containing eight Li_2^+ molecules[2]. Laue and rotation photographs of the single crystals do not confirm these suggestions ; on the contrary, all the evidence points to a simple, body-centred cubic, two-atom unit cell of Laue symmetry *m3m*, as correctly assumed by all previous investigators.

Rigidity and Moisture Hysteresis in Gels

SEVERAL equations have been suggested for the swelling pressure of a hygroscopic gel, of which the best known is the approximate form due to Katz[1]. Porter[2] gives an exact and general equation for the osmotic pressure of a solution. We may, for simplicity, conform to the usual conceptions of swelling pressure and restrict Porter's equation to the case where the only pressure exerted on the solvent is that of its own vapour ; giving

$$\int_{h_1}^{p_1} s\,dp = \int_{h_1}^{h_2} v\,dh \qquad (1)$$

Here p is the applied pressure ; $(p - h_0)$ is the osmotic or swelling pressure required to raise the vapour pressure of the solution to saturation h_0 from its initial value h_1, without change in concentration, s is equal to $\frac{(\partial v)}{(\partial m)_p}$ that is, the change in volume V of the solution per unit mass of solvent removed or added at constant pressure, and V is the specific volume of the solvent vapour under the pressure h. By making V represent the volume of solution containing unit mass of dry solute, m becomes identical with the moisture content defined as the mass of solvent per unit mass of dry solute. Katz's equation may be obtained from this by assuming s to be equal to the specific volume of free water and therefore a constant.

Porter's equation is valuable because the term s stresses the importance of the elastic properties of the solution (that is, its bulk modulus). Now, gels differ from solutions elastically because in addition to the bulk modulus they have rigidity and are partially plastic. They also differ hygroscopically because gels show hysteresis in the $(m ; h)$ isothermal, whereas the $(m ; h)$ curves for solutions are reversible. The purpose of this note is to account for the hysteresis in a gel in terms of its elastic properties.

Using a derivation similar to Porter's, but allowing for shear stresses, we can obtain

$$\int_{p_{k_1}}^{p_{k_2}} s_k dp_k + \int_{p_{n_1}}^{p_{n_2}} s_n dp_n = \int_{h_1}^{h_2} v dh \qquad (2)$$

Here p_{k_0} and p_{n_0} are the hydrostatic and shear components of the directional stresses applied to raise the vapour pressure of the gel to h_0 without change in moisture content, s_k is Porter's s involving only volume change and s_n is V times the change in shear strain per unit change in moisture content.

If the shear components contained in the second integral are elastic, the work done on the gel during adsorption is recoverable on desorption and this process is reversible. If they are plastic, the work done in shear will not be recoverable and an equal work must be done again on desorption, so that the second integral in equation (2) will not change sign.

Once the plastic shear stresses have disappeared p_{k_0} will become equal to Porter's p, so the first integral is independent of plastic shear components. The second integral is always positive so it is evident that $\int vdh$ must be greater on adsorption than on desorption, which is possible if, at any moisture content, the adsorption vapour pressure be greater than the desorption, except at the upper and lower limits of the integrated cycle.

This appears to be a valid explanation of the hysteresis in gels. If the gel is only partially plastic, hysteresis will still occur, but to a smaller extent, so the narrowing of the hysteresis loop at lower vapour pressures is thus explicable in terms of the increasingly elastic behaviour of gels as they become drier.

Some explanations of hysteresis which have been suggested, for example by Zsigmondy[3] or McBain[4], can only be valid for liquid held by capillary forces and cannot account for hysteresis in liquid held by purely molecular sorption on the surfaces of the micelles but, in wood at any rate, there is also evidence of hysteresis in molecular sorption[5]. Urquhart[6] postulates that the swelling of the gel opens up fresh intermicellar surfaces to the sorption, and this is probably true, but it is difficult to see why this effect should not be reversible if sufficient time is given for equilibrium to be established on desorption, unless the deformation is plastic.

The points in favour of the theory of hysteresis here presented are (1) that it depends only on considerations of energy, and (2) that it is accounted for in terms of those elastic properties which distinguish gels from solutions.

The work done in shear will depend on restraints imposed on the gel during moisture changes and will not be a property of the gel itself. The restraints may, however, be inherent in the form in which the gel usually occurs, so evidence is required to show that shear stresses are likely to occur during actual drying or wetting. In wood we have a material which provides definite evidence of shear stresses arising, during natural shrinkage, from the ordered change in shape of the cell structure. During drying, the shrinkage (change in volume per unit volume) of the external dimensions of the hollow cell is considerably less than that of the cell wall material, owing to the restraint imposed by the thin outer sheath (the primary wall) in which the cell is encased, and the area of the void centre therefore becomes a larger proportion of the total cross section. This introduces a shear strain in the cell wall which may be approximately determined. The gel material of other natural fibres is likely to have similar restraints imposed on it during shrinkage. In amorphous gels also, it is probable that shear stresses are introduced because they consist of a network of micelles and it seems unlikely that, by removing water, a reduction in the external dimensions of such a network would be possible without distorting the interlocking meshes. The micelles possess rigidity so some work will be done during this distortion and, if they are partially plastic, the hysteresis must result.

The Sligo Artefacts

WHEN, in 1927[1], I announced the discovery of the Sligo artefacts, it was asserted, by certain observers, that these specimens were not of human origin, but had been flaked by wave-action which, at times, is very powerful on the west coast of Ireland.

During 1941, fourteen years after my discovery was made, I again visited Sligo, and found that no further specimens, such as I had collected originally, were visible upon the site. Indeed it was obvious that no fracturing by wave-action of the limestone rocks there had taken place since 1927; though, if such fracturing were a reality, the conditions present appeared to be admirably suitable for its successful operation.

The Sligo evidence thus disposes of the claim that wave-action is capable of fracturing hard limestone rock in a manner indistinguishable from intentional human flaking.

Symbiosis of Men and Animals

WHEN Sturt discovered the Darling River he left the following notes, for which I am indebted to Mr. Charles Daley, secretary of the Historical Society :

1. "The channel of the river was from 70 to 80 yards broad, and enclosed an unbroken sheet of water evidently very deep, and literally covered with pelicans and other wild fowl."

2. "Yet as I stood upon its bank at sunset, when not a breath of air existed to break the stillness of the water below me and saw the surface kept in constant agitation by the leaping of fish I doubted whether the river could supply itself so abundantly."

Where now are the pelicans and the fish ? And we may echo, where are the vast numbers of seals that were in Bass Straits ? And where are the fish which were also abundant ? The fish scarcity is entirely man made, and if men act sensibly they can rectify much of the damage ? It will be noted that though pelicans were abundant, so were the fish. There is a symbiosis both with regard to pelicans and fish, and seals and fish. The experience of the Priviloff Islands makes that perfectly clear.

RESEARCH ITEMS

Archæology of Buena Vista Lake, California

The Smithsonian Institution has recently issued a volume on the "Archæological Investigations at Buena Vista Lake, Kern County, California" by Waldo R. Wedel (Bureau of American Ethnology, Bull. 130). Buena Vista Lake lies at the southern end of the great Californian valley which runs roughly north and south inland and parallel to the Pacific coast. Houses were excavated and a rich haul of finds resulted. These included objects made from steatite, chipped and ground stone, basketry (both coiled and twined), as well as skeletal remains. There were two main culture levels. It would appear that contacts with folk to the north, settled further down the San Joaquin River, can be predicted, but probably too, especially at the time of the later culture levels, some connexion was established with the folk of the Santa Barbara coast region which, though the other side of the hills, is only some fifty to sixty miles away and reached by several passes. At no time were the Buena Vista people highly civilized, indeed their economy was always elementary. Especially was this true of the earliest occupation where the mano and mealing slab occurred to the exclusion of the pestle and mortar, and the material culture was of the simplest. The dead were buried in the extended position in shallow graves near the camping-grounds. The date of this first occupation is unknown, but at least one of the sites would have been later for a time uninhabitable when, as shown by the deposits, the general level of the lake rose during a period of greater precipitation. The more recent culture shows several distinctive traits and was considerably more developed, perhaps because of its greater contact with the Santa Barbara coastal region. While the results of the investigation do not appear to be startling, they do supply important information about the archæology of a little-known area and fill in one more gap in the regional survey of Southern California.

Horticultural Development of the Cauliflower and Broccoli

An interesting paper by Walter F. Giles (*J. Roy. Hort. Soc.*, 66, Pt. 8, August, 1941) traces the horticultural history of cauliflower and broccoli derivatives from the wild *Brassica oleracea* of our sea-shores. Cauliflowers probably originated in Cyprus, but the time of their appearance does not seem to be known with certainty. The earliest literary reference to a terminal proliferation suggestive of this plant is by Dodoens in 1559. He described the "Flourie Colewort" where "the small stems grow together in the centre, thick set, and fast throng together". Switzer apparently first mentioned broccoli by name in 1728, when he had three kinds growing in his garden at Vauxhall. A great improvement took place in the early years of the nineteenth century, when the modern conception of broccoli as a hardier variant of the cauliflower maturing in winter and spring was established. The origin of broccoli from *B. oleracea* was confirmed by Prof. Buckman, who in 1863 obtained a new hardy sprouting type from the wild plant without hybridization.

Diseases and Pests of Gladioli

The recent widespread increase in cultivation of gladioli has brought a corresponding increase in the number and severity of pests and diseases of this ornamental crop. Lucia McCulloch and C. A. Weigel have recently described these maladies as they affect the plant in North America (Farmers' Bull. No. 1860, Washington, D.C., May, 1941). Some diseases have migrated from other crops, but several parasites, including *Sclerotinia gladioli*, causing dry rot, *Penicillium gladioli* and *Fusarium oxysporum* var. *gladioli*, were associated with this host before the era of its intensive cultivation. The most severe and widespread insect pest is Gladiolus thrips, which appeared in the United States in 1929, and spread rapidly, even threatening the future existence of the crop. Methods of control for this and the other maladies are described in the bulletin.

The Larger Fungi of Trinidad

Three preliminary lists of the fungi of Trinidad appeared between 1911 and 1931, but R. W. Rayner has now published a more detailed account (Memoir No. 6, Imp. Coll. Trop. Agr., Dept. of Mycol. and Bacteriol., Trinidad, April, 1941). The fungi are classified according to a North American system by Murrill. Most of the thirty-five species now listed are somewhat infrequent members of the European flora, but *Pluteus cervinus*, *Psalliota campestris* and *Auricularia Auricularia-Judæ* appear to be as common in this tropical region as they are in Great Britain.

Earthquakes in India

The seismological bulletin of the Government of India Meteorological Department for April, May and June 1940 has just been received. At Agra 82 earthquakes and tremors were registered during the quarter and at the other observatories of Bombay, Calcutta, Colombo (Ceylon), Dehra Dun, Hyderabad and Kodaikanal about the same number were recorded by the seismographs. Some of the earthquakes registered were world-shaking earthquakes from distant epicentres such as the great Peru earthquake of May 24, but a considerable number were shocks in India and the surrounding countries from Persia to southern China. The earthquakes of India and Burma, macroseismic evidence of which has been collected by J. M. Sil at Poona, numbered 7 during the quarter. The first, on April 10, was slight and had an epicentre near 29° N., 81° E. in Nepal; the second, on April 19, was felt at Gauhati, scale 5 (Rossi-Forel); the third, on April 25, was felt at Drosh (scale 6); the fourth, on May 11, had an epicentre near 23° N., 95° E. in Upper Bumar; the fifth, on May 13, was felt at Katamandu in Nepal (scale 5); the sixth, also on May 13, was felt at Dibrugarh (scale 6) and the seventh, on May 27, was felt at Srinagar (scale 6) and Peshawar (scale 4). This last had its epicentre in the Hindu Kush Mountains near latitude 36·5° N., longitude 70·5° E. and its depth of focus was greater than normal, being between 180 and 200 km. deep.

Earthquake Intensities

R. C. Hayes has recently examined the connexion between the intensities of earthquake shocks estimated by means of macroseismic data collected by 132 observers in New Zealand and the same intensities estimated from seismograms ("Measurement of Earthquake Intensity", R. C. Hayes, Bull. S. 61, Dominion Observatory, Wellington, New Zealand,

1941). In New Zealand, Jagger-type strong-motion seismographs were found difficult to standardize effectively and so Wood-Anderson torsion seismometers are being installed. Four of these latter are now in operation in New Zealand, and the logarithmic scale of intensity initiated by Gutenberg and Richter is being used in their interpretation. A plot of instrumental magnitudes so obtained against the surface intensity (Rossi-Forel scale) shows some scatter, which Hayes attributes to variations in depth of focus. In southern California the smallest reported earthquake felt was 1·5 on the logarithmic scale, but on the same scale in New Zealand the smallest felt is seldom less than 3. In New Zealand magnitude $4 \equiv R.F.\ 4$, magnitude $5 \equiv R.F.\ 6$–7 and destructiveness begins about magnitude $6 \equiv R.F.\ 8$.

Molecular Weight of Gliadin

THE molecular weights of gliadin, the protamine of wheat, determined by different methods have been discrepant. The protein is inhomogeneous but the predominant fraction has been separated. Sedimentation gave 27,000, diffusion 27,500, and the shape of the dielectric constant – frequency curve 27,000 for the molecular weight, whereas amino-acid determinations and osmotic pressures gave 42,000 and 40,000–44,000, respectively. P. P. Entrikin (*J. Amer. Chem. Soc.*, 63, 2127; 1941) has redetermined the dielectric constant – dispersion curves with fractionated gliadins. It appears that previous results were not made over a sufficient range of frequencies, and the range 25,000–30,000,000 cycles per sec. was used. The results are accounted for quantitatively by the theoretical equations if the molecules are assumed to be ellipsoidal with a ratio of 8 for the major to minor axes. The molecular weight is 38,000. The results of dielectric constant – frequency, amino-acid, and osmotic pressure methods are thus brought into fairly satisfactory agreement, and gliadin comes into line with zein, the alcohol-soluble protein from maize, for which the molecular weight determinations are 39,000 from composition, 38,000 from osmotic pressure, 40,000 from sedimentation and diffusion, and 38,000 from dielectric constant – dispersion experiments. The high value 8 for the ratio of major to minor axis is similar to that for zein, and these are practically the only molecules belonging to the 40,000 molecular weight class with such high dissymmetry. Dipole moment calculations show that gliadin is much less polar than zein.

Mechanical Behaviour of Bitumen

A TECHNICAL report on the "Mechanical Behaviour of Bitumen", by W. Lethersich, has been issued by the British Electrical and Allied Research Association (Ref. A/T 83. Pp. 28. 15*s*.). Using the classification for bitumens adopted in B.S. No. 688, the author gives the results obtained on six samples of bitumen. He determines also the temperature at which softening occurs, and illustrates apparatus for measuring the extensions of bitumen rods under load and how these extensions are effected by heat. The variation of viscosity with temperature is explained by the fact that the asphaltenes become more widely separated as the temperature increases, thus allowing the dispersion medium to flow more readily between them. The principal conclusions arrived at are that the mechanical properties of bitumen may be represented by an equivalent circuit, either mechanical or electrical, comprising elements containing four physical constants, namely, two viscosities and two elasticities. A knowledge of these constants enables the reaction of a given material to be predicted for various kinds of stress and the regions of plasticity and brittleness to be determined. Bitumen is largely used for the insulation of electrical apparatus and of cable joints and so the problem of 'cracking' due to sudden overloads of current causing mechanical stress is both important and interesting physically. The static value of the bitumens tested over the range of temperature adopted varies little. The dynamic elasticity and the viscosity required to withstand a rapid high stress (impact) or a high alternating stress should be low. Decrease of viscosity with increase of strength (structural viscosity) would appear to be an asset.

Hydrocarbon Flames

SPECTRA of flames of methane, ethylene and acetylene and of compounds found as intermediate products in the chemical studies of their combustion have been examined by W. M. Vaidya (*Proc. Roy. Soc.*, A, 178, 356; 1941). The flames of the Bunsen and Méker burners were also studied. A flame separator was used to get independent observations of the outer and inner cones. The outer cones gave a spectrum identical with that of the CO flame. The inner cones gave in general C_2, CH, HO and the ethylene flame bonds. It is suggested that C_2 may be produced through collisions of CH. Prevalent theories of hydrocarbon combustion are surveyed in the light of the *spectroscopic* observations.

General Classical Theory of Spinning Particles

IN a joint paper H. J. Bhabha and H. C. Corben (*Proc. Roy. Soc.*, A, 178, 273; 1941) give the complete classical theory of a spinning particle moving in a Maxwell field. The particle is assumed to be a point, and its interaction with the field is described by a point charge g_1, and a point dipole g_2. The Maxwell equations are assumed to hold right up to the point representing the particle. Exact equations are then derived for the motion of the particle in a given external field which are strictly consistent with the conservation of energy, momentum and angular momentum, and hence contain the effects of radiation reaction on the motion of the particle. In the paper following (p. 314), H. J. Bhabha gives an exact classical theory of the motion of a point dipole in a meson field, taking account of the effects of the reaction of the emitted meson field. The two papers occupy 78 pages.

Spectrum of the Corona

ACCORDING to Edlén, the prominent green line in the spectrum of the corona is due to Fe thirteen times ionized by some unknown excitation process (*Science News Letter*, 291, May 10). The next three strongest lines, two in the infra-red and one in the ultra-violet, he ascribes to Fe twelve times ionized. Weaker lines are caused by Fe nine and ten times ionized, while eleven and twelve times ionized Ca, and eleven, twelve, fourteen and fifteen times ionized Ni account for others. The ionization energy involved is about 400 v. Boyce points out that Edlén's theory indicates that ultra-violet light of much shorter wave-length than that hitherto considered must fall on the upper part of the earth's atmosphere, a result which will obviously affect the formation of the various ionized layers.

CHEMISTRY IN IRELAND

By Prof. John Read, F.R.S.

An interesting booklet has recently been published which shows us that, despite great handicaps several branches of science were cultivated in Ireland during the seventeenth, eighteenth and nineteenth centuries*. Among them, chemistry was closely linked with medicine, whether studied in institutions or less formally in hedge-schools or as a hereditary interest. Thus, the illustrious Robert Boyle entered chemistry through medicine; and it was during his lifetime that the institutional development of chemistry in Ireland began with the foundation in 1683 of the Dublin Philosophical Society. Richard Kirwan, when he left Ireland for France in the middle of the following century, had received his early education, including a good grounding in chemistry, from a well-known master of a hedge-school at Ballyragget, named Patsull. A century later, Cornelius O'Sullivan—"the founder of the modern science of biochemistry"—won a scholarship from his humble school in Bandon which paved the way for him to study chemistry under A. W. Hofmann in London, and later to specialize in the chemistry of brewing. These are three Irish chemists who rose to eminence at different periods and became fellows of the Royal Society; and there are many others of note in the list of sixty-three names forming the index to the booklet now under notice.

Unlike England and Scotland, Ireland had few links with alchemy or early chemistry. Perhaps the earliest connexion may be discerned in the preparation of a distilled spirit called *usquebaugh* ('water of life'), which gave its name to the later 'whisky' and is said to have been made and appreciated in Ireland so far back as 1100. Even during 1652–53 Robert Boyle found his native land so disturbed that it was "hard to have any Hermetic thoughts in it;" and except for the charlatan, William Butler, the only reputed alchemist in the list we are considering is Peter Woulfe, who invented 'Woulfe's bottle', discovered picric acid, and gained the Copley Medal of the Royal Society in 1768—so that he was not much of an alchemist after all.

Boyle and Woulfe were born in Ireland but prosecuted most of their chemical work elsewhere, and a similar statement applies to many other chemists in the list. Thus, Bryan Higgins, who is said to have almost forestalled the Leblanc soda process, opened a school of practical chemistry in Greek Street, Soho, in which he conducted research work during 1774–96; William James MacNeven, sometimes called the 'father of American chemistry', held the chairs of chemistry and materia medica during 1812–20 in the New York College of Physicians and Surgeons; and James Muspratt, born in Dublin in 1793, became the founder of the alkali industry in England. Muspratt's soda, made at Liverpool by the Leblanc process, was originally given away "so as to prejudice people in its favour", whereupon the demand rose to such heights that new works were erected at St. Helens in 1828. One of his four sons, James Sheridan Muspratt, discovered, in collaboration with Hofmann, *p*-toluidine and *m*-nitraniline, and achieved further fame through his celebrated dictionary of "Chemistry as Applied and Relating to the Arts and Manufactures", published in 1860, to the editing of which Michael Murphy (from Co. Clare) "devoted sixteen hours a day for two years".

Of those chemists who went to Ireland from outside and rendered service to Irish chemistry, Sir Humphry Davy was a veritable bird of passage: in 1810 he gave six popular lectures on electro-chemistry before the Royal Dublin Society for a fee of five hundred guineas, and followed this up in 1811 by six more lectures on agricultural chemistry for which he received seven hundred and fifty pounds. In 1813, Edmund Davy, encouraged perhaps by his cousin's account of Ireland as a sphere of operations for chemists, took up the professorship of chemistry at the Royal Cork Institute, an appointment which he held until 1826, when he succeeded William Higgins in the chair of chemistry of the Royal Dublin Society; it was ten years later that he discovered acetylene.

Chemistry in Ireland in the second half of the nineteenth century owed much to the Royal College of Chemistry, opened in London in 1845 with A. W. Hofmann as the first professor. Of Hofmann's original staff and students, Thomas Rowney, Robert Galloway, John Blyth and Edmund Rolands were all in the course of time appointed to chairs of chemistry in Ireland. In later days such men as Alfred Senier, Sir W. N. Hartley, and Sir G. T. Morgan went to Ireland and made valuable contributions to the development of chemistry in that country.

There is an impressive roll of native Irish chemists who carried out their work mainly in Ireland. Among these may be found, at about the end of the eighteenth century: David MacBride, a contemporary of Joseph Black (himself a son of Belfast parents); Richard Kirwan, author of the well-known "Essay on Phlogiston" (1787); and William Higgins, nephew of Bryan Higgins and occupant of "a place of honour in the development of the atomic theory". Sir Robert Kane, a distinguished figure in Irish scientific and academic circles, is known in chemistry for his preparation of mesitylene from acetone and as the author of a popular text-book entitled "Elements of Chemistry", first published in 1841–43. Maxwell Simpson, professor of chemistry in Queen's College, Cork, during 1872–91, studied under Kolbe and Bunsen, and afterwards worked with Wurtz, in Paris. He "takes his place among the great chemists who laid the foundations of organic chemistry in the nineteenth century". Last in chronological order, but one of the first in chemical genius, comes Hugh Ryan, who worked with Emil Fischer in his classical researches on sugars, and held the chair of chemistry in University College, Dublin, from 1908 until 1931. His death in that year, at the age of fifty-eight, was a severe loss to Irish chemistry, for it is said with truth that Ryan "was undoubtedly the leading organic chemist in Ireland in his day".

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

MONDAY, NOVEMBER 24

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. A. J. Curtin Cosbie: "Brewing, the Story of a National Industry"—2: "The Brewing Process" (Cantor Lectures, II).

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 3 p.m.—"Spitsbergen in 1941" (Geographical Film).

TUESDAY, NOVEMBER 25

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Prof. J. L. Myres: "Nomadism".

ROYAL INSTITUTION OF GREAT BRITAIN (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Prof. J. C. Drummond: "Recent Advances in the Science of Nutrition and their Significance in War-Time".

WEDNESDAY, NOVEMBER 26

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. Howard Robertson: "The Post-War Home, its Interior and Equipment"—1: "The Contributory Industries, What Are They, and how can they help Re-employment?."

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 2.30 p.m.—Dr. A. P. Cawadias: "Hermaphroditism" (Thomas Vicary Lecture).

SATURDAY, NOVEMBER 29

BIOCHEMICAL SOCIETY (at the Courtauld Institute of Biochemistry, Middlesex Hospital, London, W.1), at 11 a.m.—Dr. G. M. Findlay will open a general discussion on "The Mode of Action of Chemotherapeutic Agents".

INSTITUTE OF PHYSICS (MANCHESTER AND DISTRICT BRANCH) (in the Physics Department, The University, Manchester), at 2.30 p.m.—Prof. M. L. Oliphant, F.R.S.: "Physics in the United States and Recent Practical Applications of Nuclear Physics".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DEPUTY BOROUGH ELECTRICAL ENGINEER—The Town Clerk, Town Hall, Birkenhead (November 28).

SENIOR PHYSICS MASTER at the Rutherford College Boys' School, Newcastle-upon-Tyne—The Director of Education, City Education Office, Newcastle-upon-Tyne, 2 (November 29).

RESEARCH ASSISTANT IN VETERINARY SCIENCE under the Alan, Duke of Northumberland Memorial Fund—The Hon. Secretary, King's College, Newcastle-upon-Tyne (November 29).

LECTURER IN PHYSICS—The Acting Clerk to the Governors, South-East Essex Technical College, Longbridge Road, Dagenham (December 3).

SENIOR LECTURER (UNGRADED) IN THE DEPARTMENT OF BIOCHEMISTRY—The Registrar, The University, Liverpool (December 6).

ASSISTANT POWER STATION ENGINEER for the Basrah Port Directorate—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M/9746).

LECTURER IN AGRICULTURE—The Registrar, The University, Reading.

Nov. 29, 1941

SCIENCE AND ACADEMIC ISOLATION

THE recent Conference on Science and World Order organized by the British Association has undoubtedly done much to clarify among men of science a realization of their social responsibilities. More than this, it has initiated, we hope, a deeper understanding on the part of our leaders and statesmen of the vital position science occupies in a modern community. For science is no mere collection of facts and theories, but a living force for progress. Technological advance would be impossible without the background of a scientific culture. The development of the arts of peace owes much to science. The technique of industrial production is an application of scientific knowledge to human needs ; large-scale agriculture demands the close collaboration of the farmer and the man of science ; public health measures and preventive medicine are often based on the most recent scientific discoveries. It is clear then that increasing the well-being of the ordinary citizen is largely a scientific task. It is equally clear that men of science have not been allowed to direct the application of their results in the social and economic fields to the extent that the importance of their work demands.

In time of war this situation becomes of more serious import, for it is not the development of society which is at stake but its very existence. The exigencies of war raise special problems which can only be solved by the immediate application of scientific knowledge. Yet men of science are employed by Government departments and industrial concerns mainly as advisers with little or no executive authority. Consequently their advice runs the risk of being overlooked or insufficiently implemented. The Civil Servant or factory manager, who in general is not conspicuous for the depth of his scientific knowledge, finds it difficult to understand that an integrated scientific plan is essential for the efficient operation of the war economy. Piecemeal methods often defeat their own ends. The relevant scientific facts must be considered in totality in determining policy. A better state of affairs would result if men of science were given executive authority in those spheres of the national effort in which their work is directly applicable. Mr. Anthony Eden, in his address of welcome to the foreign representatives attending the British Association Conference, suggested that diplomacy in future must be the servant of science, instead of vice versa. It would be an excellent thing if a beginning along these lines could be made now without waiting for the termination of hostilities.

But the onus does not rest solely on statesmen and politicians. It rests very largely on men of science themselves. The undoubted fact that the applications of scientific knowledge for the common welfare have often been frustrated or misused has been regarded with complacency or even cynicism by some men of science. Even to-day there is a too prevalent attitude to let things run their appointed course. There still lingers in the minds of some men of science, including several of considerable achievement, a doubt as to the necessity for the planning of science and organization of men of science for social ends. That this doubt is considerable and honestly held is clear. Planning and organization are held to be detrimental to the absolute freedom of the individual man of science to undertake what research he will when he will.

While the maximum freedom in science is necessary, that such *absolute* freedom of choice is desirable, or even usually obtains, is debatable. It is not sufficiently realized that the type of work that a man of science undertakes in the great majority of instances is conditioned by the fact that he has to earn his living by that work. Except for people with private means and a handful of established university teachers, complete indulgence of the individual's scientific curiosity is impossible. Even in a democratic society, scientific research, taken as a whole, is subject to inevitable restraints and conditions. The problem is not to eliminate them, but to make sure that they are reasonable, socially useful conditions, and that their operation is in the hands of the men of science themselves. This requires democratic organization.

Too often to-day the general guidance of scientific work is in the hands of laymen or persons whose scientific knowledge is incommensurate with the responsibility of their task. We need here to distinguish sharply between conditions of work in university laboratories and research institutions, and those obtaining in industrial and Government laboratories and factories. We need also to appreciate that, particularly in time of war, the overwhelming majority of scientifically trained men and women work under the latter conditions. Sufficient evidence has been accumulated, notably by such bodies as the Association of Scientific Workers, to show that there is room for considerable improvement in many of these places. There can be a great waste of effort among a team of scientific workers if their research is poorly directed and co-ordinated. We are not satisfied that the best use of our scientific brain-power is, in fact, being achieved in this connexion. The frustration the younger scientific worker must inevitably feel when working under inadequate direction was the subject of comment in the leading article of a recent issue of NATURE (November 1). The loss to the nation's effort as a result should also be emphasized.

The long-term view of scientific planning characterized the recent Conference on Science and World Order. It showed that men of science are thinking, in advance, of their part in the planning of the post-war world. Doubts have been expressed as to whether this historic Conference will, in fact, give rise to anything concrete. Surely the correct attitude is to realize that this meeting of men of science was merely an initiation of activity; but, it should be pointed out, of activity on an international scale. Positive results will only be forthcoming in direct ratio to the amount of help given by the individual man of science. The Division for the Social and International Relations of Science of the British Association has set up several committees to deal with some of the problems arising out of the Conference. These committees should not be left to work in isolation but should be given the fullest assistance and encouragement. It is sincerely to be hoped that they will receive the support required to enable them to make contributions of real and lasting value to society.

The British Association, however, is not a formal representative organization of scientific men, and as such its usefulness, although considerable, is limited in certain respects. There are in Great Britain a number of learned and professional societies and associations. In the past these bodies have been mainly concerned with their own particular interests. Yet in so far as they represent men and women with specialized knowledge, they owe it to their members and to the community to participate in the wider affairs of the nation. At the moment their voice is too often silent. The tradition of academic isolation dies hard.

There are several encouraging features in the present situation. The chief of these is the renewed determination to get things done which is exemplified by many of our leading men of science. It is not generally realized how deeply this is reflected among the younger rank-and-file scientific workers. Reference to the desirability of including younger brains on many scientific committees was made in the leading article in NATURE already referred to. But in many cases suitable committees do not exist and need to be formed. We are concerned at the present time primarily with the relation of science to winning the war. Regional production committees need not necessarily seek scientific advice, or accept it after having sought it.

In this respect it should be noted that the Scientific Advisory Committee of the Trades Union Congress seems not to function, although it, or a similar

body, could now express itself directly through T.U.C. members of planning committees. Ways and means should be thought out of bringing scientific advice *directly* to bodies dealing with industrial production. The application of even elementary scientific research to production problems has resulted in the past in an immense saving both of money and labour. There is no reason for supposing that we have reached saturation point in this respect.

The present war situation calls for considerably increased effort by men of science as much as by the factory worker or farm hand. Pre-war concepts of the pursuit of knowledge for its own sake are not now applicable. Every available scientific brain must be at work on problems connected with the War, and co-ordination of effort must be effected. As Mr. J. G. Crowther said at the British Association Conference, a country which has produced Newton, Clerk Maxwell, Faraday, Rutherford and other towering figures does not lack good men of science, and is not to be defeated for want of them. What we must ensure is that the maximum use is made of them in this critical time for ourselves and our Allies. It is timely, therefore, that the Association of Scientific Workers has announced a conference to be held in January on the general topic of science and the War effort (see p. 657). As this body represents in the main young working men of Science and engineers directly engaged with war and production problems, its voice should receive attention. The general body of scientific workers and technicians should use this opportunity of discussing together their important place in the nation's effort. At the meeting of Soviet men of science held in Moscow on October 12 (NATURE, October 25, p. 490) an appeal was broadcast to scientific workers of the world. Their colleagues in Great Britain have the responsibility of answering their appeal concretely and quickly. Messages of support and encouragement serve a limited purpose only. British men of science and engineers must pool all their knowledge, skill and ingenuity to fulfil their part in the pledge which has been given by Lord Beaverbrook: "We've spoken the word, but you must do the deed."

CHRISTIANITY AND THE MECHANISTS

Christianity and the Mechanists
By Dr. W. Osborne Greenwood. Pp. 296. (London: Eyre and Spottiswoode (Publishers), Ltd., 1941.) 9*s*. net.

WHY are writers who approach religious problems from the angle of the sciences so often haphazard in their reasoning, striding forward regardless of obstacles, the moment they quit the strictly scientific beat? They are as reckless as the theologians who dabble in science, and with less excuse; for their scientific training should have taught them to be more careful. The book before us provokes this question. Not that it is lacking in interest or merit, at all events in its negative contentions. The author is a medical man conversant, both within his professional field and outside of it, with the opinions and needs of the public, especially of the younger generation. He knows how their outlook upon the larger problems of life has been prejudiced by uncritical acceptance of the dogmatic tradition of Victorian science, a tradition which still dominates popular thinking, despite the fact that recent developments in physics have gone far to undermine its dogmatism. The majority of the students in our secondary schools and universities still echo the outworn shibboleths and are convinced before their minds are fully fledged that science has scotched religion. It is to such as these, and not to specialist readers, that the author addresses himself.

Dr. Greenwood writes as a believer in Christianity, with engaging sincerity and in a clear and attractive style. He opens with a brief survey (four chapters, comprising the first quarter of the book) of present-day physics, treating with admirable lucidity of the structure of the atom and the problem of entropy, in order to show the grounds that have led many of the leading physicists to postulate a divine mind as the author of the universe. But his main concern is with biology, partly as the field of his own life-work, but chiefly because it is the biologists rather than the physicists who are most solid in their resistance to the hypothesis of theism. He is out to expose the inadequacy of a mechanistic interpretation of the phenomena of life and mind, save in so far as it is regarded as a methodological assumption. "We must be on our guard against overloading a working hypothesis with more than it will or can carry" (p. 146). He shows clearly that a living organism cannot be fully explained by the analytic method which resolves the whole into an aggregate of its parts (p. 129), and that the *form* of organization (this holds also of the physical atom and of the electron) is not a material entity or composed of material entities as its constit-

uents (cf. 44 f., 67). "There is something more in an organism than its several organs and this something is what controls the creature as a whole." How paradoxical is the view which holds the more complex biological structures and activities to be the result of chance is illustrated by a detailed study of *Epeira diademata* (Chapter 10) and of the brain and nervous system (Chapter 11). A like measure is meted out to Loeb's theory of tropisms (Chapter 9).

This argument might have been rendered even more convincing if Dr. Greenwood had instanced the impracticability of giving any mechanistic account of truth. If Loeb's belief in his own theory and its rejection by a disbeliever are equally and alike "conditioned reflexes", what meaning can be attached to the claim that one of the two opposed beliefs is true, and the other false? The beliefs in both cases are determined mechanically by the psychical and physical antecedents, and there is no more to be said.

It is when we pass to Dr. Greenwood's inferences to theism that the question we asked at the outset becomes urgent. He seems to think that the rejection of a mechanistic explanation carries with it of necessity a reference to God as the ultimate ground of Nature. As though these two were the only possible alternatives! He rushes to his conclusions—which, be it observed, may well be true—with a swiftness that makes the reader gasp. Take, for example, the argument on p. 188, based on the unquestioned evidence of religious belief (as of artistic skill) in the cave-dwellers of the third interglaciation period.

"At this juncture it may very usefully be asked of the mechanist, Of what survival value is all this? Any mechanical method of development is at least consistent in one respect, that if any variation appears, be it in organ or habit, function or any characteristic whatever, which is not of some distinct survival value, it is ruthlessly suppressed and cut out. It must be of some definite advantage to the individual or to the race in order to become perpetuated and be a characteristic worth preserving. But a religious spirit and leaning would, among these primitive folk, be precisely one of those possessions which would not help in a material sense to preserve either individual or race. It would not ensure more success in hunting, nor would it, *per se*, help in combat if there *were* such a state of affairs as intertribal war. The religious spirit, therefore, which has not only persisted in spite of these disabilities but grown to the sublime conceptions of to-day, cannot be regarded as due to any mechanical causation but can only be understood when viewed as a divine gift."

An objector will urge, first, that primitive religion has a definite survival value as promoting courage in the individual and social cohesion in the tribe, while the observable decay of religious beliefs in the civilization of to-day is due to the loss of survival value that they once possessed. Further, he will note that Dr. Greenwood is equally ready to credit God with the authorship of much that assists survival and that this, if it be true, seems to show that the presence or absence of survival value is irrelevant to the case for theism. To regard its absence as evidence of divine origin is scarcely complimentary to the Deity. Moreover, even if we allow that mechanical causality fails to explain the phenomena of religion, it by no means follows that they must be interpreted as a divine gift.

There are a host of alternative explanations that call for consideration. A goodly array of philosophers will contend that to seek a ground for the world as a whole is beyond the competence of human reason; that the causal relation holds only within the universe and only of the connexions of events in space and time. It may be questioned, again, whether the universe is a whole and not rather a mass of inter-related phenomena within an ever-expanding context. Even Aquinas held that reason could not disprove the eternity of the material world and that the belief in Creation could be authorized only by revelation. Again (if we are to indulge in this line of speculation), Hume's suggestion that the world is a self-developing organism merits serious discussion, say, in the form given to the theory in Alexander's "Space Time and Deity". Finally, there is the case for regarding the universe as a spiritual whole; in other words, for pantheism. If, as the author contends in agreement with Jeans, the solid matter of the traditional physics has been sublimated into something that looks uncommonly like mentality, why should not the purposiveness discernible in Nature, and the evolutionary process that culminates, for our present knowledge, in mind and personality, be ascribed to the agency of an immanent world-spirit or society of world-spirits? No appeal to Christian theism that ignores these speculative alternatives is likely to evoke a response from the inquiring minds of the present generation.

Our sympathy with Dr. Greenwood's aims makes us all the more sensitive to the shortcomings of his argument. His leading concepts seem to stand sorely in need of clarification. The interesting suggestion (p. 114) that the increase of entropy may be arrested and even reversed by the higher energy of life raises doubts as to the equivocal use of the term 'energy', which are intensified by its extension to spiritual activity as displayed by Christ's *Kenosis* at the Incarnation (p. 65). Later in the book (Chapter 13) we hear of a vitally

important distinction between mind and personality, but are left greatly in the dark when we ask for the precise nature of the difference. It is not enough to be told (p. 213) that personality is conscious individuality; and is the fact that the amœba splits into two instead of dying (pp. 220—221) really pertinent to the Christian hope of immortality? 'Creation' is another ambiguous term of constant recurrence. What does Dr. Greenwood mean when he tells us (p. 197) that "man's mind is of the same nature and essence" as the infinite mind behind the universe, "for it does (within its limited scope) the same creative things"?

God, in creating, creates *ex nihilo*, that is, with no material to work on other than himself. In this lies the radical difference between His creative act and the releasing of pent-up energy from an inert chaos with which it is identified in an earlier passage (p. 47). Perfect inertness and complete absence of organization are not 'nothing' in the absolute sense demanded by orthodox theism. The analogy between divine and human creation has been treated recently, with much more subtlety and caution, by Miss Dorothy Sayers in "The Mind of the Maker".

We offer these criticisms in the hope that Dr. Greenwood may find time, amid his many useful avocations, to develop his constructive argument to theism in more detail. That he has the ability to do this is shown by his convincing refutation of materialism. But there is much in his more positive contentions that needs expansion and clearing up. As it is, he has set himself to prove a little too much and has actually proved much too little.

W. G. de Burgh.

ADJUSTMENT IN MARRIAGE

Happy Marriage

By Norman E. Himes. English edition revised by Lella Secor Florence. Pp. 368. (London: George Allen and Unwin, Ltd., 1941.) 12*s*. 6*d*. net.

Few people would care to deny that marriage relations constitute an important source of the variance of total social happiness. A reasonable interpretation of available evidence makes it likely that marriage originally came into existence as an institution in response to the need for safeguarding the family and its property and hence to acquire rights over the procreative activities of the female. But monogamous marriage in modern society, *de jure* if not entirely *de facto*, still exercises proper functions in regulating the sexual and parental impulses and in providing for various other social and psychological needs. The permanence and stability of marriage are very sensitive to economic and ecological conditions in society. One current difficulty comes to mind. The exigencies of war, compelling prolonged separation and abstinence and, consequently, frustration and conflict, have certainly raised the incidence of psychoneuroses in married women. It is surprising therefore that so little scientific attention has been given to the conditions of a stable and happy union on one hand and of the difficulties that may arise from this union on the other.

The admirable work of Prof. L. M. Terman and his associates at Stanford University is outstanding in this field, and much that is of value in the book under review is a diluted account of Terman's conclusions. Dr. Himes is not concerned in the present study to deal with fundamental problems nor are any new data presented. The reader is offered a handbook of prudent guidance enriched by long experience in the medical problems of contraception. Excursions into economic advice for prospective couples to which a few chapters are devoted may serve a purpose for some of the more suggestible members of the public.

Late age at marriage, by curtailing the child-bearing period, is one factor contributing to a reduced fertility, and it is encouraging to see the strong plea made in this book for earlier marriages both in the interests of fertility and to facilitate sex adjustments in general. The most useful chapters are those that deal with pre-marital and marital sex relations, contraceptive techniques, sterility and venereal disease.

Two points deserve comment. First, the excess of males in the sex ratio is not, as Dr. Himes supposes, due to the higher death-rate of females *in utero* but to the greater number of males conceived; the death-rate of male is higher than that of female embryos. Secondly, to advocate homogeneity of the prospective partners in respect of race, religion, economic and social status, age, education and outlook is dangerous when little or no evidence is adduced in support of the merits of this advice. Such restrictions would strengthen existing class and group stratification and obstruct genetic combinations which are in the interests of the community as a whole.

John Cohen.

ADMINISTRATION AS A SOCIAL PROCESS

Dynamic Administration
The Collected Papers of Mary Parker Follett. Edited by Dr. Henry C. Metcalf and L. Urwick. Pp. 320. (London: Management Publications Trust, Ltd., 1941.)

THE happily chosen title of this collection of papers strikes the keynote which gives them their unity. Behind the admirable analysis of the principles of administration contained in them lies the conception of administration and organization as dynamic rather than static. The task of the administrator is not that of crystallizing the experience of the past in set forms which will guide him in dealing with present or future situations. It is rather that of understanding the whole situation confronting him, recognizing the interacting and unifying elements, and so relating their functions that he sets in motion a process which continuously promotes unity and coherence.

This conception of leadership as the relating of experience and organizing it into power over the situation is elaborated most fully in the two papers on "The Psychology of Control" and on "Leader and Expert", and these with the further paper on "Some Discrepancies in Leadership Theory and Practice" may make the most direct appeal to the scientific worker as such. The same ideas, however, are found in all the papers, the ultimate value of which is indeed in the challenge they offer to constructive and creative thinking at a time when many are being called to fill new administrative posts and when the character of administration over wide fields is subject to searching scrutiny. No reader of those keen examinations of administration and policy provided by the forty or so reports of the Select Committee on National Expenditure can have any doubts as to the great service which Major Urwick and Dr. Metcalf have rendered by editing this collection of lectures at the present time; it is unfortunate that they have not completed their work by providing the book with the index it deserves.

With the exception of the final paper, "Individualism in a Planned Society", which in somewhat different form has been published in the "Papers on the Science of Administration" edited by L. Gulick and L. Urwick, these papers, some of which were delivered in Great Britain but never published, have not been readily accessible, and it is a tribute to the vitality of Mary Follett's thought and the keenness of her analysis that they should make such appropriate reading after the lapse of a decade or more. This is true of international no less than of business situations. Her observation in March 1927 that "we shall never be able to make an international settlement and erect some power to enforce it; the settlement must be such as to provide its own momentum" is a warning for post-war reconstruction that has been forcibly underlined by experience of the last two decades.

A large part of the stimulus of these papers lies in the new points of view they suggest or the new approach to existing problems. They do not provide ready-made solutions to problems that the administrator is likely to encounter, but they do assist him to the fundamental thinking about his problems or situations which will enable him to reach real solutions or control. The emphasis throughout is on the psychological foundations, and the papers on "The Giving of Orders", on "The Meaning of Responsibility in Business Management" and on "Power" are examples of the way in which Mary Follett first demonstrates the shallowness of much conventional thinking, and then enables us to reach the real meaning of situations or problems so essential if the integration on which she insists is to be achieved.

This fundamental thinking is the most valuable feature of these papers, and its applications to the situations that are arising daily in war production or to the problems that will be encountered in reconstruction are almost unlimited. The observations on depersonalizing orders and discovering the law of the situation afford a clue to the solution of many of the acute problems which arise in the control of labour under war-time conditions. These are ideas to be explored further, and they are a typical example of the integration on which Miss Follett insists throughout. They lead naturally to views on conciliation and arbitration and on co-operation advanced in two papers on the psychology of consent and participation and on the psychology of conciliation and arbitration, which some will find novel if not startling.

If these papers can be warmly commended to the practical administrator, they are equally valuable as a contribution to the creative and constructive thought which must precede as well as inspire the making and execution of plans and policy in reconstruction. Miss Follett is more than an expositor of the fundamental principles of organization, so clearly outlined in the final paper

"Individualism in a Planned Society". She sees administration as a social process which, whether in a Government department, an industry or a business, must be integrated with the purposes and welfare of the society of which the more limited activity forms a part. Her view of administration as a continuous and progressing activity is in line with the ideas advanced by Mannheim in "Man and Society in an Age of Reconstruction", and the final two essays provide as complete an answer to those who reject the idea of planning as they do a corrective to the prejudiced or narrow thinking which sometimes characterizes the approach to management problems. Indeed, their contribution to efficient administration is scarcely more direct than it is to the creative thinking by which alone we can evolve the collective controls required to preserve and expand our tradition and heritage of freedom.

R. BRIGHTMAN.

THE LIFE OF INVERTEBRATES

A General Zoology of the Invertebrates
By G. S. Carter. Pp. xxviii+510+13 plates. (London: Sidgwick and Jackson, Ltd., 1940.) 25s.

IN the periodic swing of interest between form and function morphology had a long innings in the schools of Britain, and even now that the animal alive has won its meed of study, the textbooks in general use scarcely reflect the change in outlook that this century has seen. With a telling contribution to the literature of the classroom Dr. Carter has supplied the missing link, and teacher and student will appreciate the labour of collecting and collation which has gathered in a unified survey the results of many scattered investigations.

Two impressions stand out from a reading of his volume: one is of the broad conception of the plan and the thoroughness of its execution, and the other is of the ease and effectiveness of the writing.

The plan is laid around four major topics. The first deals with the properties of protoplasm, the cells and the 'Protista', which are regarded as single cells, for the author rejects the non-cellular conception of the Protozoa since he looks upon a cell as the unit of organization of all animal protoplasm. The second topic, the multicellular body, gives an opportunity for excellent reviews of such subjects as regeneration, dedifferentiation and reconstitution, axial gradients and organizers, and various aspects of the problem of growth. But we miss here any discussion of ecdysis in the Arthropoda or of discontinuous growth in general, or of the recent work upon various types of cuticle.

Comparative physiology is discussed in the longest and most detailed section of the book, marked by a particularly good account of nervous co-ordination. Finally, general problems of invertebrate zoology include life-histories, comparative behaviour, ecology and evolution. Limitation of space has resulted in a somewhat sketchy treatment of the first three, but the last embodies a very interesting speculation upon the evolutionary relationships of invertebrate phyla. The suggestion is that the Metazoa should be divided into two superphyla—the Echinoderm superphylum, including only Echinoderms and Chordates, characterized by pluteus larva, radial cleavage, equipotential development and enterocœl; and the Annelid superphylum including all the remaining Metazoa, except the Cœlenterates and Sponges, with trochosphere larva, spiral cleavage, mosaic development and schizocœl.

The distinctions, however, do not always hold, as the author points out, and in the matter of cœlome development it might be stated that Hamann, Dawydoff, and recently H. Barraclough Fell have shown that even in some echinoderms the cœlom is schizocœlic.

The grouping of the Lamellibranchs as sessile animals is unusual; the figures of the prophase of mitosis scarcely represent the modern view; and in the figures showing parasitic modifications in copepods, that of Achtheres is inaccurate, Penella has an incomplete head, and the series might have been completed by the addition of Xenocœloma, described by Caullery, with its gonads and ducts included in the host and only a pair of egg-sacs outside. The only misprint we have noticed is in the legend of Fig. 51.

These are small matters; the great matter is that here is a work, well indexed, with a useful bibliography mainly of monographs and general reviews, which, as a highly successful and up-to-date synthesis of the biology of invertebrates, meets a long-felt need and will give a new drive to the study of the living animal.

RAMANUJAN

BY PROF. L. J. MORDELL, F.R.S.

PROF. G. H. HARDY who, some thirteen years ago, supervised the editing of Ramanujan's collected papers, has now produced a new volume dealing with Ramanujan.* It is a series of essays rather than a systematic account of his work. However, it includes most of his more important discoveries, and also much recent work associated with the results found by Ramanujan. There are twelve essays, and it will make my subsequent remarks more intelligible if I give their titles in full: (1) The Indian mathematician Ramanujan; (2) Ramanujan and the theory of prime numbers; (3) Round numbers; (4) Some more problems of the analytic theory of numbers; (5) A lattice point problem; (6) Ramanujan's work on partitions; (7) Hypergeometric series; (8) Asymptotic theory of partitions; (9) The representation of numbers as sums of squares; (10) Ramanujan's function $\tau(n)$; (11) Definite integrals; (12) Elliptic and modular functions.

I may as well say at once that the book is beautifully written in an informal style, and reads as smoothly and fascinatingly as a delightful novel. The simplicity and clearness of the style, and the care in setting out the formulæ, are so marked everywhere as to make it plain that the book is certainly a labour of love on which its author has spared no effort. Proofs are given with a minimum of unpleasant detail, with the right emphasis on the salient features and with useful and interesting comments and notes. The book is a model of good exposition. It is a handsome quarto volume printed in such a way as to make it a pleasure to read and a credit to the printers.

The main facts of Ramanujan's career are well known, and the lives of few other mathematicians for some generations past have been so full of human interest. The story of his life is that of the rise of an obscure Indian in the face of the greatest difficulties to the position of the most famous mathematician that India has ever produced and of his early death just after he had won the most coveted distinctions. The publicity given to him suggests that the world likes to hear about mathematicians; and in fact Lord Riddell, the journalist peer, who heard of Ramanujan from Mr. Montagu, at one time Secretary for India, was so interested that he sent for a copy of Ramanujan's collected works and wrote a review, confining himself, of course, to an account of Ramanujan's life.

Ramanujan was born in 1887 near Kumbakonam, a fair-sized town about 160 miles from Madras. Like many other mathematicians, he came of poor and humble folk. His schooling was normal, though at an early age he was recognized as a boy with exceptional abilities. He went to the local high school from the age of seven to sixteen, and in 1904 entered the Government college at Kumbakonam, where he won a scholarship. In no other science as in mathematics is it so easy for a student's interest to be aroused at an early age. The simplest properties of numbers which occur in arithmetic, or the simplest properties of geometrical figures, have often sufficed. Apparently Ramanujan's interest displayed itself when he studied trigonometry and found for himself results given in Part 2 of Loney's "Trigonometry." Then, at the age of sixteen, he borrowed an old book by Carr, "A Synopsis of Elementary Results in Pure and Applied Mathematics". This covers roughly the subjects of Schedule A of the present Mathematical Tripos, and contains the enunciation of some six thousand theorems with proofs that are often little more than cross-references. Carr has sections on algebra, trigonometry, calculus and analytical geometry, and emphasizes in particular the formal side of the integral calculus. It was this book that really awakened Ramanujan's genius. It secured such a grip on him that he is said to have spent all his time at college—including lecture periods in other subjects—upon his mathematics. Many years ago Huxley (and probably many others before him) said that one of the most important objects of any educational system should be to catch the small percentage of the population with some special aptitude, to turn them to account for the good of society, to see that they are not starved by poverty, and that they are put in the positions in which they can do the work for which they are specially fitted. If Ramanujan had lived in Britain he could have started early specialization in preparation for a scholarship examination at one of the universities, with what wonderful results no one can imagine. Unfortunately, the educational system at Kumbakonam was not elastic enough to deal with persons like him. As a result, his neglect of college work other than mathematics led to disaster. He lost his scholarship, left college, ran away from home, came back, returned to college, but did not make up for his absence. He then entered Pachaiyappa's College, Madras, in 1906, but, falling ill, returned to Kumbakonam. He

* Ramanujan: Twelve Lectures on Subjects suggested by his Life and Work. By Prof. G. H. Hardy. Pp. vii+236. (Cambridge: At the University Press, 1940.) 25*s*. net.

appeared as a private student for the F.A. examination in December 1907 and failed. In England he would probably then have been in the middle or near the end of his college career, with possibly the Tripos before him, and also an immediately successful career.

But from 1907 until 1912, Ramanujan was adrift in the world without any definite occupation except his mathematics, which must have absorbed most of his energy. The results of this are embodied in some now famous note-books. In 1909 he married and so, as remarks his biographer, he had to find some regular employment. He had great difficulty in finding any because of his unfortunate college career. In 1910 he began to find more influential friends, who tried in vain to find a tolerable position for him. But in 1912, at about the age of twenty-five, he became a clerk in the office of the Port Trust of Madras at a salary of about £30 per annum. Not much has been published about his life during these critical years 1907–1912. His first substantial paper had been published in 1911 in the *Journal of the Indian Mathematical Society*. In 1912, he began to secure some recognition in India. It is really an easy matter for anyone who has done brilliant mathematical work to bring himself to the attention of the mathematical world, no matter how obscure or unknown he is or how insignificant a position he occupies. All he need do is to send an account of his results to a leading authority. One can recall the classic instances of Jacobi's letters to Legendre announcing his discovery of the elliptic functions, and of Hermite's letters to Jacobi containing his new discoveries in number-theory.

Ramanujan wrote to Hardy in January 1913, sending him the enunciation of a great many results he had found, many of them strikingly original and thoroughly intriguing, others well known, and some false and yet not without considerable interest and significance. Events had begun by this time to take a more favourable turn in India. The University of Madras gave him a scholarship of some £60 per annum, adequate for a married Indian, and he was also sounded about a trip to England, which he declined. In 1914, however, he was prevailed upon to go to Cambridge with help from the University of Madras and from Trinity College. There he had three years of uninterrupted activity and continuous contact with Hardy, the results of which are visible in his "Collected Papers." He fell ill in 1917, and never fully recovered, dying in 1918 shortly after his election to the Royal Society and to a fellowship at Trinity College. He was the first Indian to have been awarded either honour.

It may well be asked at once what kind of mathematics could be done by a person with Ramanujan's training, especially before he came to England, and what characteristics his talents display. Mathematical research is possible in many directions, and two extreme ones suggest themselves. In one, for example, modern algebra, it is necessary to master a technique requiring considerable preparation and study, and research is practically impossible without this. In the other comparatively little pre-knowledge is required; only native wit and exceptional ability and intuition. This applies especially to identities involving infinite series, products, continued fractions and integrals. Probably many of the results found will not be new.

Thus the simply periodic functions, for example, those for which $f(x+1)=f(x)$, and in particular the elementary trigonometric functions, lead to the well-known series and products associated with the sine function, as well as to the familiar Bernoulli numbers in the expansion of $1/(e^x-1)$ in ascending powers of x. Then the hypergeometric series

$$\sum_0^\infty \frac{a.\, a+1.\, \ldots a+n-1.\, b.\, b+1.\, \ldots\, b+n-1}{n!\; c.\, c+1.\, \ldots\, c+n-1} x^n,$$

which includes most of the series occurring in elementary mathematics, lends itself to all sorts of extensions and generalizations. This series is also closely associated with the gamma function $\Gamma(x)$. This function, the characteristic property of which is $\Gamma(x+1) = x\,\Gamma(x)$ and which is a generalization of $x\,!$, is rich in applications to identities of the kind mentioned above.

There are also two classes of far more abstruse functions of the greatest importance in the mathematics of the last century. One is the elliptic or doubly periodic functions, the chief property of which may be typified by

$$f(x+1)=f(x), \qquad f(x+\omega)=f(x),$$

where ω is a complex constant. The simplest elliptic functions are those called $\wp(z)$, sn z, cn z. From the eliptic functions arise the modular functions, of which the simplest have the curious general periodicity property that if ω is a complex variable and α, β, γ, δ are any integers such that $\alpha\delta-\beta\gamma=1$, then

$$f\left(\frac{\alpha\omega+\beta}{\gamma\omega+\delta}\right)=f(\omega).$$

The function which naturally arises in studying such functions can be written as

$$\Delta\,(\omega_1, \omega_2) = (2\pi/\omega_2)^{12} q^2 \prod_1^\infty (1-q^{2n})^{24}.$$

Here ω_1, ω_2 are two complex numbers whose ratio $\omega=\omega_1/\omega_2$ has a positive imaginary part, and $q=e^{\pi i\omega}$ so that $|q|<1$. Then

$$\Delta\,(\omega_1, \omega_2) = \Delta\,(\alpha\omega_1+\beta\omega_2, \gamma\omega+\delta\omega_2).$$

The general theory of elliptic and modular functions has been treated in monumental works by Klein and Fricke, and by Weber, and reveals

at once the most beautiful and fascinating series and products, and enables us not only to prove directly any relevant identities but also to state beforehand their nature and form. Many of these identities can be found by quite elementary means and others by the display of great ingenuity. There may then be no connexion with the general theory, and the results may appear to one unfamiliar with it as an extraordinary collection of strange, curious and isolated results, an impression sometimes heightened by the unusual form in which they can be expressed.

Finally, the theory also shows that if $f(\omega)$ is a modular function and n is any positive integer, then algebraic equations of great interest called modular equations connect $f(n\omega)$ and $f(\omega)$, and that these can be expressed in a multiplicity of ways. Further, if we put $f(n\omega) = f(\omega)$, which then involves $n\omega = (\alpha\omega + \beta)/(\gamma\omega + \delta)$, so that ω is a complex quadratic surd, the equations are solvable by radicals, as was shown by Abel about a century ago. Some of these equations can be solved very simply, while the solution of others involves a wonderful collection of surds.

It was chiefly in these subjects that Ramanujan's best work was done. They gave him ample scope for his exceptional and brilliant genius, which displayed such wonderful imagination, intuition and insight. For formal manipulation of infinite processes and an instinctive feeling for algebraical formulae, he was unrivalled since the time of Euler and Jacobi. His fertility in producing a host of strange and curious results was unbounded and ceased only with his death.

I mention first some results illustrating his inductive powers.

Suppose that q is a complex number and $|q| < 1$. Write

$$1/\prod_1^\infty (1-q^n) = 1 + \sum_1^\infty p(n)q^n.$$

Then the coefficient of q^n in the series is a very important function of n known as the partition function, of which more later. It is easily shown to be the number of solutions in positive integers $x, y, z, t, \ldots$ of

$$x + 2y + 3z + 4t + \ldots = n.$$

Though it had been known and studied since the time of Euler, very little was known of its properties; for example, it is even now not known when $p(n)$ is even or when it is odd. Ramanujan found by observation that $p(5n + 4)$ is divisible by 5, and then proved it. Though no one else had noticed this result, it is easily suggested to anyone studying the numerical values of $p(n)$. A proof is also obvious from the identity

$$p(4)+p(9)q+p(14)q^2+ \ldots = 5\{(1-q^5)(1-q^{10})(1-q^{15})\ldots\}^5\{(1-q)(1-q^2)(1-q^3)\ldots\}^{-6},$$

due to Ramanujan who, however, never published a proof. Many such identities, though striking in appearance, are in fact simply particular results in the theory of the modular functions.

Another result on a rather different footing found inductively without proof by Ramanujan is

$$1+\sum_1^\infty \frac{q^{n^2}}{(1-q)(1-q^2)\ldots(1-q^n)} = \frac{1}{(1-q)(1-q^4)(1-q^6)(1-q^9)\ldots}.$$

What seems remarkable in this formula is that in the product on the right-hand side, the indices of the powers of q are of the form $5n \pm 1$, while in the series on the left-hand side, 5 plays no part in the indices. Such an identity seems very difficult to discover empirically, but still it might be possible for someone without his genius. The formula, which seemed difficult to prove, was in fact originally found and proved by Rogers and then overlooked for some twenty years.

The most remarkable result Ramanujan found inductively, again without proof, is one which would have occurred to very few people indeed. Write

$$q\{(1-q)(1-q^2)(1-q^3)\ldots\}^{24} = \sum_1^\infty \tau(n)q^n,$$

where the product is associated with the important modular function $\Delta(\omega_1, \omega_2)$, so that it can be expected that the coefficients $\tau(n)$ are also important. Then Ramanujan conjectured that

$$\sum_1^\infty \tau(n)n^{-s} = \prod_p (1-\tau(p)p^{-s}+p^{11-2s})^{-1},$$

where the right-hand product is extended over all primes p. This identity implies in particular that $\tau(mn)=\tau(m)\tau(n)$, when m and n are prime to each other. The identity was afterwards proved by Mordell, but only recently Hecke found independently the formula, the proof, and important extensions. Ramanujan also conjectured that if p is a prime number, $\tau(p) \leq 2p^{\frac{11}{2}}$, whence it follows that $\tau(n)$ is of order of magnitude $n^{\frac{11}{2}+\epsilon}$, but no one has ever proved this. Recently Rankine has got so far as $n^{\frac{29}{5}}$.

The most pregnant result stated by Ramanujan is that the coefficient of x^n in $(1-2x+2x^4-\ldots)^{-1}$ is the integer nearest to

$$\frac{1}{4n}\left(\cosh \pi\sqrt{n} - \frac{1}{\pi\sqrt{n}}\sinh \pi\sqrt{n}\right).$$

This statement is false, but the formula is a genuine approximation, though not so close as Ramanujan imagined. This result, included among those sent by Ramanujan to Hardy in 1913, obviously led to the corresponding problem for the function $p(n)$ and to their joint work on partitions. This was the beginning of the method. developed

by Hardy and Littlewood, for solving problems dealing with the partitions of numbers in various ways, and transformed later almost out of recognition by Vinogradoff. Thus Vinogradoff has proved that every sufficiently large odd integer is the sum of three primes. The final result of the original application of the method was to obtain a series giving exceedingly good and rapid approximations to the value of $p(n)$; for example, when $n = 200$, the error made in taking eight terms of the series gives an error of only 0·004 in the value of $p(n)$, a number of thirteen digits. Rademacher has recently replaced the asymptotic series by an equally effective convergent series.

In hypergeometric series, there is an important and fundamental formula involving many parameters due to Dougall; this was rediscovered by Ramanujan, and probably the methods he used would have led to a rigorous proof. From it he deduced a host of other results. He was in possession of yet others, suggesting that he had not revealed all the results in his possession.

Definite integrals greatly interested Ramanujan. Many of his results were found before he came to England and while he held a research scholarship at the University of Madras. It will suffice to mention the following:

$$\int_0^\infty x^{s-1}(f(0)-xf(1)+x^2f(2)-\ldots.)dx = \frac{\pi}{\sin\pi s}f(-s).$$

The result is a purely formal one. It is obviously not true unless the function $f(x)$ satisfies appropriate conditions, since the formula implies the false result that $f(s)$ is identically zero when $f(0)=f(1)=f(2)=\ldots=0$. Often with results found formally without rigorous proof, it is a routine matter to obtain such a proof, but this does not apply to the present one. As shown by Hardy, the proof involves ideas and methods of which Ramanujan knew nothing in 1914 and which he had scarcely absorbed before his death. The formula is a really interesting one suggesting many other results, some of which can be proved in other ways. I wish that Prof. Hardy had given an account of other definite integrals evaluated by Ramanujan, for example, those associated with Gauss's sums. For Ramanujan was the first to evaluate, in a characteristically original way, definite integrals such as $\int_0^\infty \frac{\cos tx}{\cosh x} \cos mx^2\, dx$, which had not been done by writers such as Kronecker and Hardy himself, who had both studied related integrals.

This seems to be the place to speak of Ramanujan's characteristic trait, which made him in his earlier days before his stay at Cambridge almost unique among mathematicians. A mathematical theorem is invariably associated with proof, and no mathematician would be satisfied with a result unless he had a proof. It may happen that he is led to believe in the truth of results which he cannot prove, but this in no way diminishes his desire to find proofs, which are ever his goal. But as Littlewood says: "Ramanujan had no clear cut conception of proof; if a significant piece of reasoning occurred somewhere, and the total mixture of evidence and intuition gave him certainty, he looked no further." This is all the more surprising as the idea of proof is so fundamental even in elementary mathematics. But even in his very first long paper already referred to, which deals with Bernoulli's numbers, after writing down the values of twenty of them, he states that it will be observed, *inter alia*, that the numerator of $B_{2n}/2n$ in its lowest terms is a prime number. He takes the numerical evidence as sufficient, and there is no trace of any suggestion that there is need of other proof of these results, which as it happens, are well known. Proofs of many of the results stated in his notebooks and letters were given afterwards by Hardy and G. N. Watson.

Ramanujan was not a well-read mathematician. In India, he apparently did not avail himself of books that were accessible to him. The only reference I find to books influencing his early work, in addition to those of Loney and Carr already mentioned, is to Edwards's "Differential Calculus" and Hardy's tract on "Orders of Infinity". There were available at Madras several books a study of which might have had a decisive influence on his work, for example, Bromwich's "Infinite Series" and Whittaker's "Modern Analysis", one of which Hardy thinks he may have seen, and also Matthews' "Theory of Numbers". He would have realized that some of the ideas expressed in his early letters were well known; such as the meaning of $\Gamma(n)$ when n is negative, and methods of attaching meanings to non-convergent series. He would have seen how vital it was to replace some of his naive points of view by more rigorous ones; for example, that a distinction must be made between $\sum_1^\infty f(n)$ and $\lim_{s\to 0} \sum_1^\infty f(n)n^{-s}$; and he would not have been so easily led astray by false analogy, as in his work on primes mentioned later. Strangely enough, he must have studied most assiduously some book on elliptic functions, probably Greenhill's. As already remarked, this subject is particularly rich in infinite series and products of a type in which Ramanujan revelled, including applications to modular functions and singular moduli. Greenhill's is an old-fashioned book, and so Ramanujan would be unaware that many of his results, strange and fantastic as they seem to those who have not a modern knowledge of the subject,

are often particular cases of a general theory with which he was unfamiliar. A comparison which suggests itself is that of finding areas and lengths of curves. Before the invention of the calculus, each result proved was no mean feat. After its invention, however, the centre of interest shifted, though one might still admire now and then ingenuity displayed in obtaining special results. Needless to say, Ramanujan showed remarkable ingenuity, and gave proofs of many of his results, but of others he could have had no rigorous proof.

Ramanujan's methods were peculiarly his own. Probably no other mathematician has relied so much upon his native wit. Most mathematicians find it a great advantage to have as extensive a knowledge as possible of lines related to their own. This increases the possibility of successful research, though sometimes there is much to be said in favour of attacking difficult problems unhampered by current ideas as to the method of approach. It is futile to wonder what Ramanujan could have done with the better tools he might have had in more favourable circumstances.

Ramanujan had very little systematic knowledge of number theory. Most of his work on this subject dealt with number-theoretic functions the values or properties of which could be investigated in a non-arithmetical spirit. Prime number theory has so developed during the last fifty years as to suggest that adequate knowledge and training are indispensable for work in this field. Ramanujan had neither, with the result that most of the results to which he was led, some by false and unproved analogies (though even thinking of some of them required a vivid imagination), were either erroneous or erroneously proved, and very little was of permanent value. This applies also to an assertion in one of his first letters to Hardy that "the number of numbers between A and x which are either squares or sums of two squares is

$$K\int_A^x \frac{dt}{\sqrt{\log t}} + \theta(x),$$

where $K=0{\cdot}764\ldots$ and $\theta(x)$ is very small compared with the integral." He later gave a false estimate for $\theta(x)$. The problem was solved by Landau in 1908 and the solution depends upon the application of the standard methods of prime number theory.

Another result mentioned in an early letter to Hardy dealt with a lattice point problem which can be expressed as follows. To find the number of positive integer values of x, y for which $ax + by \leq n$, where a, b are given and n is large. This is an important problem afterwards considered by Hardy, Littlewood and Ostrowski, and it is surprising what interesting developments arose from so innocent looking a problem.

Much more important were Ramanujan's contributions to the question of the representation of numbers as sums of squares; that is, for given k, n to find the number $r_k(n)$ of solutions in integers $x_1, x_2, \ldots x_k$ of $x_1^2+x_2^2 \;\ldots\; +x_k^2=n$. If we write $\theta(q)=\sum_{m=-\infty}^{\infty} q^{x^2}$ the question reduces to that of finding other expressions for $\theta^k(q)$ which allow of simple expansions in powers of q. Thus, as shown by Jacobi,

$$\theta^2(q) = 1+4\left(\frac{q}{1-q}-\frac{q^3}{1-q^3}+\frac{q^5}{1-q^5}-\ldots\right),$$

from which $r_2(n)$ is four times the difference between the number of divisors of n of the respective forms $4m + 1$, $4m + 3$. Expansions had been found by several writers over a period of years in the case of an even number of squares, but there had seemed to be no straightforward method for establishing the formulæ. A general identity was given by Ramanujan for $\theta^{2s}(q)$ without proof but with the characteristic remark "it can be shown". The proper approach to results of this kind is the methods of the theory of modular functions discovered by Mordell, which are also appropriate for the more difficult case when the number of squares is odd, as was discovered later by Hardy.

A fair proportion of the material which Prof. Hardy has now discussed was discovered by Ramanujan in the five years after he left school, and recorded in the notebooks he kept. Some of my previous remarks have shown how unfortunate it was that he had not at an earlier age the advantage of expert guidance and supervision, so that his talents could be properly directed. This would have spared him a great deal of time spent upon known work or upon erroneous ideas, or upon unnecessary elaboration in producing a great many detailed results where perhaps a few would have been sufficient. He would have learnt the importance of rigorous proof. There is of course always the possibility that he might have proved unresponsive to guidance; and after all there is much to be said for experience of any kind that can produce results.

Though Ramanujan had a hard and difficult struggle in his earlier days, it was not so after he wrote to Hardy. In fact, he could not have found a more appreciative, a more generous or a more influential patron, collaborator and friend. Thus it is through Hardy that Ramanujan's name is associated jointly with several beautiful theorems in which he had been anticipated, for example, in the Rogers-Ramanujan identities and in the Dougall-Ramanujan hypergeometric identity. I recall that in the first edition of one of Landau's books, Kakeya's name is attached to a theorem,

but the name completely disappeared in the second edition after Landau had discovered that Kakeya had been anticipated by Eneström. Again, Hardy associates Ramanujan's name in Lecture VIII of the present volume with the asymptotic formula for the number of partitions of n. The proof depends upon Cauchy's integral for a function of a complex variable, a subject of which Ramanujan knew practically nothing. Of course the first suggestions as to the possibility of such results and some indication of their form were due to Ramanujan, and no doubt he was full of suggestions as to the form the final results should take. There would obviously have been no such formula without Ramanujan, and one can easily understand Hardy's gratitude for having come in contact with Ramanujan.

In attempting to assess the standing of Ramanujan as a mathematician, it is difficult not to be influenced by admiration and wonder at his success in becoming a professional mathematician in spite of the greatest difficulties. The estimate depends, as for all mathematicians, essentially upon the novelty and importance of his original work. Though some of it was wrong, and some of no permanent value; though some was over-specialization of results embodied in general theory; though some of his most interesting work was anticipated or not proved, nevertheless, there remains an impressive and formidable balance which has had great influence in shaping the direction of some of the best research since his death. To very few other mathematicians are Klein's remarks made many years ago so appropriate as to Ramanujan. "The secret of gifted productivity will always be that of finding new questions and new points of view, and without these mathematics would stagnate. In a certain sense, mathematics has been advanced most by those who are distinguished more for intuition than for rigorous methods of proof."

THE COSMICAL ABUNDANCE OF THE ELEMENTS*

By Prof. Henry Norris Russell

EIGHTY-EIGHT chemical elements have been isolated. Their separation by chemical means is sometimes easy, sometimes very difficult, and the best available tests differ greatly in sensitivity. Spectroscopic analysis provides a test for all constituents at once; but these tests, too, are unequally sensitive. Fortunately, the two methods supplement one another.

The composition of the earth's crust—above an arbitrary depth, such as ten miles—is well known. Oxygen is the most abundant element, whether by weight or number of atoms. Silicon is next, and then aluminium, iron, magnesium, calcium, sodium and potassium. These eight elements account for 98 per cent of the whole mass—the hydrogen in the oceans for but a quarter of the remainder.

The high mean density of the earth, and the seismological evidence for a liquid core, show that the 'crust' is not a fair sample of the whole. We may hope to do better with meteorites, taking an average of the various types (stone, iron, sulphides) in the ratio of their abundance (10 : 2 : 1, according to Goldschmidt). The result is significantly, but not greatly, different. Iron, magnesium, nickel and sulphur are more abundant; silicon, aluminium, and the alkali metals less. Just these differences are to be expected if the granitic 'crust' of the earth has segregated from a main mass similar in composition to meteorites.

Recent photographic observations of bright meteors show that their orbits were elliptical and of short period, so that they are samples of the solar system rather than the cosmos. Other selection processes may have operated. The spectra of comets suggest strongly that some of the solid bodies whence the gases escape may be composed largely of carbon compounds. Such a body accompanying a stony meteorite in its flight through the earth's atmosphere would be immediately destroyed.

Outside the earth, we must rely on the spectroscope alone. In the stars, the conspicuous differences along the spectral sequence are known to arise from differences of temperature and ionization. Miss Payne's conclusion (1925) that the general run of stars are very similar in composition has been fully confirmed.

Sixty elements have been identified in the sun; and the apparent absence of almost all the rest explained by unfavourable situations of their ultimate lines in the inaccessible ultra-violet. More than forty have been identified in Pegasi.

On good *coudé* spectrograms, equivalent widths of stellar lines may be well measured; and the data for the sun are extensive. To find from these the 'effective numbers of atoms above the photo-

* Abstract of an address delivered at the symposium on September 26, in connexion with the celebration of the fiftieth anniversary of the University of Chicago.

sphere' concerned in producing the line demands a knowledge of the curve of growth. Its theoretical form is well known, but involves the temperature of the atmosphere, the broadening of the stronger lines by collision damping, and the possible effects of turbulence—all involving parameters which must be found from observation.

The 'effective number of atoms' depends on the degree of ionization of the element, the Boltzmann factor for the lower state involved, and the transition probability (or f-value). The first two may be found from the observations if the third is known for enough lines. We have to depend for these at present mainly on an approximate theory. Good observed values are badly needed, and are now being obtained. The position of the 'photosphere' depends on the general opacity and its variation with wave-length (for which our best values still come from the limb-darkening of the sun).

The most comprehensive attempt at quantitative analysis of the sun's atmosphere is still my reconnaissance in 1929, based perforce on Rowland's estimates of intensity, and omitting many refinements for lack (at that time) of data. The calibration thus derived turns out to agree surprisingly well with modern curves of growth.

An analysis by Dr. Leo Goldberg, with all present refinements, is in progress. Through his generosity a comparison with his unpublished results may be presented. They cover at present only the more abundant elements. Omitting elements for which the older determinations were noted as doubtful, the logarithms of the number of atoms above the photosphere differ, on the average, by $\pm$ 0·28, corresponding to a factor of 1·9, while the range in abundance is 200,000-fold. Allowance has here been made for differences in the assumed temperature of the solar atmosphere, and in zero point. Goldberg's absolute values are smaller by a factor of about 30, owing to allowance for collision damping, which was unthought of in 1929.

For these same elements, the relative abundances in the sun, and in meteorites (according to Goldschmidt) show an average discordance of $\pm$ 0·45 in the logarithm, which in view of the uncertainties of determination does not indicate any definite difference in composition. For the rarer elements, the solar values of 1929 are smaller than Goldschmidt's by a factor as great as 20 for the rarest. The abundance of these elements, unlike the others, is found from very faint solar lines. An error in the old calibration of such lines (which was difficult) would account for the discrepancy.

There is therefore no present reason to conclude that meteorites differ in composition from the sun's atmosphere, so far as the metals are concerned.

For the lighter non-metals, the situation is very different. Carbon, nitrogen, oxygen and sulphur have lines in the infra-red, from which the numbers of atoms in the corresponding excited states can be found. But the Boltzmann factors are very large, and the temperature is not known well enough to permit their accurate evaluation. The hydrogen lines are so sensitive to broadening that they cannot be used to obtain its solar abundance.

No fewer than six indirect methods have been developed by various investigators. These give for the ratio of the number of hydrogen atoms to that of all the metals together values ranging from 1,000 to 8,000.

The inert gases show no absorption lines in the sun This serious gap in our knowledge has been filled by an investigation by Unsöld based on measures of line-widths in spectra of the star τ Scorpii, taken at the McDonald Observatory. This gives what appear to be reliable values for the abundance of the light elements, and also of magnesium, aluminium and silicon. For every atom of magnesium or silicon (which are almost equally abundant) there are approximately three of carbon, six of nitrogen, sixteen of oxygen, eighteen of neon, 3,000 of helium, and 16,000 of hydrogen. The enormous preponderance of hydrogen is again confirmed, and helium turns out to be a rather good second. Fluorine, sulphur, phosphorus and argon should be determinable in the same way.

Only the large differences in composition among the stars can be detected, pending study of high-dispersion spectra. The most notable example is furnished by the stars of classes R and N, the spectra of which show enormously strong bands due to carbon molecules and carbon compounds. Here there is no doubt that, as the late R. H. Curtiss first suggested, we have to deal with reducing atmospheres in the ordinary chemical sense, containing more carbon than oxygen, while the great majority of the cooler stars have oxidizing atmospheres, the excess of oxygen permitting the formation of the metallic oxides, which show in their spectra.

At higher temperatures, where compounds are dissociated, differences in composition are spectroscopically less conspicuous. One star of about the sun's temperature, R. Coronæ Borealis, has been found by Berman to contain carbon in great excess, and little hydrogen; and another, υ Sagittarii, analysed by Greenstein, shows helium in great preponderance, and hydrogen almost absent.

In the gaseous nebulæ, and the envelopes of novæ, the density is very low, and the dilution of the exciting radiation great. These conditions strongly favour the emission of forbidden lines, and favour the detection of those elements which have such lines accessible. Nitrogen, oxygen, fluorine,

neon, sulphur, chlorine and carbon have this advantage. Hydrogen and helium, which show strong permitted lines, must be very abundant. The metals are at a great disadvantage, but faint lines of several have been found. Allowing for the very different conditions of excitation, there is small evidence of composition differing from the stars.

The isolated atoms and molecules which absorb interstellar lines are all in the lowest component of their ground-states. Magnesium, silicon, and many other elements are thus removed from observation, and the spectra of the rest reduced to a very few observable lines. Sodium, potassium, calcium, titanium and iron have been detected, and the compounds CH and CN. The electron-abundance, found by comparison of Ca and Ca^+, shows that hydrogen, though not directly observable, is very abundant. In general, there appears to be a great similarity of composition, except for the solid bodies, which are just what might be expected in masses segregated by condensation.

BIOLOGY IN HUMAN RELATIONS*

By Mrs. S. Neville-Rolfe, O.B.E.
British Social Hygiene Council

VICTORY of arms will not remove the causes of war. These lie in the lack of ability, character and emotional development of man himself. If the forces he has created are to be readjusted and canalized to human service and welfare, it is urgent to fit man for the task. The recognition of this possibility and a concentration of effort in an endeavour to understand and improve the quality of man, both of to-day and to-morrow, intellectually, emotionally and physically, would give a re-birth to hope.

The attempt of the Economic Conference to reduce financial tensions by a planned money policy failed owing to the recognition that man has not attained a standard of integrity and trustworthiness requisite to success. Countless instances exist of man's inadequacy being the barrier to progress.

Since the beginning of the century, research workers of the universities, the experimental farms, the consulting rooms and the hospitals have added much factual knowledge to our store, but its application to man has been checked by its seeming conflict with traditional values and by the barriers of prejudice and unreasoning fears inherent in man himself. Biology is being applied to his material advantage in agriculture, in medicine and in food production, but hardly at all to man himself. Psychology has been discovering why man behaves as he does and disclosing the extent to which unrecognized and repressed emotions result in individual and group action entirely contrary to the dictates of intelligence. Physiology is explaining something of the interdependence of mind and body and the results of glandular disharmony on character. Anthropology and sociology demonstrate the dependence of the individual on the group and of the interaction between man and his environment. What we now need is a concerted endeavour to collate, interpret and apply these various discoveries.

Social biology rests on the factual contributions made by all sciences bearing on the development of man. Its task is to correlate and devise methods for their application, related to ethical principles, suited to the general pattern of each social structure.

A wide range of war and post-war problems awaits attention; to select but a few: migration and evacuation in relation to the family; nutrition and maternal mortality; miscegenation; family allowances; optimum marriage age; fertility, care and status of the unfit. The problems are legion. The present urgency is to democratize existing knowledge under responsible auspices.

An ignorant population is in danger—a prey to exploitation in the biological, as well as in the economic and political, fields. The harm can be irreparable when personality itself is injured. We see a terrifying example in the psychological conditioning of Nazi youth to cruelty and the harnessing of its emotional drive to the false values of national aggrandizement. In the biological field the same applies to the ease with which a distorted interpretation of eugenics has been imposed on a biologically ignorant population and used as a political weapon.

Even after two generations of education in Great Britain, the omission of social biology in school curricula has deprived science of an understanding public. Facts are discovered and published, but make little impression on individual practice, social behaviour or administration, as they relate to no emotionally accepted values.

Knowledge of nutrition, heredity and health is

* Substance of a paper read at the Conference on Science and World Order, on September 28.

available, yet bad feeding, unprotected defectives and irresponsible sex behaviour prevail. The evacuation disclosures of habits at direct variance with accepted standards of cleanliness, all demonstrate the futility of a system of education which ignores preparation for life in a living world. Such an omission is a serious handicap to a nation at war.

Measures should be taken forthwith to relate social biology to ethical values, and to apply present knowledge to current problems. This is admittedly incomplete, but each additional fact, each extension of our intellectual range and of our capacity to appreciate beauty in form, sound, colour and sense, each new harmony between intuition and science that illuminates truth, clarifies our spiritual vision. Social biology, drawing its facts from science, may be pictured using them as pieces of a jigsaw puzzle from which each generation must compose the ever-deepening and satisfying key-picture of what man is and can be. We must produce, on the basis of existing knowledge, a rough and tentative outline of that picture, now dimly perceived, of complete and developed man.

Of equal urgency is to promote a wider understanding and development of the whole man. Every educational system has concentrated on the training of intelligence, none has yet taken cognizance of the paramount influence of the emotional condition of man on his behaviour, or attempted to apply even our present knowledge of psychology. We are a world of emotional children with adult minds—babies playing ball with bombs.

A true democracy can only be created by the emotionally and intellectually developed, inspired with a positive purpose in life.

Emotion and intelligence, united in a common objective, obtain astounding results in thought, in action and in conduct, as exemplified by the ideal of the League of Nations, the Battle of Britain, the brotherhood of the bombed and homeless.

Unfortunately, even the groundwork of emotional understanding does not yet form a necessary part of the training of our leaders. Though some training in psychology is given to teachers, little emphasis is placed on the emotional aspect. Normal psychology and emotional development have no definite place in the training of the medical and allied services or in that of the judiciary.

Yet, how can a medical practitioner understand the whole personality of his ordinary patient when the only psychology he has studied is that of the abnormal ? How can the midwife and the health visitor handle problems of family adjustment and emotional stress with no understanding of this side of her own or her patients' nature ? How can the magistrate on the bench judge wisely actions arising from subconscious repressions when these to him appear irresponsible excuses ?

We are adolescents who have grown out of our clothes. The manners and customs fitting the knowledge available in the past constrict development ; the tight buttons of outworn prejudice and the belts and bands of repressed emotion seriously check healthy personal growth and racial progress.

That the younger generation welcomes information and guidance on matters of social biology is evidenced by more than a hundred thousand of the 16–25 age group who have attended *ad hoc* courses of lectures presenting a biological outline of how minds and bodies function, and encourage discussion on the related personal and social questions. These have been provided by progressive local authorities through the British Social Hygiene Council. Since 1934 the Educational Advisory Board of the Council has worked to promote the introduction of biology related to man into the educational system, and has made steady, if slow, progress, now gaining momentum through war conditions.

Up to date, local authorities have sponsored fifteen teachers' courses, and twenty teachers' conferences, and about thirty are now interested in, or considering, emergency programmes. It is a beginning in the effort to equip youth for personal and public life.

It is recognized already in military circles (though not always practised) that those trained and experienced in the War of 1914–18 are not the best improvisors of strategy and tactics for a war of dive-bombers and tanks. This principle applies even more strongly to questions which affect the development of man himself.

The emotionally immature, belonging to a previous generation, with a background of traditional dogma as religion, of *laisser-faire* as social economics, of philanthropic charity as good citizenship, and an idea of the 'equality of man' which ignores biological evidence, are not qualified to govern, or to lead youth in the present world crisis ; yet it is they who are in control to-day. The old in experience and young in mind have ever been outstanding leaders, but the old in mind and years are unable to grasp the new problems or to relate new knowledge to spiritual values. They fear youth and from a mistaken sense of duty they continue to bear burdens beyond their years, and are barring advance. Hence the time-lag between the laboratory and the public is greatest in social biology.

It is vital to reach the younger generation in service and civil life, the parents of the future, and gain their intellectual interest and emotional drive behind the idea that man may control and

direct to the service of man the forces that he has set in motion.

To bring youth into world affairs, they must learn how to participate in the solution of daily problems. In science, in every firm and works, on committees of management, the Whitley Councils, staff and workers' conferences—let the under-twenty-fives be included to an adequate extent in each group represented and secure an equal proportion in each local government committee, social organization and voluntary body. Once the young see some hope of taking an effective share in the national effort, the service will not be lacking. The intelligence quotient reaches its adult level at about thirteen or fourteen. Experience is needed, but so are drive, a new outlook, and faith in man's destiny.

The claim of youth to the knowledge that could equip them for life, the demand for opportunity to enable them to grapple with those problems beyond the grasp of the old in mind, must be met soon, if the younger generation is to contribute effectively to the War and the post-war endeavour.

The present 'youth movement' was inspired from Germany; though misdirected in aim, its methods were effective in giving the Nazi leaders what they sought, because emotional and intellectual efforts were united, leadership was entrusted to youth, and its driving force was positive. The Scout and Guide movement, British in origin, also owed its success to its positive ideal and the leadership of youth. The present youth movement in Britain has not included the biological essentials. The control of the 'movement' is with few exceptions in the hands of older members of education committees, and of voluntary organizations established to meet older ideas and conditions. It is unrelated to reality and therefore unrelated to youth.

The young to-day have a deeper sense of spiritual values, but their positive philosophy must embody all truth as at present perceived. They are politically minded and see in personal freedom and impartial justice man's most precious possession, but of the present incomplete interpretation of the idea of Democracy, of Fascism, Nazism or Bolshevism, indeed of all existing systems, they tend to say "a plague on all your houses; we want something better!" Let them have the opportunity to create it.

PERCH IN BRITISH LAKES

A NEW FISHING INDUSTRY

By Dr. E. B. Worthington

Freshwater Biological Association, Wray Castle

It is common knowledge that progressive changes in the physical conditions of an environment are paralleled by changes in the plant and animal communities inhabiting it. One of the first workers to elaborate the principle for the freshwater environment was Pearsall[1], who illustrated it with reference to the plant communities of the English lakes, but recognized that the animal communities were subject to corresponding changes. Thus, in the fish fauna of the English lakes there is a tendency for the original association of species, dominated by char (*Salvelinus willughbii*) and brown trout, to change into one dominated by perch and pike. Under natural conditions the change is very slow, being connected with the accumulation of silt and the general increase in productivity of water resulting therefrom; but in certain cases unconscious intervention from man appears to have accelerated the process. Thus for Windermere there is some documentary and much hearsay evidence that during the past fifty years the char and trout, which formerly gave rise to prosperous food and sporting fisheries, have been largely superseded by perch and pike, the change having probably been hastened by a general increase of productivity resulting from the addition of sewage.

From the fishery point of view the perch are recognized as a curse not only in Windermere but also in many other lakes in the district (see Watson[2]), because, as their numbers have increased they have become so dwarfed in average size as to be practically valueless to either the angler or the housewife. In order to save the fisheries, it seemed necessary to force evolution backwards, as it were, and thereby to cause the lake's fish biology to revert to the condition it was in, say, a century ago. The War has provided a use for these millions of small, unwanted fish. Their removal will, it is expected, benefit the post-war fishery, and at the same time initiate a large-scale ecological experiment which is likely to repay study for some years to come.

The perch of Windermere was first studied scientifically by Allen[3], who found that for most of its life the perch is a direct competitor with the

trout for food supplies, and showed, with the aid of unbaited traps, that the perch undergoes a definite annual migration, from water deeper than 60 ft. where it spends the winter, into water shallower than 30 ft., to spawn in the spring and afterwards to spend the growing period of summer.

Soon after the outbreak of war in 1939, Allen's results were followed up on a larger scale to ascertain whether a method could be devised for catching perch in numbers large enough for practical fishery purposes, and also to obtain more detailed information about their interesting seasonal migration. Unbaited traps made of wire netting were fished near Wray Castle in depths of water ranging from 5 ft. to 100 ft. continuously for more than twelve months, the traps being lifted three times each week for the removal of fish. A few perch were taken throughout the year, but immediately after the fish had moved into the shallows in the spring they entered the traps in really large numbers for a period of about two months. A catch of five hundred fish from one lift of a single trap was by no means exceptional. The fish taken were all small, averaging a little less than 1 oz. each in weight, and the total weight taken at the optimum depth per trap per night's fishing averaged 8½ lb. over a period of eight weeks.

These perch traps are easy and cheap to make, costing less than £1 each, complete with rope and a marking float. Their manipulation requires but little labour since they remain in the water throughout the fishing season, serving not only to catch the fish but also to store them alive until the appropriate time for landing. Some pike and eels find their way into the traps following the perch, but char are never caught and trout only in the proportion of one to about 50,000 perch, and even these few can be returned to the water undamaged. Therefore, these traps seemed to be ideal instruments with which to make available perch for human consumption, and at the same time to improve the post-war fisheries.

A scheme was drawn up for the Freshwater Biological Association to start a commercial trap fishery on Windermere in the spring of 1941, using 380 traps, the correct depth of fishing to be determined by a pilot series of traps in one part of the lake. Through the good offices of the Development Commissioners and the Ministry of Agriculture and Fisheries, a grant was made to go part way towards the capital cost, and the materials for the traps were made available. Volunteer evening labour was organized among some thirty fishers living near the Lake, so that all the traps could be lifted on two or three evenings each week. British Fish Canners Ltd., of Leeds, conducted trials with samples of the fish and found that by suitable processing they could be canned like pilchards, and this firm offered to purchase the whole catch.

The first season's operations were restricted mainly to the north basin of Windermere and were essentially experimental, but they had the satisfactory result that during two months more than a million perch were sent to the canning factory at Leeds and, packed in about 150,000 tins, are being marketed as 'Perchines (Lakeland Perch)'. In addition, more than 500 eels and about 200 pike were removed from the lake. For the area of water less than 20 m. in depth, which is inhabited by these fish, the cropping rate worked out at about 46 lb. per acre. From the commercial point of view this fishery paid its way handsomely: after deducting running costs such as labour, bonuses to the volunteer fishermen, transport of fish, and allowing a 10 per cent depreciation on the gear, the proceeds from fish sold gave a net return on capital expenditure of 69 per cent during the first season of two months.

Now that the method has been demonstrated, it is hoped that a considerable expansion of this fishery will take place in 1942 and 1943. With this object in view the catching propensities of a few traps were tried out in some eight other lakes in the Lake District during the spring of 1941. In most of these results were promising, and in some the perch traps were found to catch large quantities of eels, which are of considerably higher food and cash value than perch. The method is applicable primarily in those waters where trout fishing is practised, and as such does not in any sense prejudice the angling interests of our freshwaters, but on the other hand offers an opportunity for their improvement. Apart from the Lake District itself, there are many lakes and reservoirs in England, Wales, southern Scotland and Ireland which are suffering likewise from a superabundance of perch. The new method of catching them may have a particular application in storage reservoirs, from which the removal of a crop each year is highly desirable to keep the water in good condition.

Thus it is expected that this new industry has considerable opportunities for expansion during and perhaps after the War, if the necessary organization can be brought into being. In 1942 it is hoped to enlarge considerably the fishery on Windermere and to establish similar fisheries on several other waters in the Lake District. At the same time a few traps will be given a trial in as many other likely waters as possible to prepare the ground for further commercial development in 1943.

OBITUARIES

Prof. A. G. Green, F.R.S.

BY the death of Prof. Arthur George Green on September 12, at the age of seventy-seven, the British dyestuffs industry has lost its foremost chemist and an indefatigable champion whose experience had extended over fifty-six years. His genius as a chemist lay in his capacity to produce a simple solution to any problem in hand derived from facts already known, a solution so simple that it had been overlooked by smaller minds enmeshed in the difficulties of a more complex approach.

Green first showed this capacity when, in 1887, at the age of twenty-three, having been appointed to the staff of Brooke, Simpson and Spiller in 1885, he made primuline by the fusion of *p*-toluidine with sulphur, and finding that when sulphonated it possessed affinity for the cotton fibre, he proceeded to diazotize its free amino-group and couple it with various components on the fibre, thus establishing the process of ingrain dyeing which gave to cotton users organic dyes faster in many respects than those they had had heretofore. As an offshoot to this work, in collaboration with Cross and Bevan, he laid the foundation of the modern diazotype copying processes, using diazotized primuline as the light-sensitive medium and developing the screened areas where the diazo-compound had not been destroyed by light, thus producing positives direct. For this he received the Silver Medal of the Royal Society of Arts in 1891.

The dye-making industry was then declining in the face of Continental competition, and a less tenacious man might well have left so unpromising a field from which he had won little but a broad reputation. Green saw, however, that this decline was due to the failure of the empirical methods which had brought Britain success in the Industrial Revolution, and that the cause was to be found in the application by its competitors of a new technique in industry to which the key was the close application of science from day to day, exemplified in the highest degree in the manufacture of the synthetic organic dyes. He refused, therefore, to desert the industry, the salvation of which became a life cause with him, and from 1894 until 1901 he was manager to the Clayton Aniline Company, and after two years as a consultant in London became in 1903 professor of tinctorial chemistry in the University of Leeds.

In his unique combination of theoretical knowledge and practical experience, Green was henceforward recognized as the leading British authority on the dyestuffs industry, and he made every effort to show that its fate in Britain was due to neglect of research. His influence now became profound, for his students included men who were afterwards to carry out the task of rebuilding the British industry, as well as those who were to make their mark among the dye-users. With them he carried out researches on the constitution of aniline black and of the stilbene dyes, together with other work on azo, triphenylmethane, and quinone-imine dyes, much of it inspired by the quinonoid theory of colour.

Green was well known in Germany, where he had a strong friendship with Caro; the spectacle of the creeping madness which has engulfed Germany gave him great pain. On the outbreak of war in 1914, he turned to the question of the supply of explosives, and his method of making picric acid starting from 1 : 2 : 4-chlorodinitrobenzene was widely used. He served on the Ministry of Munitions Committee throughout the War. He resigned his chair at Leeds in 1916 and became director of research to Levinstein Ltd., at Manchester, where in 1917–18 he established the manufacture of mustard gas on the technical scale, a duty the necessity for which he strongly disliked. In 1919 he returned to the dyestuff field and was particularly attracted by the problem of dyeing cellulose acetate silk, for which fibre he produced the first range of special dyes, the ionamines; these are aminoazo bases solubilized as *N*-methyl-ω-sulphonates which are decomposed in the dyebath, regenerating the finely divided base with which the fibre is dyed. Also his work on the sulphuric esters of the β-hydroxyethylarylamines led eventually to the 'solacet' dyes of the Imperial Chemical Industries, Ltd. Unable to agree with the policy of the board, he left the British Dyestuffs Corporation in 1923 and returned to his private practice, which was extensive both in Europe and the United States.

An interest in chemotherapy was early aroused in Green, especially by Ehrlich's view that the action of a drug may be considered as the selective dyeing of the organism invading the body. In partnership with Dr. M. Coplans, he brought out a stabilized form of calcium acetyl salicylate, and in recent years he had been working with the α-sulphonate of *N*-ethylsulphanilamide. He was a member of the Industrial Solvents Committee of the Medical Research Council.

Green was elected to the Royal Society in 1915 and to the livery of the Dyers Company of the City of London in 1918. He was awarded the Dyers Company's Gold Medal for research with two bars, the first and second (with W. Johnson) awards being for his work on aniline black and the third for the ionamines. He was Perkin Medallist in 1917, and in 1934–35 jubilee president of the Society of Dyers and Colourists; as a member of learned societies, he was active in all movements to improve the status of the profession of chemistry.

Green was educated at Lancing and studied under Williamson at University College, London. His shy, sensitive and inquiring nature rebelled at the authoritative tone of the classical-clerical teaching of the 'seventies, which suffered no questioning and no criticism and held the scientific outlook in gentle derision or contempt. Hence his appreciation of much that the humanities stand for was seared; he jettisoned from his mind anything that might bear the taint of mysticism and under a quiet exterior he

applied to life an austere and almost fierce logic which made him a tenacious worker in the laboratory and an uncompromising opponent in the council room. He was a great teacher, visiting his students or staff at the bench. He would carry out a novel synthesis of several stages in test-tubes, and obtain sufficient product both to make a dyeing and a rough assay of its fastness properties; thus he imparted directly his skill, experience and enthusiasm. In return he was given loyalty and affection in an uncommon degree. He disliked all forms of ostentation and few knew how often he gave help to the unfortunate, including the victims of Hitlerite oppression. Finally, in his later years, he had the satisfaction of seeing in the policy of Imperial Chemical Industries, Ltd., towards research the realization of the cause for which he had fought, and nothing gave him greater pleasure than his periodical visits in his advisory capacity to the new laboratories of the Dyestuffs Group at Blackley.

Green's garden was his recreation, but even there he could not resist the urge to experiment, and he had obtained results indicating that traces of fluorescent dyes applied to the soil can affect the growth of plants.

His marriage with Constance Fanny, daughter of Henry Charles Heath, miniature painter, lasted for fifty-two years, and they showed to a wide circle of friends a perfect example of married life. She was a woman of great courage, and had it not been for her influence Green might never have emerged from a life of monastic seclusion to play the part he did. The shock of her unexpected death in January 1941 was one from which an already weakened heart could not recover, and he died suddenly and peacefully in his sleep nine months after her.

K. H. SAUNDERS.

Dr. J. S. Plaskett, C.B.E., F.R.S.

JOHN STANLEY PLASKETT, late director of the Dominion Astrophysical Observatory, Victoria, B.C., who died at Victoria on October 17 at the age of seventy-five, was the doyen of Canadian astronomers. Educated at Woodstock High School in Ontario, and apprenticed to the Edison Electric Company at Schenectady, he gained valuable engineering experience with the Canadian Edison Company at Sherbrook. His chance of securing a university education came somewhat late in life—as he graduated with first-class honours in mathematics and physics at the University of Toronto at the age of thirty-three. It was four years later that his engineering knowledge and experience together with his proved powers of research in photography and spectroscopy led to his appointment to the astronomical branch of the Department of the Interior at Ottawa. In 1905 he led the Canadian Eclipse Expedition to Labrador and was appointed to the post of astronomer at the Government Observatory of Ottawa. Here he was placed in charge of the new 15-in. telescope for which he had already designed the spectroscopic equipment.

Plaskett's early work on stellar radial velocities and on the solar rotation led him to press for a larger telescope to be placed in climatically more suitable surroundings. His efforts were successful and when the Canadian Government established a new observatory at Victoria, B.C., with a 72-in. telescope, on Plaskett fell the main task of dealing with all the optical and engineering problems that had to be faced; to him also naturally fell the task of directing the work of the new observatory. Stellar radial velocities, spectroscopic orbits of eclipsing variables, the physical nature of early-type stars—particularly *O*-type stars—such were the main subjects of his own work and of the researches of his staff. The distribution in space of the interstellar matter which gave the fixed calcium lines in early type spectra was a subject to which he gave much attention. The part of the Milky Way which was accessible to the Victoria Observatory became its special field of work, and Dr. Plaskett was a strong supporter of the scheme to place a companion large telescope at the Radcliffe Observatory, Pretoria, to complete the study of the southern regions of the Milky Way.

Dr. Plaskett was a regular and welcome attendant at the gatherings of the International Astronomical Union, serving on a number of its working committees. After his retirement from Victoria, he was fully occupied with work in connexion with the optical parts of the 80-in. telescope of the Fort Macdonald Observatory in Texas; recent publications have shown with what success he carried out this task. The value of his scientific work was freely recognized. He became F.R.S.C. in 1910, F.R.S. in 1923, and C.B.E. in 1935 on retirement. He was Gold Medallist and George Darwin lecturer of the Royal Astronomical Society, Bruce Medallist of the Astronomical Society of the Pacific, Draper Medallist of the National Academy of Sciences, and was the recipient of honorary degrees at a number of universities. He leaves a widow and two sons, one of whom is Prof. H. H. Plaskett, professor of astronomy in the University of Oxford.

F. J. M. STRATTON.

Dr. Walter Granger

STUDENTS of mammalian palæontology will have learnt with great regret of the death on September 6 of Dr. Walter Granger of the American Museum of Natural History at the age of sixty-eight.

Granger started his career in 1890 in the American Museum as a taxidermist, but an expedition to the Bad Lands of Dakota after living animals, a part of the world famous for its fossils, changed his outlook and started a love of palæontology which determined his future career. How many expeditions he afterwards made to the western States of the United States to search for fossils the writer of this short account, who has a happy personal memory of one of them, cannot record, but the number must have been well over twenty. In addition, Granger worked for a season in the Fayum Desert of Egypt and was second-in-command to Dr. Roy Chapman Andrews, now director of the American Museum, on the important and successful expeditions to Mongolia sponsored by that institution.

As a collector in the field Granger had very few equals. By long experience he seemed to have acquired an extra sense which led him to the places where the best things were to be found and, when discovered, his superb skill in their excavation and preservation, the result of his acquired knowledge and great patience, came into play, as many a specimen in the galleries of the American Museum bears permanent witness.

He was, however, far from being only a skilled collector. His scientific work, chiefly on the mammals of the Eocene Period, if not as great in quantity as that of some of his colleagues, was in no way behind in quality. His papers are models of clarity and conciseness which students would do well to study.

Granger was a most lovable character, entirely loyal to his friends and colleagues and to the American Museum. He was almost unduly modest about his own attainments, but he never withheld sound and generous advice whenever his help was asked. His quiet sense of fun and his good humour and unperturbability over the various worries incident to expeditions will be well known to those that have had the opportunity of being with him in the field.

Born in Vermont, he left for New York at an age too early for a university training, but towards the end of his career Middlebury University of his native State honoured him and itself with a doctorate *honoris causa*.

Granger was one of a band of vertebrate palæontologists who gathered around the late Prof. Henry Fairfield Osborn, and in his career of just over fifty years in the American Museum he performed a life work which is a monument to his memory.

C. FORSTER-COOPER.

Prof. W. H. Heaton

THE death on October 20 of Prof. W. H. Heaton at the age of eighty-five brought to an end a personal association with University College, Nottingham, almost from its beginning.

William Haslam Heaton, born at Bolton in 1856, attended Manchester Grammar School, where he won an open scholarship at Brasenose College, Oxford. He had a distinguished university career and gained the highest distinctions in both mathematics and physics. He was appointed lecturer and senior demonstrator in the Clarendon Laboratory of Physics at Oxford, and was repeatedly appointed examiner to the Universities of Oxford, Durham and Sheffield.

In 1884 he became professor of mathematics and physics at University College, Nottingham, which had been opened only three years before. There were flourishing evening classes, but scarcely any day students. Prof. Heaton's popular evening lectures on scientific subjects were very successful, but a more difficult task was to build up the full-time day work. One step forward was when an Education Department was opened in 1890. In this he played a leading part, as also in setting up a Department of Engineering, which was later followed by a Department of Mining.

Prof. Heaton became vice-principal in 1896, and in 1906 his teaching responsibilities were lightened by the establishment of a separate chair of physics; this gave him more time for consideration of general College policy. In spite of his own tastes lying in the direction of science, he clearly perceived that the development of the College had been one-sided, with the Faculty of Arts lagging far behind. In 1911 he became principal, and at once instituted new professorships of English and mining, to be followed later by several other chairs. Many developments in general policy were made at the same time, and the status of the College soon began to rise. This progress was checked by the outbreak of war in 1914, but a new period of rapid development began in 1919. New laboratories were opened and emergency accommodation of every possible kind was added, but the College grew too large for its existing site. Then came the splendid benefactions of Lord Trent and the opening of new College buildings at University Park in 1928.

Prof. Heaton retired in 1929, but still retained an active interest in College affairs and was repeatedly consulted by his successors in the principalship. His death represents a very great loss to the College he served so well.

H. T. H. PIAGGIO.

Prof. S. Kopeć

NEWS has been received that Prof. Stefan Kopeć, professor of biology in the University of Warsaw, and his son were among those executed near Warsaw as a reprisal for the killing of a Polish 'quisling'. In his early days Kopeć worked on the metabolism of insects with Prof. Garbowski at Cracow. After work on growth in rabbits at the Polish National Institute for Rural Economy at Pulawy he went with a Rockefeller fellowship to the Department of Animal Genetics at the University of Edinburgh. On his return he published a very extensive series of papers on growth and the body proportions of mice. In 1932 he was appointed professor in charge of the Biological Laboratory of the University of Warsaw where he continued his studies on growth. Lately he had been engaged in experimental studies on density of population problems as affecting fertility and growth. His death is a great loss to biological science.

WE regret to announce the following deaths:

Dr. E. S. Beaven, the well-known agricultural botanist and plant breeder, on November 12, aged eighty-four.

Dr. J. A. Hood, founder of the Hood chair of mining in the University of Edinburgh, on November 19, aged eighty-two.

Prof. Walther Nernst, For. Mem. R.S., professor of physical chemistry in the University of Berlin, aged seventy-seven.

Mr. J. F. F. Rowland, formerly public analyst for St. Marylebone, an authority on analytical and bacteriological examination of foodstuffs and water, on November 2, aged seventy.

NEWS AND VIEWS

Veterinary Laboratory, Weybridge

DR. W. HORNER ANDREWS vacated the post of director of the Veterinary Laboratory, Ministry of Agriculture, Weybridge, at the end of September, having held the appointment since 1927. He has taken up an appointment in the office of the Animal Health Branch, Ministry of Agriculture. Prior to taking over the Weybridge post, Dr. Andrews held research appointments in South Africa, where he served on the staff of the late Sir Arnold Theiler. He went to South Africa in 1909 and shared in the research work which led to the development of the Onderstepoort Laboratory near Pretoria which is now so well known. During 1914–18 he joined the South African Army Veterinary Corps and saw service in German South-West Africa, but was recalled to civil duty in 1915. In Africa he had wide experience of virus diseases of animals, Protozoan infections, livestock poisoning and poisonous snakes, and contributed to the literature on these subjects. When a veterinary degree was established in South Africa Dr. Andrews was appointed professor of physiology, and for some years after his return to Great Britain he was an examiner in physiology for the Royal College of Veterinary Surgeons. He was thus able to bring wide experience when he took over the Weybridge Laboratory. In the nature of that appointment much time was devoted to committee work and questions of policy, and much of the development of veterinary research in Great Britain during recent years has been influenced by work done on such committees. Dr. Andrews' personal attention was perhaps directed largely to research on foot-and-mouth disease, consideration of problems relating to bovine contagious abortion, the organization of a growing department dealing with poultry diseases and a host of other questions. The good wishes of his friends go with him in his new field of work.

PROF. T. DALLING is retiring from the chair of animal pathology in the University of Cambridge at the end of this year to assume the directorship of the Ministry of Agriculture's Veterinary Laboratory at Weybridge. He graduated at the Royal (Dick) Veterinary College, Edinburgh, in 1914 and served throughout the War of 1914–18 with the Royal Army Veterinary Corps. Later he joined the late Prof. S. H. Gaiger at Glasgow, and together they worked on some important sheep diseases. Dalling was conspicuously successful in dealing with lamb dysentery, and within a few years, in the course of which he joined the staff of the Wellcome Physiological Research Laboratories at Beckenham, he had discovered the cause and devised a means for its prevention which has resulted in the annual saving of enormous numbers of lambs. This led him and his colleagues to some valuable comparative studies on the transference of maternal immunity to the offspring in different animal species.

At Beckenham Prof. Dalling interested himself with other problems and was one of a team which recognized that a form of infectious jaundice in dogs is caused by the same spirochæte as Weil's disease in man. He was also largely responsible for overcoming the difficulties involved in the preparation and distribution on a large scale of the prophylactics used in the Laidlaw-Dunkin method of immunizing dogs against distemper. He also worked on fowl pox, fowl paralysis, bacillary white diarrhœa and other diseases of poultry. Recently, in collaboration with the late A. Stanley Griffith, he obtained evidence to suggest that the vole type of acid-fast organism discovered by A. Q. Wells may prove of value as an immunizing agent against tuberculosis in cattle.

The Society of Glass Technology

THE twenty-fifth anniversary meeting of the Society of Glass Technology was held at the Department of Glass Technology, Sheffield, on November 19, when in addition to the technical papers which were presented, the day was marked by two interesting official functions. The first was the presentation at lunch of a gold watch and a cheque to Mr. G. S. Duncan, who has recently retired from the post of librarian and assistant to Prof. W. E. S. Turner, after twenty-two years continuous service. These gifts were subscribed by a number of friends in the industry and the presentation was made by Dr. S. B. Bagley, president of the Society. A graceful tribute was paid to Mr. Duncan by Prof. Turner, Head of the Department, who emphasized the almost unique experiences that Mr. Duncan has had, as teacher, soldier and a member of one of the large publishing houses. It is safe to say that no one who has been to the Department of Glass Technology has not received advice and help from Mr. Duncan, and the remarkable development of the Society of Glass Technology is due in no small measure to him.

Later another presentation was made, this time to Prof. Turner himself. Prof. Turner had conferred upon him the honour of fellowship of the Royal Society in 1937 and to mark the occasion a portrait was painted of him in his academic dress by Mr. Edward Halliday, R.A. This portrait was exhibited at the Royal Academy in the summer of 1939 and the portrait was to have been presented to Prof. Turner in October of that year. Owing to the intervention of the War, however, and later to the illness of Prof. Turner, the presentation was not made until recently and it was felt that the twenty-fifth anniversary of the Society was an appropriate occasion. The presentation itself was made by Dr. C. J. Peddle, who was president of the Society in 1939, in a speech which emphasized the importance and unique character of the work that has been carried out in the department by Prof. Turner and his staff. Prof. Turner in replying commented on the

fact that when he first went to the Department of Physical Chemistry at Sheffield in 1904, Dr. Peddle was his first honours student, and later his first research student, and that one of his early students was Dr. S. English, who is president-elect of the Society. Attention was directed to the fact that the painting of the portrait was made possible by gifts from 417 members of the Society, representing eighteen different countries, including some of those with which we are now at war. Coloured photographic replicas of the portrait have been made, and one of these is being kept by Prof. Turner and the other is being sent to the United States, where it will hang in the building of the American Ceramic Society at Columbus, Ohio. Finally, Prof. Turner offered the portrait to the University of Sheffield and this was accepted by Sir Henry Stephenson, pro-chancellor of the University.

Science and the War Effort

THE Association of Scientific Workers is organizing an open conference on the general topic of "Science and the War Effort", to be held in the Caxton Hall, Westminster, during January 10 and 11, 1942. The president of the Association, Mr. R. A. Watson Watt, will open the Conference at 10 a.m. on January 10. The proceedings will then develop in two parallel sessions; one session will be concerned with technical education, which will include the university training of men of science and technicians, also the special technical training of personnel for the Forces and for industry. The parallel session will be discussing building, housing and A.R.P. in the morning; and, during the afternoon, food and agriculture. After tea, both sessions will unite for the main discussion on the latter subject. The session on January 11 will be entirely devoted to discussion of immediate scientific problems in relation to war production and the services. One topic which will be thoroughly examined is the utilization of scientific personnel, about which subject the Industrial Committee of the Association has collected a great deal of material. The remainder of the day will be occupied with the examination of the application of scientific knowledge to production problems and to services problems. This will include consideration of industrial health, conditions of work, and related topics. The final session after tea will be devoted to summing up the results of the Conference.

A feature of the proceedings will be the ample provision for discussion, both during the sessions themselves, and in the tea intervals. It is hoped that members of the general scientific, engineering and technical community will avail themselves of this opportunity. It should be noted that this is the first open conference to be held in Great Britain of scientific workers to discuss their part in the national effort. The Conference Sub-Committee will welcome inquiries and suggestions, both from individuals and from scientific and technical bodies. All communications should be addressed to the Conference Secretary, Association of Scientific Workers, 30 Bedford Row, W.C.1.

American Mathematics and the U.S.S.R.

THE following reply to the message sent by American mathematicians to their colleagues in the U.S.S.R. (see NATURE of November 8, p. 560) was sent from Moscow on October 7:

"Your splendid message, dear colleagues, found wide response in the hearts of the scientists of our country. We read it with feelings of all the more appreciation and satisfaction in that it again emphasized the community of thoughts and the friendly ties between the mathematicians of the U.S.A. and the U.S.S.R. Many years we jointly worked with you on the development of our science, many of our American colleagues were our welcomed guests, while with a still greater number of American scientists we conduct friendly scientific correspondence. This mutual co-operation was very fruitful and led to a number of important scientific discoveries. In recent years our country became the centre of gravity for eminent European mathematicians who were forced to flee the lands downtrodden by the heel of Nazi barbarians. Our country too is subjected to the invasion of these gloomy medieval forces. The Hitlerites seek to smash the U.S.S.R. in order to make their forces afterwards available for destroying also your great country. The fight now being waged by our people is the fight for the progress of all mankind, for everything advanced, the fight for the flourishing of civilization and of science.

"Our science too has been placed at the service of our country for the destruction of Nazism. Soviet mathematicians, like all Soviet scientists, participate in this fight in common with the whole people. This struggle of Soviet scientists is the common cause of the scientists of all democracies, against the fiend who shoots children, burns libraries, smashes universities, and destroys science. On this momentous day your message, dear friends, has been received by us as the proof of the unity of Soviet and American scientists and their determination to fight the twentieth-century vandals till the end. Let the friendship of the Soviet and the American scientists be the surety of the friendship of our great nations, the surety of the victory of democracy over the dark forces of Hitlerism."

The message was signed by sixty-four Russian mathematicians including A. Sobelev, director of the Steklov Mathematical Institute of the Academy of Sciences of the U.S.S.R., and P. Alexandrov, president of the Moscow Mathematical Society.

Colonial Affairs

MR. G. H. HALL, Under-Secretary of State for the Colonies, made a statement on Colonial policy in the House of Commons on November 20. After a striking tribute to the "universal uprush of loyalty to the Throne and support for our cause in all the peoples of the Colonial Empire", Mr. Hall announced that it has been decided to appoint a Colonial Labour Advisory Committee, to function on the lines of the committees already in existence on medical matters and on education. The Committee, which will be a

small one, will consist of representatives of the Colonial Office, and members of the Trades Union Congress and of employers' organizations interested in Colonial affairs. The Colonial Office already has a labour adviser, and the new Committee will serve to strengthen this side of its work. It may be anticipated that as the various provisions of the Welfare and Development Act come more extensively in force, this Committee will grow in importance and its activities play a prominent part in the future of the British Colonial Empire.

A brief survey of Colonial Office activities during the past year was also given by Mr. Hall. Even under war-time conditions it has been possible to send officials of the Colonial Office overseas to examine problems on the spot. Lord Hailey is presiding over a committee examining post-war problems which are likely to arise. Many schemes, amounting to hundreds of thousands of pounds, submitted under the Welfare and Development Act, have been approved. The appointment of an economic and financial adviser to work with Sir Frank Stockdale is being considered. The needs of Colonial peoples in Great Britain have also been examined ; a welfare officer and an assistant welfare officer, the latter an African, have been appointed, and an adviser to Colonial students, who is a West Indian, is being appointed. Mr. Hall concluded by emphasizing that our duty is now to improve the lot of the Colonial peoples, to develop their resources so as to raise their standard of living, and to enable them to take an ever-increasing responsibility in their own government.

Federation of American Societies for Experimental Biology

IN March 1942 the Federation of American Societies for Experimental Biology will issue the first number of a quarterly publication to be named the *Federation Proceedings*. This will be published by an editorial board representing the five constituent societies of the Federation : the American Physiological Society, the American Society of Biological Chemists, the American Society for Pharmacology and Experimental Therapeutics, the American Society for Experimental Pathology, and the American Institute of Nutrition. Four numbers will be published each year. The March issue will appear just previous to the annual meeting of the Federation, and will be composed of two parts. Part 1 will include the abstracts of all the papers to be presented at the annual meeting, about a thousand in all. Part 2 will comprise the programme of the scientific sessions of all the constituent societies of the Federation. The June and September issues will include the full text of perhaps twenty of the papers presented at the annual meeting as selected by the editorial board, including probably the papers on the joint programme of the Federation as a whole as well as the papers of one symposium of each of the five societies. The December issue will include material pertinent to the Federation membership formerly published in the Federation Yearbook, which will hereafter be discontinued. The *Federation Proceedings* will be distributed without further charge to all members of the Federation. The subscription price to non-members will be four dollars (4.50 dollars foreign) payable in advance. Further information can be obtained from Dr. D. R. Hooker, Managing Editor, 19 West Chase Street, Baltimore, Maryland.

Therapeutic Research Corporation

A NEW step in the rationalization of the British fine chemical industry has been taken by the formation of the Therapeutic Research Corporation of Great Britain, Ltd., the directors of which are Lord Trent, of Boots Pure Drug Company, Ltd., Mr. C. A. Hill, of the British Drug Houses, Ltd., Mr. H. Jephcott, of Glaxo Laboratories, Ltd., Mr. T. B. Maxwell, of May and Baker, Ltd., and Mr. T. R. G. Bennett, of the Wellcome Foundation, Ltd. Although each of the directors of the new Corporation is managing director of his own concern, the Corporation is not an amalgamation of these five firms. Each will retain its freedom of action in its special field, but will contribute to the common research pool ; in effect, a much extended research team now becomes available for work on new drugs, and overlapping effort should be eliminated. It is also hoped to secure the interest and co-operation of research workers in academic institutions. The Corporation will have in the various chemical, physiological and bacteriological laboratories at its command the choice of many different lines of approach to its problems and the call on the extensive scientific personnel and equipment of the five companies which are collaborating. This should make for a hopeful start and lay the foundation of a promising superstructure.

Norway: Present and Future

MR. GATHORNE-HARDY's pamphlet "Norway and the War" (Oxford Pamphlets on World Affairs, No. 51. 4*d*. net) gives an account of the physical characteristics and resources of Norway, its people and their democracy, and relations with their Scandinavian neighbours and other powers, which could scarcely be bettered as a contribution to the understanding of the Norwegian resistance to Nazism and of Norway's future. Although little more than a third of the pamphlet deals with Norway and the War proper, the pamphlet contains nothing irrelevant, and it emphasizes the close ties between Norway and Great Britain through the marked similarity of outlook, the ties of the sea, and the long association of various kinds.

Despite the appeal of Germany in scientific and technical circles, Norwegian thought, with its passionate insistence on individual liberty, free speech and parliamentary democracy, is diametrically opposed to the totalitarian ideology, and her neutrality had no spiritual basis. Mr. Gathorne-Hardy emphasizes the important part which confusion, rather than deliberate treachery, played in the situation when Norway was invaded, and also the credit due to the Norwegians for the toughness of their resistance in a singularly desperate situation. After a brief account of the German occupation, he

indicates the re-orientation which is taking place in Norwegian foreign policy, now that isolated neutrality and Scandinavian collaboration have proved insufficient security. As an Atlantic and seafaring nation, Norway seems likely to look for help and collaboration mainly to the free nations overseas—the British Empire and the United States.

Recent Earthquakes

ACCORDING to a message in *The Times*, a violent earthquake was experienced about noon (local time) on November 12 at Erzinjan in Anatolia. A number of buildings were damaged in the town but only a few persons were injured. It is feared that the damage and casualties will be greater in the villages near Erzinjan, and further information is awaited. It will be recalled that a very great earthquake struck the same region on December 27, 1939 (NATURE, January 6, 1940, p. 13).

An earthquake of considerable severity (probably the most severe for eight years) shook Los Angeles on November 14. The electric power station in the Beverly Hills district was temporarily stopped and about a hundred small buildings together with some oil storage tanks were wrecked. Gas and water mains were broken, and some suburban homes in the Torrance Gardena district were damaged. Several parked motor-cars were damaged when the front of a store fell into the street. Damage in one district is estimated at a million dollars. No deaths or serious injuries are reported and further information is awaited. Los Angeles and Hollywood were affected by strong earthquakes on October 11, 1940 (NATURE, November 30, 1940, p. 720), and January 28, 1931, besides numerous other occasions.

Dr. George Birkbeck and Technical Education

ON December 1, a century ago, Dr. George Birkbeck died in London and was buried in Kensal Green Cemetery. His name to-day is recalled by Birkbeck College, London, which began its career as the London Mechanics' Institution with Birkbeck as its president. There were at one time hundreds of such institutions, and no doubt many of them exist to-day, but they may all be said to have sprung from the classes for mechanics started by Birkbeck in 1800 at the Anderson College of Glasgow, in which as a young man of twenty-four he held the chair of natural philosophy. Born in Settle, Yorkshire, on January 10, 1776, Birkbeck studied medicine at Leeds, London and Edinburgh, but he began his active career as a lecturer. In 1804 he set up in practice in the City of London and there became known to Hume, Grote, Brougham, and many other men of liberal ideas. In 1809 he assisted in founding the London Institution, in 1824 became president of the Mechanics' Institution, and was a projector of University College, and a supporter of the Society for the Diffusion of Useful Knowledge. He was, as his biographer J. G. Godard says, a "National Reformer". In the prospectus of his class of 1800, he stated that it was "for persons engaged in the exercise of the mechanical arts, whose education in early life has precluded even the possibility of acquiring the smallest portion of scientific knowledge". He lived to see knowledge brought within the reach of all.

Recent Investigation of New Plant Fibres

AN investigation has been carried out by the Royal Botanic Gardens, Kew, in collaboration with the National Physical and Chemical Laboratories and the Imperial Institute, of the mechanical properties of the fibre from nettle stems (*Urtica dioica*) and other plants native to Great Britain, and of methods of extraction. The nettle fibre has been found to be suitable for the manufacture of high-grade paper, and possibly of textiles, while the leaves are commercially valuable for the extraction of chlorophyll. Arrangements were made for the extensive collection of this abundant raw material during 1941.

The Night Sky in December

THE moon is full on Dec. 3d. 20h. 51m. U.T. and new on Dec. 18d. 10h. 20m. Lunar conjunctions with the planets occur on the following dates: Saturn on Dec. 2d. 9h., Saturn 2° N.; Jupiter on Dec. 4d. 7h., Jupiter 4° N.; Venus on Dec. 21d. 16h., Venus 4° S.; Mars on Dec. 26d. 22h., Mars 4° N.; Saturn on Dec. 29d. 11h., Saturn 2° N.; Jupiter on Dec. 31d. 7h., Jupiter 4° N. Jupiter is in opposition to the sun on Dec. 8, and on Dec. 29 Venus attains its greatest brilliancy; the planet is then 38 million miles from the earth. Mercury is a morning star until Dec. 21, then an evening star. Venus, Mars, Saturn and Uranus are evening stars. Neptune is a morning star and Jupiter is a morning star until Dec. 7, then an evening star. The sun enters the sign Capricornus on Dec. 22, the winter solstice. About this time of the year we have the interesting phenomenon of the mornings decreasing in length while the afternoons and the whole periods from sunrise to sunset are increasing; this, as is well known, is due to the equation of time. The first magnitude star α Tauri (Aldebaran) is occulted on Dec. 30d. 22h. 23·4m., reappearance occurring at 23h. 46·6m. The Geminid meteor shower is active during Dec. 7–15, the radiant being close to α Geminorum. Many interesting objects can be seen during the month, such as the great nebulæ of Orion and Andromeda, the open star clusters of Perseus, the Pleiades and the Hyades, and many well-known double stars and variable stars.

Announcements

PROF. BJORN HELLAND-HANSEN, the well-known hydrographer and head of the Meteorological Institute of Bergen, was arrested some six months ago and is still in prison.

THE title of professor of mining geology in the University of London has been conferred on Dr. W. R. Jones, in respect of the post held by him at the Imperial College of Science and Technology.

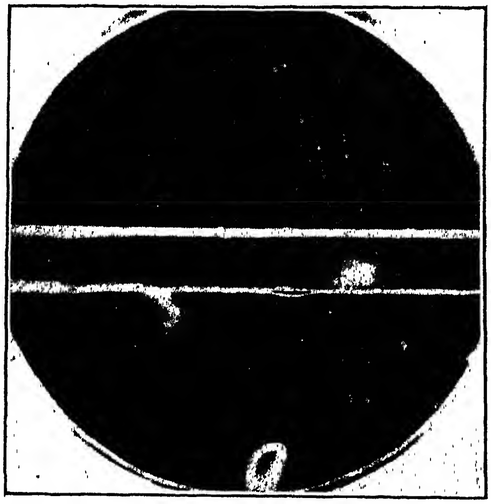
PROF. F. C. BARTLETT, professor of experimental psychology in the University of Cambridge, has been appointed a member of the Medical Research Council in the vacancy caused by the death of Prof. A. J. Clark.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

Cloud Chamber Investigation of Penetrating Showers

THE existence of penetrating showers, different from electron cascades or knock-on showers, has been established by counter experiments[1,2]. These experiments are most easily interpreted in terms of showers containing several penetrating particles, though other interpretations cannot be excluded[3].



To investigate the nature of these penetrating showers, we have used a deep cloud chamber controlled by a counter system selective for penetrating showers. The counter system consists of three trays each containing two counter sets. The expansions are controlled by sixfold coincidences, namely, coincidences between six counters, one out of each set. The trays are separated by lead absorbers of sufficient thickness to cut out cascade showers. The total thickness of absorber is 30 cm. The cloud chamber is placed between the top tray and the middle tray. In order to distinguish electrons from penetrating particles, a lead plate 2·3 cm. thick is placed across the middle of the chamber.

The rate of sixfold coincidences is 8 ± 1 counts per 100 hours and is due to the following processes: (1) penetrating showers, (2) triple knock-on showers, (3) casual coincidences. The rate of (2) is estimated as 0·7 counts per 100 hours, while that of (3) as 0·5 counts per 100 hours. Thus most of the observed coincidences should be due to penetrating showers.

One of our photographs, reproduced herewith, shows three penetrating particles traversing the lead plate. The stereoscopic projection shows that the three tracks diverge from a point situated in a lead absorber of 2 cm. thickness which is placed over the top counter tray. A somewhat similar photograph has been reported recently by Powell[4]; pairs of penetrating particles have been reported by various observers[5]. A pair of penetrating particles may consist of a meson and knock-on proton, but this explanation is excluded if there are more than two penetrating particles. Three penetrating particles originating from one point indicates the occurrence of multiple processes.

The accompanying table contains a classification of 32 photographs.

Total number of photographs	Photographs with definitely more than one penetrating particle	probably more than one penetrating particle	one penetrating particle	Big showers	Unclassified photographs
32	2	3	6	4	17

We know from other experiments that the extension of penetrating showers is large compared with the area covered by the cloud chamber and therefore only a fraction of the penetrating particles in any shower is photographed. Further, the density of tracks in the photographs classified as 'big showers' is so great that it is impossible to say whether or not they contain penetrating particles. The photographs obtained may, therefore, be considered compatible with the view that all penetrating showers contain associated penetrating particles. In any case, we can conclude that a not inconsiderable fraction of the penetrating showers contains associated penetrating particles.

It appears from the photographs that the penetrating showers do not consist simply of simultaneous mesons, but are rather complex.

The thirty-two photographs obtained show nine heavily ionizing tracks due to slow mesons or slow protons. Though heavily ionizing particles are known to occur in showers[6], the rate of heavily ionizing particles per photograph in the present investigation is rather high. It seems therefore that the heavily ionizing particles are connected with the penetrating showers.

Absolute Sensitivity of Geiger Counters

THIS subject has, in recent years, become of interest partly (*a*) in cosmic ray experiments, where information can be gained on the specific ionization of cosmic ray particles (Danforth and Ramsey[1]), or on shower sizes (Ramsey and Danforth[2]), and (*b*) in various applications of the coincidence-counting technique to nuclear physical problems, for example the determination of nuclear level schemes. The latter problem has been admirably discussed by Dunworth[3], following work by Feather and Dunworth[4].

We have carried out some preliminary experiments with single β- and γ-ray counters with the view of determining the absolute yields of some nuclear disintegration processes. Unfortunately, it has become necessary to terminate the work before accurate results could be obtained. The possible errors are indicated below. The greatest experimental difficulty is to bridge the gap between natural ($\sim$2 Mev.) and artificial ($\sim$10 Mev.) γ-ray sources.

In the first place, the counting of cosmic ray particles and γ-rays (2—17 Mev.) involves two different mechanisms, the former utilizing ionization in the gas of the counter and the latter the emission of photo-electrons from the cathode. The counter efficiencies in these two sets of conditions show large differences. For example, Street and Woodward[5] reported efficiencies of about 94 per cent for cosmic-ray particles, using a Geiger counter telescope, and measured the average number of ion pairs/cm. of path produced by the rays. C. G. and D. D. Montgomery[6] quoted data for primary specific ionization in various gases, and the requisite pressures for different efficiencies with a 1 cm. mean free path through the counter; thus air at 2·5 cm. mercury pressure gives 50 per cent and at 16 cm. pressure, 99 per cent efficiency. Again[1], the measured efficiencies were found to agree very closely with those deduced from a knowledge of the primary specific ionization caused by the operative cosmic rays, and assuming that each ion pair caused a counter discharge (100 per cent efficiency).

For the measurement of γ-rays ($\sim$2 Mev. energy) the problem is to calculate the magnitude of secondary electron currents from the counter cathode. The absorption coefficient for 2 Mev. γ-rays (μ/ρ cm.^{2}/gm.) is given[7] as 0·04, variations of μ/ρ with energy being small, so that the above figure approximately holds for the radium family γ-rays. Taking $\mu=0{\cdot}4$ for copper, the percentage loss for 0·8 mm. (the cathode thickness for the tubes used in our experiments) is approximately 7 per cent. If we assume that all the absorbed quanta give rise to 2 Mev. electrons (range in copper$\sim$0·1 cm.) distributed uniformly throughout the absorber, it seems that the counter efficiency should be about 0·7 per cent. It is also assumed that the electronic absorption curve is linear, that all the secondary electrons are projected forwards (that is, the Compton effect $\gg$ the photo-electric effect), so that the second wall of the counter cathode is inoperative, and that any secondaries from the pyrex wall are absorbed by the cathode.

This figure agrees with experimental data. Norling's[8] curve shows (for 2 Mev. γ-rays) an efficiency of about 1·2 per cent for brass, 0·2 cm. thick, data being also given for lead and aluminium. Dunworth's[3] figure, for 0·12 cm. thick brass, is about 0·3 per cent; taken from a very complete curve covering the range 0·2—3 Mev. The shape of such curves was calculated by von Droste[9] and Yukawa and Sakata[10].

Our experiments, in which the expected accuracy was not high, were carried out with single counters located at known (large) distances from calibrated sealed-off radium sources. Care was taken to eliminate scattering so far as possible. It has been stated (Kovarik[11]) that $7{\cdot}3 \times 10^{10}$ and $5{\cdot}6 \times 10^{10}$ quanta/sec./gm. are emitted from radium in equilibrium with its short-lived products with a filter of 0·1 cm. glass and 1·5 cm. lead respectively. In the latter case a brass tube which cut off about 2 per cent of the radiation was also used. The efficiency of a typical counter (4 in. cathode, 1 in. diameter, air at 3·5 cm. pressure) was found to be 0·5 per cent (possible error ± 10 per cent) at 1600 v., with a counter striking potential of about 1450 v. The source used was 0·2 mgm. radium in a monel capsule 0·2 mm. thick at a distance of 80 cm. from the counter. Other counters gave similar efficiencies.

We also determined the efficiency of a β-ray counter (ionization now produced largely in the gas of the tube, not the walls) with a duralumin cathode 6 cm. long 2·54 cm. diameter and $3{\cdot}5 \times 10^{-3}$ inch thick strengthened with circumferential ribs. The counter contained air at 3·5 cm. pressure and was run at 1600 v. (striking potential about 1450 v.). The standard source was 1.21 gm. of powdered uranium nitrate (*A. R.* $UO_2(NO_3)_2.6H_2O$) in a 2 mm. thick brass pot 2 cm. high and 1·7 cm. internal diameter, forming a layer about 3 mm. deep. With the counter 9 cm. from the active layer a count of 512 ± 5 per cent in 20 sec. was obtained. Absorption in the counter walls would be almost complete for the uranium rays, hence the number of disintegrations per gm. uranium per minute is taken[12] as $7{\cdot}2 \times 10^5$. After allowing approximately for the source thickness[13] and the finite dimensions of the counter and source (the errors for this arrangement would be much greater than those for the γ-ray experiment described above), the counter efficiency was found to be 0·27 ± 30 per cent, that is 18–35 per cent. The error could probably be reduced to ± 10 per cent by more accurate calculation. Bramley and Brewer[12] obtained 11 per cent efficiency for one of their counters.

Interchange of the Ammonium and Potassium Ions in Muscle and Yeast

SINCE the muscle membrane is permeable to the ammonium ion, from the theory of potassium equilibria previously described[1,2], the following should hold:

$$a/a_1 = k/k_1 = h/h_1$$

where a, a_1, k, k_1 and h, h_1 are the concentrations of ammonium, potassium and hydrogen ions outside and inside the membrane. On investigation, it appeared that the ammonium ion (or possibly the minute amount of associated free base) has a marked effect on the membrane itself, all ratios being lowered across it (Fenn and Cobb have described such an effect of ammonia on potassium[3]).

With the sartorius muscle of the frog immersed at 2–3° C. in a Ringer fluid designed to maintain constant volume[2], and in which a has the low value of 1 mgm. NH–N/100 ml., k being 117 mgm./100 ml. (30 m.eq./litre), the equilibrium a/a_1 value of 2·1 is reached quickly, but that for potassium very slowly, since much potassium must come out under these conditions and sodium enter. After forty-eight hours the k/k_1 value approaches that for a/a_1 and has fallen from an initial figure of 4·0–2·3.

When the external potassium is much raised—to upwards of 300 m.eq./100 ml.—with provision for maintaining constant volume[2] the k/k_1 ratio across the membrane is much lowered both theoretically and experimentally, and then small ammonium concentrations have no apparent effect on it. After twenty-four hours in the cold, with external k of 150, 210 and 300 m.eq./litre, the a/a_1 values are 1·51, 1·33, and 1·28, the k/k_1 equilibria even without any ammonium being 1·56, 1·36 and 1·28. The results are therefore in accord with theoretical expectation and show a specific effect of the ammonium salt on the muscle membrane.

Yeast. The specific membrane effect of the ammonium ion (or associated base) on muscle is not evident with yeast, and ammonium ion can be made to replace the *whole* of the potassium within the cell, after which it can be taken out and the potassium replaced. (At the same time it may be noted that the simple equilibrium equations applicable to a distensile membrane are not valid for the comparatively rigid membrane of yeast.) A striking peculiarity of the yeast permeability is that the replacement with ammonium goes at a practically negligible rate unless the yeast mixture *is bubbled with carbon dioxide* (3–10 per cent), bubbling with oxygen at the same pH being almost ineffective. Even with carbon dioxide the entrance is very slow compared with muscle and considering the size of the yeast cell. After forty-eight hours at room temperature all the potassium can be taken out, though much the greater part is lost in twenty-four hours and occasionally practically all of it. The following example may be given:

Sample of pressed bakers' yeast suspended in Ringer solution for a short time and centrifuged.

K content	450 mgm./100 gm.
NH–N ,, ...	< 1 mgm./100 gm.

Bubbled for 24 hr. with 3 per cent CO_2, 97 per cent O_2, in Ringer fluid containing 11·9 m.eq. bicarbonate/litre and varying strengths of NH_4Cl.

NH_4Cl in Ringer fluid →	$N/5$	$N/20$	$N/100$
NH_3–N in yeast	400	174	51
K—in yeast (mgm./100 gm.)	0	192	268

Yeast centrifuged and washed in a similar Ringer fluid containing 30 m.eq./KCl per litre and no NH_4Cl; then bubbled in this fluid as before for 24 hr.

NH_3–N in yeast	47	17	7
K—in yeast (mgm./100 gm.)	425	455	436

The complete replacement of the potassium with NH_4 followed by the subsequent reversal shows that potassium in yeast is altogether in the ionized condition.

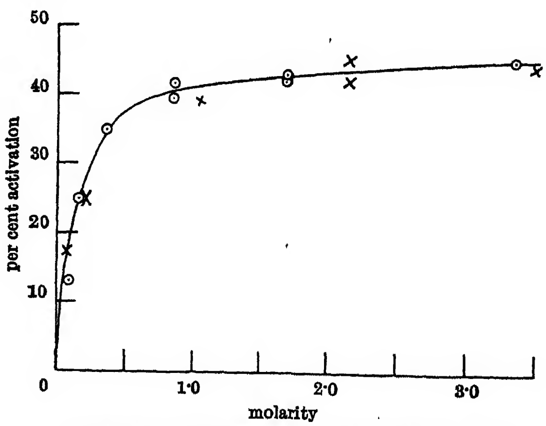
Effect of Sodium and Potassium Ions on Cholinesterase

Mendel, Mundell, and Strelitz[1] reported inhibition by potassium ions, and activation by calcium ions, of cholinesterase from horse serum; and they suggested that certain physiologically antagonistic actions of these ions might be explained on this basis. Nachmansohn[2] stated that sodium and potassium ions in high concentrations activate the cholinesterase from the electric organ of the Torpedo to the same degree, but no experimental data were given. Nachmansohn's communication evoked critical replies from Mendel, Mundell, and Strelitz[3], and Massart and Dufait[4]. The former authors raised the possibility of differences in the enzyme systems in horse serum and Torpedo, and also suggested that the sodium and potassium salts used by Nachmansohn may have contained sufficient of the activating bivalent metals to give the effect he reported.

In order to throw light on this controversial issue the present study was made, dealing with the effect of the addition of chemically pure sodium chloride and potassium chloride to cholinesterase-acetylcholine chloride systems using dialysed horse and rabbit sera as sources of the enzyme. The usual manometric method employing the Warburg apparatus was used with the substitution of 0·20 per cent $NaHCO_3$ for bicarbonate-Ringer solution. The accompanying figure demonstrates the activating effect of both salts upon the activity of the rabbit enzyme. However, neither of the salts produced a consistent activation



EFFECT OF SODIUM AND POTASSIUM IONS ON CHOLINESTERASE IN RABBIT SERUM.

×, NaCl; ⊙, KCl. Hydrolysis measured at 30° C. in a total volume of 4 c.c. containing 15 mgm. acetylcholine chloride and 0·2 c.c. dialysed serum. Reaction period, 120 minutes. Corrections applied for non-enzymatic hydrolysis in presence of the corresponding concentration of the appropriate salt.

or inhibition of the horse serum enzyme. In some experiments small activations or inhibitions were observed, but these were not reproducible, and hence must be considered the result of experimental variation.

The points of accord and conflict between the present findings and previously published work are apparent. In agreement with the suggestion of Mendel, Mundell, and Strelitz[3], it would appear that the source of the enzyme is a crucial factor in determining the effect of sodium and potassium ions on cholinesterase. Nachmansohn's statement[2] that ". . . the enzyme is only active in the presence of divalent cations. After dialysis the enzyme practically completely loses its activity" may apply for cholinesterase from the electric organ of the Torpedo, but does not for the enzyme from horse or rabbit serum.

Science in the U.S.S.R.

THE words quoted by Prof. J. B. S. Haldane[1] occur in a letter written by Boyle at the age of nineteen years and nine months. One can well imagine how their author in his maturity might have deprecated what has been read into them, in some such way as "I scruple not to say, that those who know me best, will scarce believe me apt to constrain Natural Philosophy into a course so strait, as some wou'd pretend".

Prof. Haldane also makes the remarkable assertion that Thomas Sprat, the literary divine who was the early historian of the Royal Society, postulated "a class basis for science". That is exactly what Sprat did not do; nor, so far as I know, did any of the creators of the Society, for they came of all classes and they held it open to all who were able. Thus, another letter from the youthful Boyle, written five months after that which Prof. Haldane has used, remarks of the leaders of the Invisible or Philosophical College that, "though ambitious to lead the way to any generous design, [they are] of so humble and teachable a genius, as they disdain not to be directed to the meanest, so he can but plead reason for his opinion; . . .". And there should be set against Prof. Haldane's sentence taken from Sprat's "History of the Royal Society" a number of passages from the same work, which show the "comprehensive Temper" of British science as it then was; I choose one only (1667 ed., p. 67):

"But, though the *Society* entertains very many men of *particular Professions*; yet the farr greater Number are *Gentlemen*, free, and unconfin'd. By the help of this, there was hopefull Provision made against *two corruptions* of Learning, which have been long complain'd of, but never remov'd: The *one*, that *Knowledge* still degenerates, to consult *present profit* too soon; the *other*, that *Philosophers* have bin always *Masters*, & *Scholars*; some imposing, & all the other submitting; and not as equal observers without dependence.

"The first of these may be call'd, the *marrying of Arts too soon*; and putting them to generation, before they come to be of Age; and has been the cause of much inconvenience. It weakens their strength; It makes an unhappy disproportion in their increase; while not the *best*, but the *most gainfull* of them florish: But above all, it diminishes that very profit for which men strive. It busies them about possessing some petty prize; while Nature itself, with all its mighty Treasures, slips from them; . . ."

So far as a movement must be judged at all by isolated quotations instead of by the sum of acts and deeds, these two passages convey, I believe, a much less misleading idea of historical fact than do those which Prof. Haldane has chosen.

J. I. O. MASSON.

The University,
Sheffield.
Nov. 15.

[1] NATURE, **148**, 598 (Nov. 15, 1941).

WHAT Mr. Maisky said exactly and what was the context make such a difference that I do not propose to argue or comment on his words. Short quotations without the full story are very dangerous and unfair, as I know to my cost.

It is with Prof. Haldane's conclusions as to British science that I wish to deal. The words of Boyle and Sprat may indeed have been inspired by the desire at that time to get going an organization of real science, as compared with alchemy, and the difficult task with this was, I have no doubt, the fact that it had to be wrapped up with the possibility of utility.

To say, as does Prof. Haldane, that British science is applied and not pure seems to me a travesty of fact. If it were so, some of the great work of the past must have been related to objectives rather than to knowledge for knowledge's sake. It would follow that Darwin did his work in order to organize a menagerie; that Crookes's work on the exhausted tube was based on a keen desire to develop neon advertisements; that Thomson juggled with electrons in order to sell radio sets; and I suppose Eddington's theory of the expanding universe might at a future date be related to a keen desire to increase the value of real estate.

If there is a criticism to be made of British science, then I think it is that the team of applied scientists do not rally enough round the pure scientists. The standard example of this is the discovery of the great dyes, which were turned into an industry in Germany by the applied scientists in that country.

I have at the present time the honour of being associated with many physicists working on *ad hoc* problems connected with the War. It is indeed remarkable what they do, and they deserve the nation's profound thanks. I do notice, however, a keen desire on their part to get away from the particular to the general. I like this tendency. It is healthy and praiseworthy, but according to Prof. Haldane against the traditions of British science. I cannot accept this.

RESEARCH ITEMS

Electrical Phenomena in Heart Muscle During Activity

J. A. E. EYSTER, in a paper read at the Autumn Meeting of the U.S. National Academy of Sciences held during October 13–15, dealt with the electrical potentials which develop in the heart in the interval immediately preceding and during the contraction of the organ, and their relation to the contraction process. Potential-time curves of two types, unipolar and differential, are recorded by means of direct current amplifiers and cathode ray oscillographs, along with a constant reference curve. The characteristics of these curves and their relation to each other and to the onset of contraction in the various localized regions of the heart will be discussed. The electrical phenomena are characterized by their polar distribution. Regions of positive and negative potentials arise simultaneously, undergo growth and decline, and a certain shift in their spatial relations during the action potential period. It is shown that the onset of contraction in any region is coincident with the maximum flow of electrical current in the region, established by neighbouring regions in which the potentials are respectively above and below the potential of resting muscle.

Defective Fat Metabolism and Arteriosclerosis

THIS was discussed by L. R. Drogstedt in a paper read at the Autumn Meeting of the U.S. National Academy of Science held during October 13–15. Arteriosclerosis is not a necessary part of the ageing process, since not all old people develop it. The following evidence suggests that it may represent a metabolic defect associated with disturbed fat metabolism. The feeding of cholesterol in excessive amounts produces arteriosclerosis in rabbits that resembles very closely the human disease. The incidence of arteriosclerosis is abnormally high in patients with diabetes mellitus and occurs not infrequently in young individuals. Diets rich in fat are especially apt to produce arteriosclerosis in diabetics, and conversely, low fat diets have a protective effect. A similar high incidence of arteriosclerosis is found in depancreatized dogs in which a disturbance in fat utilization is produced by deprivation of lipocaic.

Origin of the Temperate Floras of South America

THIS was discussed by D. H. Campbell in a paper read at the Autumn Meeting of the U.S. National Academy of Sciences during October 13–15. The continents of North America and Eurasia have very similar temperate floras and have always been more or less closely united. The climate is a continental one with great extremes of temperature. There is in the northern regions a preponderance of conifers and deciduous angiosperms. In South America, the temperate regions are very limited in extent, and the climate is much more temperate, with no such marked differences between winter and summer. The vegetation has little in common with the north temperate floras, but in the extreme south has many types common to New Zealand and Australia, and to a less degree to South Africa. As shown by fossils from the tertiary of Argentina, there is a large element derived from the tropical regions of Brazil, while at the south the 'sub-antarctic' flora predominates. It is evident that the modern floras differ but little from the tertiary ones. It seems likely that the northern and southern temperate floras have always been separate, and they have probably been distinct since the late Palæozoic.

Foot-Rot in Sheep

THE spreading destruction of superficial parts of the underlying epithelium of the sheep's foot, leading to detachment of the horn, is a disease hitherto very prevalent in the moderate rainfall areas of southern Australia. The primary causal agent has now been shown by Beveridge (Bull. 140, Australian Council for Scientific and Industrial Research, 1941) to be a newly discovered bacterium for which the name *Fusiformis nodosus* (n. sp.) is suggested. It is a large, anaerobic, Gram-negative, non-mobile, rod-shaped organism, usually with enlargements at both ends. Probably *Spirochœta penortha* is a specific accessory causal agent, while a mobile fusiform is a constant secondary invader, doubtless playing some part in the pathogenesis of the disease. Except in artificial culture, *F. nodosus* cannot survive for more than a few days apart from lesions, of which there are three different types. It has now been possible to elaborate a plan of control of the disease which has been applied to several large sheep stations. Not only was foot-rot eradicated from these stations, but also they remained free during an epizootic in the neighbourhood.

Lamp-brush Chromosomes

PRE-TREATMENT with sodium hydroxide and urea on the salivary gland chromosomes of *Drosophila melanogaster* has been used by M. Kodani (*J. Hered.*, **32**, 147; 1941) to induce the lamp-brush effect previously obtained in the chromosomes of other organisms. The author finds that there are definite achromatic regions which contain little nucleic acid. By marking the *X*-chromosome with inversions it was possible to construct a lamp-brush chromosome map. The chromatic regions correspond with the chromosomes of Heitz in mitotic prophase and were considered to contain active gene loci. Heterochromatin within euchromatin regions differs from the heterochromatin at the proximal end. The heterochromatin in euchromatin regions corresponds in position with regions of the salivary gland chromosomes which contain few and small bands, and it is believed that mutant loci are located in the euchromatin region which is characterized by thick bands with a condensation of nucleic acid.

Earthquakes Registered in Australia

DURING the months of April, May and June 1941, seventy-two earthquakes were registered at the Riverview College Observatory, New South Wales. There were twenty-eight in April, twenty in May and twenty-four in June. The seismograms for all these have been interpreted. The greatest shock in April was on April 29 from an epicentre near 27° S., 118° E., which gave a ground amplitude of about 1/7 mm. at Riverview. In May the greatest shock was on May 17, which gave a ground amplitude of near 1/4 mm. at Riverview. The epicentre has been

provisionally estimated to be at 11° S., 166° E. The shock of May 4 was felt at Finke in central Australia, and another shock on May 4 also had its epicentre in central Australia. In June the greatest shock was on June 27, which also was felt at Finke in central Australia. The epicentre was at a distance of 1,680 km. from Riverview, where the maximum ground amplitude attained was near 1/4 mm. Microseisms hindered the interpretation of some of the records.

Nitrosyl Cyanide Salts

A STUDY of the metal carbonyls and nitrosyl carbonyls shows that, for all volatile compounds of this class, the effective atomic number is the same as the atomic number of one of the inert gases. The general tendency of elements to acquire the effective atomic number of the nearest inert gas apparently does not hold in the formation of simple compounds of the heavy metals, but the complex compounds of the heavy metals have an obvious tendency of this kind. This is shown in sodium nitroprusside, $Na_2[Fe(CN)_4 NO]$, and in the unusual manganese nitrosyl cyanide and cyanide salts $K_3[Mn(CN)_5NO]$ and $K_5Mn(CN)_6$, in which the existence of the complex ions is related to the stabilizing effect of the effective atomic number of 36 (krypton). These salts were prepared by Manchot and collaborators in 1926–28, and the method of preparation of the nitrosyl cyanide has been improved by A. A. Blanchard and F. S. Magnusson (*J. Amer. Chem. Soc.*, **63**, 2236; 1941), who have also recorded its reactions. Attempts to prepare analogous nitrosyl cyanides of cobalt, $K[Co(CN)_5NO]$ and $K_2[Co(CN)_5NO]$, were not successful.

Properties of Visual Purple at Low Temperature

THE discovery that visual purple is soluble and stable in a solvent made up of 75 per cent glycerol and 25 per cent water by volume, has enabled E. E. Broda and C. F. Goodeve (*Proc. Roy. Soc.*, A, **179**, 151; 1941) to extend the range for experiments below 0° C. At the temperature of solid carbon dioxide such solutions assume a glass-like consistency and remain perfectly homogeneous and brilliantly clear. Even at liquid air temperatures no crystallization occurs, although the great number of minute cracks developed scatter the light and prevent spectroscopic investigations. At room temperatures the spectrum is identical with that of the aqueous solution. At −73° C. the peak of the absorption curve is higher and narrower than at room temperature and it is shifted towards longer waves. The product of photodecomposition at −73° C. has a spectrum independent of *p*H and is at low temperatures thermostable and photostable. Thermal decomposition to indicator yellow occurs at room temperature. The primary product appears to be identical with transient orange. The quantum yield of the photoreaction at low and at room temperature are of the same order.

The Electronic Charge

A NEW determination of e has been made in the University of Melbourne by V. D. Hopper and T. H. Laby (*Proc. Roy. Soc.*, A., **178**, 243; 1941) using an oil-drop method in which the electric field is horizontal. The oil drops used were larger than those used by previous experimenters, and the velocity of fall and of movement in the direction of the electric field could be estimated with satisfactory accuracy. Assuming $\eta_{23} = 1830 \times 10^{-7}$ C.G.S. units, the value of e obtained was $(4{\cdot}8020 \pm 0{\cdot}0013) \times 10^{-10}$ E.S.U. (see also NATURE, **145**, 932; 1940). In work in progress, it is hoped to improve the precision of measurement of the viscosity of air by using a method suggested by Fabry and Perot. Laminar flow of air between optically flat disks is involved.

A Photographic Survey of Galactic Clusters

IN two earlier papers (*Mon. Not. Roy. Astro. Soc.*, **100**, 387, and **101**, 89) George Alter described his method of investigation of galactic clusters, and a summary of the first of these appeared in NATURE, **141**, 810 (1940). Alter returns to the subject in a third paper with the above title (*Mon. Not. Roy. Astro. Soc.*, **101**, 5, 6) which deals with seven further clusters, six of which are situated in a rich Cassiopeia region. The other cluster, N.G.C. 225, is situated outside and in front of a dark patch, and an absorbing cloud is indicated by its position in a dark patch and also by an irregularity in the range of distant moduli. Some uncertainty concerning the identification and co-ordinates of N.G.C. 133 and 146 is clarified and it is shown that the former is not really a cluster but only an accidental grouping of a few stars, while Anonymous appears on visual comparison as a cluster very similar to its neighbour N.G.C. 146. The distances found in this recent investigation are generally smaller than those previously determined; explanations can be found from the fact that in the latter case the distances were found by mere inspection of the photographs, without knowledge of spectral types or colour index, but with various assumptions as to cluster diameters and magnitudes. Tables have been prepared which show the co-ordinates and photographic and photovisual magnitudes of all measurable stars within the cluster regions under investigation, but unfortunately these cannot be printed owing to shortage of paper. Those who are specially interested can obtain copies by applying to the Norman Lockyer Observatory, Sidmouth.

Stellar Photo-electric Photometry

IN the past decade the attention paid by astrophysicists to spectrophotometry with the photoelectric cell has increased as the importance of the results so obtained became evident. Hitherto, however, the observations have been confined to two broad spectral regions, usually overlapping, and defined somewhat loosely by the characteristics of two colour filters the choice of which has been dictated more by the response of the photo-cell used than by the astronomical requirements. A recent paper by J. S. Hall, however (*Astrophys. J.*, **94**, 71; 1941), describes a method of working in which emphasis is put on the definition of the spectral energy admitted to the cell. From the grating spectra of stars formed in the focal plane of the objective, two movable slits segregate definite wave-length regions which are then reflected into the photo-cell. The paper gives more than 1,300 heterochromatic magnitudes of 67 bright stars measured in this way at as many as 13 spectral regions from 4500 A. to 10,320 A. Such measurements, especially if they can be extended to fainter stars, will give invaluable information on the extent to which colour temperatures depend on the spectral region in which they are measured, as well as on such related subjects as the effect on stellar colours of intrinsic luminosity and of selective interstellar absorption.

A STRAIGHT-GROWTH METHOD OF AUXIN DETERMINATION IN PLANTS

By E. DOROTHY BRAIN

THE Avena method of estimating auxin in plants requires such technical perfection and specialized apparatus that it is rendered useless to workers who have no access to elaborate equipment. The method described below has been worked out under ordinary greenhouse conditions and, while it is fully recognized that it cannot yield such exact quantitative results as the Avena test method, it has proved of use in comparative work and with more fully controlled conditions suggests possibilities for finer quantitative estimations.

This is an upright-growth method in which pieces of the plant material to be tested are applied with lanoline to the top of cut pea shoots. Peas are grown in soil in pots. The variety used for these experiments was Danby Stratagem. Three seeds to a three-inch pot has been found suitable and the seedlings are grown in the light until they are three or four internodes high. The growth of the internodes is recorded separately. The seedlings are then placed in a dark box, of which the relative humidity is kept up to 100 per cent by the floor being covered with damp soil, and which contains a maximum and minimum thermometer. After twenty-four hours in the dark box the growth of the separate internodes of the pea seedlings is recorded and the peas are prepared for the test by cutting off the part which is still actively growing. Using a safety razor blade, the plants are cut at the node below which growth has just ceased and the height of the remaining stump is recorded as *cut height* (1) (see accompanying figure). A vertical millimetre scale is placed behind each pea and marked at the level of the cut height and the pot level. The pea stumps are replaced in the dark box for thirty to forty minutes to give time for any bleeding from the cut surface. They are then made ready to receive the test material by the top being dried with filter paper and then covered with a layer of lanoline on which the test material is placed. The

peas are then replaced in the dark box for twenty-four hours, after which they are removed and the *cut height* (2) is measured by the millimetre rule and the millimetre scale. The maximum and minimum temperature during the experiment are recorded.

More than two hundred tests have been carried out using hypocotyls and epicotyls of different species of seedlings, examples of which are shown in Table I. Control experiments were made by using portions from the base of hypocotyls where growth was known to have ceased and others with lanoline alone applied to the pea stumps. Definite increase in the height of the pea stumps was shown by the application of the actively growing plant material and this could be measured correctly to 0·5 mm. This increased growth is attributable to the amount of growth substance which diffuses out from the plant material applied on the lanoline which restimulates growth in the pea stump.

In order to attempt some standardization of this induced growth, experiments were performed with indole-3-acetic acid in one per cent solution (0·1 mgm. acid per litre). This was first applied in lanoline, a paste being made by mixing 0·25 c.c. with 0·5 gm. of lanoline. Results from this experiment were variable owing to the difficulty of obtaining an even mixture and equal applications to each pea. More experiments were made with the indole-3-acetic acid mixed with a 3 per cent agar gel. Mixtures of equal parts acid and melted agar and one part acid to two parts agar were made into blocks which were applied to the pea stumps. The blocks were made by sucking up the agar mixture into a straw, in which it cooled and set. Then blocks of the required length can be cut with a razor blade and in applying them to the pea stump the straw acts as a support for the agar block. The blocks used were 5 mm. long and approximately 40 c.mm. in volume, which is much larger than those used for the Avena test but of approximately the same volume as the segments of *Lupinus albus* hypocotyls, with which many of the experiments were performed, and a convenient size to fit on to the pea stumps. The blocks were placed on the pea on lanoline as described above.

Results recorded in Table 2 show that a block of 40 c.mm. containing 1 : 2 parts indole-3-acetic acid in 3 per cent agar would produce an increase of 1 mm. in the pea stump. Blocks made of 1 : 1 acid and agar produce greater increase but more variable results. It is, therefore, suggested that an increase of 1 mm. in the pea stump should be regarded as a standard for measurement of the amount of growth substance which has diffused out of the test material, one 'pea unit' being that amount of growth substance which diffuses from an applied block of plant material causing an increase of 1 mm. in height of the pea stump and is equivalent to the growth caused by a block of 1 : 2 indole-3-acetic acid (0·1 mgm. per litre) in 3 per cent agar at a temperature 72–54° F. and 100 per cent relative humidity.

According to Went[1] 0·5 per cent indole-3-acetic acid solution in a 10 c.mm. agar block, at 24°C., and 85 per cent relative humidity would produce 5° curvature in the Avena test, so that the results for the pea method show that an increase of 1·0 mm. in the pea stump would approximate to 5° curvature in the pea test.

SCIENTIFIC AND INDUSTRIAL RESEARCH IN NEW ZEALAND

The fifteenth annual report of the Department of Scientific and Industrial Research, New Zealand, covers the year 1940–41 and includes the Minister's statement, the report of the Secretary, together with reports of the research committees of the Council of Scientific and Industrial Research and of the work of the Plant Research Bureau, Wheat Research Institute, Magnetic Observatory, Dominion Laboratory Geological Survey Branch, and Metrological Branch*.

The Dairy Research Institute has been occupied with urgent problems relating to the storage and transport of dairy produce under war conditions, and particularly with the view of prolonging the keeping quality of dairy produce likely to be in storage for long periods and methods of packaging and processing butter and cheese to conserve shipping space and weight and packing materials. Special starter rooms embodying the Institute's recommendations for preserving the vitality of starters were erected by some fifteen dairy factories during the past season.

The work of the Plant Research Bureau during the year has been concentrated on minimizing losses in pasture, arable and horticultural crops by intensifying control measures, the maintenance of full supplies of certified pasture and crop seeds and the propagation and collection of important medicinal plants to help supply emergency requirements in Great Britain and locally. Attention has also been given to local substitutes for imported plant materials such as seaweed products like agar and carrageen, the most efficient methods of preparing and conserving supplementary fodders and the instructional and research work required by the administration of the Termites Act, 1940. A considerable amount of work has been carried out on linen flax. The Plant Diseases Division at Owairaka, Auckland, has tested a number of organic mercurials for control of *Corticium vagum*, and has examined a number of copper compounds against standard Bordeaux mixture and biological work on sulphur sprays and the testing of derris products. Spray investigations and demonstrations in the field of fruit research have also been continued by the Division, while other work has been directed to the study of the insects attacking timber in an endeavour to select those satisfactory for testing timber preservatives and timber treatments. Tobacco research has included further work on the investigation of mosaic and that at the Cawthron Institute on control of damping-off fungi with soil dressings gave promise of success. Use of Semesan and zinc oxide with seed did not give satisfactory results, although Semesan gave satisfactory control if mixed with the soil to a depth of ½ in. The outstanding

* New Zealand. Fifteenth Annual Report of the Department of Scientific and Industrial Research. Pp. 92. (Wellington: Government Printer, 1941.) 9d.

problems in fruit research have been concerned with methods of storing under the best possible conditions the surplus of fruit thrown on the local market when export stopped. This has involved resorting to orchard storage on a greatly increased scale to supplement cold storage facilities. Experimental work in co-operation with the Cawthron Institute has yielded valuable information regarding the optimum conditions of temperature and humidity in orchard stores, the best methods of wrapping and packing and the varieties and grades of fruit best suited for orchard storage.

Work at the Plant Chemistry Laboratory received a severe set-back through the destruction of the laboratory and a greater part of its equipment by fire during the year. Very good work has, however, been done under difficult conditions in supplying a considerable amount of alkaloidal material from perennial rye-grass to the Department of Agriculture for animal experiments in connexion with facial eczema studies and in obtaining chemical data on the digestibility or nutritive value of silage from selected pastures. Chemical studies on the effect of naphthylacetic acid on the composition of cuttings and on the relation of accessory substances such as auxines and vitamins to soil fertility has continued. In collaboration with the Mines Department surveys of minerals of strategic value and special economic importance in war-time have been intensified, including surveys of local resources of such minerals as serpentine, magnesite, oil shale, sulphur, sands and clays. A special committee was set up to co-ordinate investigations by the Department of Agriculture and Scientific Industrial Research, the Cawthron Institute and the Canterbury Agricultural College on the manufacture and agricultural value of a reverted phosphatic fertilizer obtained by incorporating ground serpentine with superphosphate.

The activities of the research associations servicing the tanners, the boot and shoe manufacturers and the wool manufacturers have been directed specially to war-time manufacturing problems, including the provision of satisfactory substitutes for imported materials which are not now available. Other investigations have been concerned with local substitutes for imported pottery materials, adhesives, agar and carrageen. The Physical Testing Laboratory, in addition to a large amount of work on physical testing and precision-instrument constructing, is extending its operations in regard to standards of reference for use in connexion with the manufacture of munitions.

The Chemical Engineering Section of the Dominion Laboratory has been largely occupied with the investigation of producer gas as an emergency fuel for motor vehicles, and its semi-commercial trials on the gas storage of apples to improve their keeping qualities for local consumption has yielded valuable data. Much chemical work has been done in connexion with a survey of national coal resources, and other work has been concerned with stone preservation and spray residues on cabbages, and investigations on casein paint and on the utilization of bentonite are also in progress.

The Geological Survey has carried out special geological and geophysical surveys for the Public Works Department in the Waikato in connexion with hydro-electric developments, and a re-survey of magnetic stations throughout New Zealand is being made to provide data required by the defence services.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

SATURDAY, NOVEMBER 29

BIOCHEMICAL SOCIETY (at the Courtauld Institute of Biochemistry, Middlesex Hospital, London, W.1), at 11 a.m.—Dr. G. M. Findlay will open a general discussion on "The Mode of Action of Chemotherapeutic Agents".

INSTITUTE OF PHYSICS (MANCHESTER AND DISTRICT BRANCH) (in the Physics Department, The University, Manchester), at 2.30 p.m.—Prof. M. L. Oliphant, F.R.S.: "Physics in the United States and Recent Practical Applications of Nuclear Physics".*

MONDAY, DECEMBER 1

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 3 p.m.—Capt. R. Hamond: "Through Western Tibet in 1939".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. A. J. Curtin Cosbie: "Brewing, the Story of a National Industry"—3: "Brewing Research" (Cantor Lectures, III).

TUESDAY, DECEMBER 2

ROYAL INSTITUTION OF GREAT BRITAIN (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Prof. J. C. Drummond: "Recent Advances in the Science of Nutrition and their Significance in War-Time".

WEDNESDAY, DECEMBER 3

SOCIETY OF CHEMICAL INDUSTRY (FOOD GROUP) (Joint Meeting with the Society of Public Analysts) (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 11 a.m.—Mr. A. L. Bacharach: "The Nutritional Bases for Fortification of Foods".

THURSDAY, DECEMBER 4

ROYAL INSTITUTION OF GREAT BRITAIN (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Prof. Benjamin Farrington: "The Hand in Healing: a Study in Greek Medicine from Hippocrates to Ramazzini".

FRIDAY, DECEMBER 5

ASSOCIATION OF APPLIED BIOLOGISTS (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 11 a.m.—Discussion on "Some Problems in Wartime Horticulture with particular reference to Vegetable Production".

SATURDAY, DECEMBER 6

INSTITUTE OF PHYSICS (LONDON AND HOME COUNTIES' BRANCH) (at the South-West Essex Technical College, Forest Road, Walthamstow, London, E.17), at 2.30 p.m.—Dr. W. G. Wearmouth: "Physical Problems in the Plastics Industry".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

SENIOR LECTURER (ungraded) in the Department of Biochemistry—The Registrar, The University, Liverpool (December 6).

TEACHER OF ELECTRICAL ENGINEERING AND ALLIED SUBJECTS in the Cambridgeshire Technical School—The Education Secretary, Shire Hall, Cambridge (December 8).

ENGINEER for the Sierra Leone Public Works Department—The Ministry of Labour and National Service, Central Register Branch, Queen Anne's Chambers, Tothill Street, London, S.W.1 (quoting E. 338).

NATURE

SATURDAY
Dec. 6, 1941

THE SPIRITUAL VALUE OF RESEARCH

SCIENTIFIC workers are adding here and there to human knowledge, and from time to time it is opportune to take stock in science, to ask whether the efforts are directed towards the best ends or whether we are largely chasing our own tails in working on details of established problems.

For the purpose of this inquiry a distinction may be drawn between pure and applied scientific research, though admittedly it is improper to do so. In the first place, it is legitimate to wonder whether the best brains seek scientific work as a career. Differences in the work and in the environment of the work demand different traits of temperament and character. The level of intelligence which the honours training ensures does not necessarily mean the possession of great inventive capacity or powers of imagination. There is rather a tendency to sneer at the man engaged in utilitarian science ; one sees such expressions as the greed for gain, the prostitution of science, blatant insistence on profit making. Such accusations are frankly not true ; the scientific worker in industry, even if he has never published a paper in a scientific journal, can be and often is at least the equal of the academic worker.

The point is best illustrated by reference to the United States, where there are as many and as competent men of science at work in the universities and colleges as in Great Britain. In addition, most Americans will agree that there are as fine or an even finer set of brains engaged in perfecting the new discoveries and finding practical uses for them of benefit to man. Very often the practical use of something new has to be forced on man : he is told by means of advertisement that here is something that he really wants, whereupon he begins to buy it, but before long something of real value results from the development : this is happening more and more often. The chemists, for example, sought long to find a use for butyl alcohol : in the end, spray paints were discovered ; not only are they of the greatest value to the motor-car industry, but also they have revolutionized the paint industry. There is nothing ignoble in making something useful, while in regard to profit, large or small, unless an article can be sold at a profit the inventor can neither live, make experiments, nor even induce anyone to undertake manufacture. President Roosevelt, speaking of a report of the National Research Council to Congress, has said it "presents a clear record of how successfully we have translated our old time Yankee ingenuity for invention into American genius for research".

Some of the facts relating to the United States are striking. Thus in 1940, 2,200 industrial corporations maintained 3,500 research laboratories

employing 70,000 workers at a cost of seventy-five million pounds. In these, particular emphasis is directed towards personal qualities of the prospective employee as distinguished from scholarship. Creative urge, receptiveness to new ideas and intellectual integrity are particularly important. It is such men and their gifted leaders who have made the wholly synthetic textile 'Nylon', at a staggering experimental cost which it will take a long time to recover from profits. Nylon bids fair to make the world independent of Japanese silk. In addition, all sorts of new uses, perhaps of equally outstanding value, will be found for the fibre.

Nothing which is said here indicates any desire to check pure research; it is realized that great discoveries come only seldom and then perhaps after years of patient groundwork, also that "the wind of genius bloweth where it listeth". A difficult problem such as that of cancer must be attacked from many sides; a tiny advance here may lead to definite progress elsewhere.

There is, however, much to be gained by planning a research. In industry it is of value occasionally to review a research problem on its completion, so as to see how much time could have been saved if none but useful experiments had been undertaken: often the necessary time is but a small fraction of the time actually spent. Research expenditure is usually roughly proportional to sales: it becomes difficult to know how much money to allocate to subjects which are far in advance of the specific problems of an industry. But to-day American 'big business' men firmly believe in research and believe that they would suffer seriously were it discontinued. Chairmen produce slogans when they talk to shareholders: "The fountain of youth for a corporation is technical research which has been properly organised for profit." "Every discovery has a tremendous background. . . . Every discovery in turn is a link in the chain leading to further development." "The products of to-day's researches are a base for to-morrow's orders." "The price of progress is research which alone assures the security of dividends."

Speaking of the glass industry in the United States, in which the over-riding control is exercised by one or two organizations, Prof. W. E. S. Turner has said that "so far from resting on the position acquired, they appear to be intent on strengthening the position by research development work on a considerable scale".

It must not be forgotten that many research problems are so costly nowadays that only the largest organizations can finance them. A technical research is no longer a problem for a single man with two or three helpers; it may involve a team of a hundred scientific workers and necessitate the building of a small experimental factory.

Research expenditure in such industries as food, textiles, leather, forest products has lagged behind that in the oil, rubber, chemical and electrical industries; there is, however, just as much room for it and as much reward awaiting success. Research need, indeed, should not be confined to process inventions but extended by co-operation between management and labour to fatigue, industrial psychology and related matters. To employ each worker in a way that best suits his capabilities, to enable him to perform a full day's work with a minimum of fatigue, are all desiderata which should make the strongest appeal to any well-managed firm.

Although what has been said above had direct reference to science in industry, it also applies fundamentally in so-called pure science. As Sir Henry Dale pointed out in his presidential address to the Royal Society (p. 678), the work of the Medical Research Council and its sister bodies is evidence of the value of research under careful control exercised on behalf of the Government.

If it be accepted that no man is happy unless he works, and that the work should be worthy of the effort, then the need to ensure that each of us is enabled to do his best in congenial work is beyond question. The worker has the obligation to become fully trained, to be patient until the opportunity arises to step into his ideal post and to render service such as will justify his salary, the oncost on his job and provide something for the future development of his industry. It may take years to find out whether one has chosen a career wisely; there may be steps to be retraced, adjustments to be made, but so long as there is a spiritual desire to make good, success, however it may be defined, can only be round the corner.

There is constant complaint about the apathy of the public towards science, its ignorance of science; but perhaps the fault is as much on the side of men of science as that of the public. In general, men of science fail to tell the public what is going on; why, for example, margarine to-day is the equivalent in most respects of butter, whereas twenty years ago it was much inferior; the public cannot find this out for itself.

Men of science surely have a duty to the public to learn to write more simply, so as to bring home to a far larger audience than is reached at present what science means and what it is doing. Until this can be done, no complaint of the neglect of science is justified. We may have smashed the atom and realized the alchemists' dream by the manipulation of the bits, but it does not make sense when we let the lay newspapers hint that gold from lead has become a practical possibility.

AGRARIAN PROBLEMS OF MEDIEVAL EUROPE

The Cambridge Economic History of Europe from the Decline of the Roman Empire
Edited by Prof. J. H. Clapham and the late Prof. Eileen Power. Vol. 1: The Agrarian Life of the Middle Ages. Pp. xvii+650. (Cambridge: At the University Press, 1941.) 30s. net.

THE history of which this is the first instalment is not only a co-operative, but also an international work. The fifteen contributors to the present volume represent schools of history or economics in France, Belgium, Germany, Switzerland, Austria, Poland, Russia, Finland, Sweden, Jugoslavia, Great Britain, and the United States. The result is a series of essays in which the agrarian development of most European countries is traced by specialists, familiar alike with the original materials and the scattered literature which has arisen around them. The task of assembling these articles under war conditions must have been very difficult, and all English students of economic history should be grateful to the editors whose resolution has made it possible. The gratitude of those who use the volume will be deepened by the knowledge that Prof. Eileen Power, who planned it and prepared much of it for the press, died with tragic suddenness while the work was still in the printers' hands.

No general synthesis of results is attempted in this volume. The attempt would in any event have been unprofitable, for research in the field as a whole has not yet reached a point at which large-scale conclusions can safely be drawn. It is still possible for specialists to differ abruptly from one another on the fundamental question of the extent to which the economic life of the Roman Empire survived the barbarian invasions of the fifth and sixth centuries. What can be undertaken is a survey of tendencies, and in two articles this limited aim is brilliantly achieved. Without any evasion of controversial issues, Marc Block traces the evolution of seignorial institutions in an essay which is not only learned, but also singularly clear, and at all salient points, convincing. The introductory essay on the settlement and colonization of Europe, by R. Koebner, is a masterly description of the first discernible stages in the economic development of western Europe, and of the historical and physical factors which by their interplay determined its course. The article is of especial interest through the judicious use which it makes of the English evidence, which previous workers have often under-estimated.

The articles on individual countries form a set of regional surveys which will be very useful as an abstract of existing knowledge. The essays which deal with the remoter European States fill a gap of which English students have long been aware. For a considerable time to come, readers who wish to know about agrarian conditions in medieval Spain, Poland, the Scandinavian countries, Russia, or the Byzantine Empire will be well advised to turn in the first place to the essays, and then to the bibliographies, printed here. The fact that many of these essays are hard to read is partly due to the difficulty of explaining technical details in a narrow space, but still more to the uncertainty which overhangs much of the detail itself. For most of the countries of northern and eastern Europe, the material available for economic study is unevenly distributed both in space and time. Outside England and the regions covered by the Carolingian Empire, there is remarkably little evidence which bears directly on the origins or the early stages of economic evolution. In Denmark, for example, the oldest documentary authorities are of the late eleventh century, and the terminology of medieval records is so elliptical that scholars differ widely about its meaning at essential points. As important changes in the methods of land distribution are known to have occurred in medieval Denmark, it is not surprising that few definite facts can be given about the primitive Danish economy.

On the general question of agrarian origins, it is interesting to see that scholars in all countries are tending to use the evidence of place-names as a clue to the character of early forms of agricultural association. The evidence has been unduly neglected in the past. But the interpretation of place names, even when their original forms have been ascertained, is beset with difficulties, and there are articles in this volume in which the results of place-name study are used with more assurance than would be felt by those who have worked on these problems from the linguistic side.

All this means that medieval economic history, as yet, falls far short of scientific precision. The patterns of agrarian life, painfully reconstructed by the modern student, were evolved, even more painfully, by generations of peasants preoccupied with the task of wringing subsistence year by year from land which, on any flagging of effort, would revert to wilderness. The expedients which they adopted in the attempt to escape from the compulsion of their environment varied within each country from place to place. The economic historian, in recording the result of their efforts,

is describing the average of a vast number of experiments. The writer comes nearest the truth who realizes most clearly the number and range of the variations from this mean. Every contributor to this history brings out the diversity of the conditions with which he is dealing. But the limited space at the disposal of each writer has meant that significant variations of the agrarian system are sometimes understressed. It would scarcely be gathered from the essay which deals with England how many exceptions there are to the types of agricultural economy which historians tend to regard as characteristic of different parts of the country.

On this point, it may be suggested that the reader would have been helped by a slight addition to the content of the volume. The importance of money as a solvent of agrarian custom is recognized on all hands. But the treatment of currency problems is reserved for a later portion of this "History". The result is that the present book contains no general discussion of the conditions under which a 'money economy' came into being in different European countries. The need for a survey of these conditions is one among many reasons for hoping that the second volume of this valuable "History" will not be long delayed.

F. M. STENTON.

THE CONTINENTAL SHELF

Atlantic Submarine Valleys of the United States and the Congo Submarine Valley

By A. C. Veatch and P. A. Smith. (Geological Society of America, Special Paper No. 7.) Pp. xvi+101+10 plates. (New York: Geological Society of America, 1939.) £1 10*s*. net.

The Origin of Submarine Canyons: a Critical Review of Hypotheses

By Prof. Douglas Johnson. (Columbia Geomorphic Studies, No. 3.) Pp. ix+126+4 plates. (New York: Columbia University Press; London: Oxford University Press, 1939.) 15*s*. 6*d*. net.

DURING the past fifteen years, the methods by which hydrographic surveys are made have fundamentally changed, and both the accuracy attainable and the speed of working have greatly increased. These changes are due partly to the introduction of the echo sounder and partly to new methods of position finding when out of sight of land. The paper by Veatch and Smith, with its accompanying charts, represents one of the first products of these technical advances, and gives us, for the first time, a survey of an extensive area out of sight of land in which the positions of the soundings can be relied on sufficiently for steep bottom forms to be contoured. The area treated is off the eastern coast of the United States from Cape Henry to Georges Bank. The charts are on a scale of 1 : 120,000 and show all the thousands of soundings on which the contours are based.

As is well known, the surface of the continental shelf on the Atlantic seaboard of the United States is a relatively featureless plain sloping very gently seaward. Beyond the 100 fm. line, however, the gradient suddenly steepens to about one in forty, and large irregularities appear in the topography. It is in this area, between the 100 and 1,000 fm. lines, that the main interest of the work lies. Unfortunately, the spacing of the lines of soundings, although they are many times more numerous than in previous surveys, is too wide for the contours to be traced in a purely mechanical way. The authors have therefore assumed that the bottom forms are similar to those due to stream erosion on land, and have drawn a set of contours satisfying the observed soundings and depicting an erosion surface. The assumption considerably restricts the form of the contours, for it requires the gradient of a valley bottom never to change sign and all valleys to branch upwards. The authors explain very clearly what they have done and say that they have made numerous attempts to fit other types of topography without success. To establish whether or not the irregularities shown by these soundings do represent a stream-like pattern is among the most important problems of geology, and is one that could in happier times be easily solved by a detailed examination of a small area. From a somewhat superficial examination of the charts it appears that, while not every irregularity shown by the contours is certainly present in Nature, yet it is established that the topography consists of ridges and valleys running up and down the slope.

Whatever may be the form of the minor relief on the slope, the present charts leave no doubt as to the form and position of those major features that have been called submarine canyons. Nine major canyons occur in the area covered by the charts. The largest is the Hudson canyon, which is about fifty miles long, six miles wide and has a maximum depth of 3,700 ft. below its rim. These canyons are cut as nicks into the edge of the shelf and do not extend more than a few miles inside the 100 fm. line. They are not connected in any striking way with the present rivers on land.

Veatch and Smith, having convinced themselves of the existence of a stream-like pattern, believe that this pattern has actually been cut by streams. They boldly lower the sea 12,000 ft. some 25,000 years ago and return it to its present level so recently as 3000 B.C.

Although we have only recently acquired a detailed knowledge of the form of the canyons, their existence has been known for many years, and a great body of comment and speculation has accumulated concerning their origin. The main object of Prof. Johnson's monograph is to review critically this obscure and scattered literature. The canyons must either have been formed under the sea or out of it. If the latter, then either the land must have been raised or the sea lowered. The changes required are so large, so widespread and so recent as to reduce the argument almost to an absurdity.

If the canyons were formed under the sea, then either they were eroded by some kind of submarine current or else they were undermined by submarine springs. The hypothesis that mud-laden currents were responsible for excavating the canyons has been strongly urged by eminent authorities, but is rejected as inadequate by Prof. Johnson. He believes that undermining by submarine springs is the primary agent in excavating the canyons, and supports this view with arguments from a wide variety of natural phenomena. Quite apart from the correctness or otherwise of the views expressed, the whole book compels the reader's admiration by the extent and variety of the sources from which he has drawn his information.

Actually, this view of the genesis of submarine canyons has much to commend it. It requires no catastrophes, it does not need any straining of the laws of physics, or any very exceptional circumstances. The principal doubt is whether the structure of the shelf is such that artesian conditions are possible on the slope. At first sight this would require the slope to be a fault or erosion feature, which would be an unwelcome assumption to many. More careful consideration suggests that this may be avoided, and the more attractive idea of a lens or delta-like accumulation of sediments retained. Among other possibilities the author suggests that the water for the springs might be that expelled from the sediments during compaction.

However these doubtful matters may finally be decided, it is clear that the present data are only a beginning of a vast undertaking, and that the unravelling of even the outlines of submarine geology will occupy many years. Further improvements in technique will be necessary to extend the work to deep water. This will require the solution of many difficult and interesting problems in physics, seamanship, and geology, and will require the close co-operation of experts in these matters.

E. C. BULLARD.

CONCEPTS OF ELECTRICITY

Introduction to Electricity and Optics

By Prof. Nathaniel H. Frank. Pp. xii+398. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 24*s*. 6*d*.

THIS book has been written as a text-book for second-year students at the Massachusetts Institute of Technology. "The goal to which it aspires is a compact logical exposition of the fundamental laws of the electric and magnetic fields and the elementary applications of these laws to circuits, to a study of the electrical and magnetic properties of matter, and to the field of optics." A slight acquaintance with the calculus and a knowledge of elementary physics is assumed on the part of the student.

There are no descriptions of apparatus or experiments or historical accounts of the development of the subject, and the physical principles have not been used simply as pegs on which to hang mathematical problems. An account of the principles on which the theory is based, of their meaning and the way they are related to one another, is aimed at. In fact the author is trying to teach physical instinct directly by an unhurried and in some respects very skilful presentation of 'key' facts and calculations, and not by letting the student acquire it unconsciously by drill in calculation and experiment. Elementary alternating current circuits, Maxwell's equations of the electromagnetic field, the theory of dispersion and Planck's radiation law are done in an elementary manner, but there is no reference to, for example, the ballistic galvanometer. There is no obsolete or obsolescent matter in the book, but it is not too modern; the quantum is barely mentioned. In some respects the treatment is very unusual, as for example in magnetism, where the magnetic pole is relegated to a subordinate position. There are collections of good problems, but the solution of some will require help from outside the book.

The book is to be regarded, therefore, not as a conventional text, but in conjunction with the

author's companion book on mechanics and heat as a text-book on physics from an unusual point of view. It would probably be very helpful to second-year physics classes at universities where the physics is ahead of the mathematics, and generally where physics is being combined with chemistry and not with mathematics. It is undoubtedly a book for the college library. Teachers will enjoy the freshness of outlook, but may disapprove of the selection of matter. The book is well produced, but the price is high.

R. A. HOUSTOUN.

BEHAVIOUR OF IODINE IN THE BODY

The Endocrine Function of Iodine

By Prof. William Thomas Salter. (Harvard University Monographs in Medicine and Public Health, No. 1.) Pp. xviii+351. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1941.) 3.50 dollars.

ANY work dealing with the behaviour of iodine in the body is bound to be mainly an account of the physiology of the thyroid gland. It is chiefly for this that biochemist and clinician alike will consult the book under review. Neither will be disappointed; for the author shows himself to be equally at home in the laboratory and in the ward.

It is evident from the title, however, that the author considers that iodine is concerned also in the workings of the other endocrine glands. It must be admitted that the evidence for any direct connexion is a little thin; but in so far as the endocrine glands are mutually dependent, they may all be said to participate in a manner in iodine metabolism. Their mutual relationships are well discussed; and in expounding the view that all the endocrines are dependent on and controlled by each other (rather than all directed by the pituitary) Dr. Salter is able to coin a new and topical phrase—"the pituitary-thyroid axis"—which, with its variants, may in time replace Cushing's older orchestral simile.

Interesting as these speculations are, they have at present no direct clinical application; the instrument which the clinician most hopes the biochemist will provide him with is an unequivocal method of determining the amount of circulating thyroid hormone in the blood. Given this instrument, many of his problems would automatically be solved, and many questions settled which he can now only speculate about. The introduction of methods of estimating iodine in small quantities of blood has brought that goal within sight; but before it can be attained, an improved technique of separating the active from the inactive iodine is required.

The form in which the thyroid hormone circulates n the blood is not at present known, but it may be presumed to be a protein, containing thyroxine among its amino acids. Therefore, so far as the hormone is concerned, only that fraction of the plasma iodine which is bound to protein is of interest. Iodine is bound, however, to the proteins of the plasma with varying degrees of intensity; how much this linkage is a matter of chemical combination, and how much of adsorption, is far from clear. The greater part of the protein-bound iodine can be extracted with alcohol or acetone, the amount extracted depending largely on the thoroughness of the extraction. The amount so extracted by various arbitrary procedures of this type has been termed by many investigators 'organic iodine', and taken to represent the hormone itself. This premature assumption is largely responsible for the confusing results reported in the literature.

Although recognizing the many possible fallacies, the author has given close consideration to all the reported values for blood iodine in health and disease. In spite of the technical weaknesses, all investigators have found that the level of the part of the iodine which is most closely related to protein corresponds roughly to the expected level of thyroid hormone. Thus plasma organic iodine is low in myxœdema and high in thyrotoxicosis, and in the latter disease it tends to return to normal after appropriate treatment of the patient.

Dr. Salter has himself confirmed these general conclusions. His method is to estimate simply the iodine which is precipitated with the plasma-proteins. (He suggests, for future use, a further subdivision—after alkaline hydrolysis—into thyroxine-like and di-iodotyrosine-like fractions.) The exceptions and difficulties are frankly dealt with, and the author makes it clear that the protein-bound iodine cannot be taken to be identical with the thyroid hormone. He describes, for example, a marked rise in protein-bound iodine on administering potassium iodide to cases of myxœdema. Nevertheless he regards the test as already of some practical use in diagnosis; although the ten cases described to illustrate this point may leave the clinician wondering whether these particular problems could not have been solved by less elaborate methods.

The recent work on the administration of iodine 'labelled' with radioactive isotopes is fully described. The most useful isotopes appear to be those of mass 128 (with a half-life of 25 minutes) and of mass 131 (with a half-life of 8 days). The work so far done on this promising subject has accomplished little more than the verification and amplification of conclusions reached by the older methods; the astonishing rate of uptake of iodine by the thyroid (particularly when hyperplastic) is illustrated by the finding that, after intravenous injection of a radioactive iodine, the peak of its concentration in the gland is attained within 10–15 minutes. The author touches on the therapeutic possibilities of radioactive iodine, by which theoretically a brief bombardment of tremendous intensity could be delivered from within the thyroid itself by what should be attainable doses. A short section describes the biological effects of the newly discovered element No. 85, which seems to have in common with iodine an affinity for the thyroid.

Other topics dealt with in this book include the artificial iodo-proteins, iodine balance and the relation of the nervous system to iodine metabolism; while an appendix gives details of the methods employed by the author to estimate and fractionate iodine in biological material. The discussion of the varied problems concerning the behaviour of iodine in the body is conducted throughout with the easy competence of one who is familiar with every by-way of his subject. The new series from the Harvard University Press could have no better introduction than this scholarly work.

W. R. Trotter.

A NATURALIST IN THE HIGHLANDS

Highland Gamekeeper
By Dugald Macintyre. Pp. 246+8 plates. (London: Seeley, Service and Co., Ltd., n.d.) 12*s*. 6*d*. net.

It is a relief in times of war and stress to turn for relaxation to books written of Nature, lofty and serene. "Highland Gamekeeper" brings to the mind happier days, for it is written by one whose whole life has been spent out of doors, studying wild birds and wild animals. The author comes of old Highland stock; his great-grandfather, Allan Macintyre, was Kintyre's last bard and foxhunter, and we are told that the immortal Gaelic poet, Donnchadh Bàn nan Oran, Duncan Ban Macintyre (who, as is known, was a natural poet of the hills and no scholar), came to the author's ancestor Allan to have his poems written out.

With this ancestry there is little wonder that the author from his early years should have found himself a keen observer of Nature. We follow him through early to mature years, when he volunteered for active service in France in the War of 1914–18—he gives a vivid picture of shooting game over a recent battle-field and seeing a snipe which he had put up driven back to him by a peregrine falcon—down to the present day when from his home in Perthshire his observant eye notes the poaching kingfishers of the Earn and the strong-flying blackcock in the high-lying glens of the strath.

There are some valuable observations in the book. Who, for example, has seen a pair of wild peregrines bathing? On p. 59 Mr. Macintyre gives a vivid picture of this, for the peregrine to him is almost as familiar as the sparrow to less fortunate folk. A crime of the great black-backed gull is brought home to us (p. 102) in a manner which loses nothing through its simple terseness. But the author's outstanding achievement was his discovery (p. 107 *et seq.*) that curlews periodically eject the epithelial lining of the gizzard. He describes how he was able to convince the sceptics that this remarkable event did indeed take place. He writes:

"The discovery was made after I had examined numbers of curious little pouches which I saw lying in the pools of a marsh. Thousands of curlew used that marsh as a roosting-place, and I at first supposed that the queer objects were partly digested turnip leaves. The finding of a newly-shed pouch containing coarse white quartz grit led to my sudden recognition of the fact that the pouches were really the cast linings of curlew gizzards."

It was perhaps natural that the authorities at first were disinclined to accept his discovery, but:

"I forwarded about fifty shed gizzards to the FIELD office, together with several newly shot curlew for dissection, and the fresh gizzard-linings of other curlew, shot and dissected by myself. In the FIELD of the following week two authorities to whom the question was referred, Mr. R. H. Burne, of the Royal College of Surgeons, and Dr. H. Hammond Smith, pathologist to the FIELD, accepted my discovery as a new and true one, and Mr. J. E. Harting, the Naturalist Editor, quoted

the following excerpt on gizzard-renewal from Professor Newton's 'Dictionary of Birds': 'As a rule the cuticle (gizzard lining) is continually wearing away and being reproduced, but many cases are known in which most of the lining is suddenly cast off and ejected through the mouth'."

The author adds:

"I often heard curlew having long spells of coughing by night, but only understood what that meant after my discovery. The function of stomach-renewal takes place in early autumn, and it is in September or early October that one finds newly-shed pouches."

Mr. Dugald Macintyre is a keen fisherman, and has found that an effective lure for seatrout in the lower pools of a river at dusk is small saithe flies. I myself have caught saithe when fishing for sea-trout in the tidal waters, and have known of one occasion when a silvery herring snatched the fly and was landed.

The author narrates (p. 136) an occasion on which a cold spell which visited Mull suddenly during October 1936 had the effect of causing stoats to turn white prematurely, and believes that the weather largely influences their change of colour.

SETON GORDON.

CAUSATION OF MENTAL ABNORMALITY

The Psychodynamics of Abnormal Behavior
By Prof. J. F. Brown, with the collaboration of Dr. Karl A. Menninger. (McGraw-Hill Publications in Psychology.) Pp. xvi+484. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 24*s*. 6*d*.

THERE are a number of faults which are common to introductory books on psychopathology. They are often written by those who have themselves but a smattering of the subject—in spite of the fact that it needs wide acquaintance with it to write easily in simple language. Such books usually deal with fundamental material, which the student could read with advantage in the original work, and so neglects the more recent advances. Finally there is often a gross bias in favour of one particular school of thought.

These faults have been avoided by the authors of the interesting book under review. It is an excellent introduction to psychopathology planned for the student, but the general physician will also find it of interest.

The writers take the organismic point of view as their basis and, although they have a strong psychoanalytic leaning, they are critical in everything they say and do not repeat simplified orthodoxy. For example, they state: "We need more precise definitions of our theoretical concepts. In our criticism of psychoanalytic theory we saw that, despite the very great genius of Freud and many of his followers, many of the concepts were ambiguous and not at the present time capable of either scientific definition or experimental evaluation. It is to be hoped that the collaboration of psychoanalysts and academically trained psychologists will bring about a sounder background for psychopathology." This broad-minded view is taken throughout the book. Everywhere the importance of psychosomatic factors is noted; for example, on p. 68 it is stated: "A discussion of the several types of mental abnormality indicates the presence of psychic factors in those usually thought of as purely somatic and of organic factors in those usually thought of as purely psychogenic."

The book is divided into five parts. Part 1 deals with the organismic point of view (the reaction of the individual in his environment), normality, abnormality, the nature of personality, the historical development of psychopathology and the psychosomatic problem. Part 2 describes symptomology, modern ideas regarding symptoms, abnormalities of the cognitive, motor and emotional processes. Part 3 deals with the theory of the genesis and structure of the personality. Part 4 gives an outline of psychiatry (including sexual abnormalities and genius). Part 5 suggests the future possibilities of the psychodynamic theory. It is this last part which is of most interest to the practising psychiatrist, since it is full of common sense and points to many fascinating developments.

The book is well presented, with excellent binding and good print. The style is clear and illustrated with diagrams. It should be easy for one who has had a little acquaintance with psychology to understand the theories presented, but naturally those who are studying medicine should augment it with a text-book of psychiatry, since the clinical descriptions are a little curtailed. The value of the book is enhanced by a full bibliography—there are eighteen pages containing some four hundred references, mainly of recent work. There are also good author and subject indexes which make the book a pleasure to use.

CLIFFORD ALLEN.

Assam Adventure

By F. Kingdon Ward. Pp. 304+16 plates. (London: Jonathan Cape, Ltd., 1941.) 12*s*. 6*d*. net.

THIS is the kind of book that makes any flower-lover's mouth water. Kingdon Ward had, of course, to make the chance for himself. But what a chance it was! Wandering about in a flower paradise with nothing else to do but collect the most glorious plants. Thirty-nine rhododendrons—that alone should be enough to satisfy most plant lovers; but in addition such treasures as the Tibetan blue poppy, known all over the world as *Meconopsis baileyi* but now more accurately described as the *Meconopsis betonicifolia baileyi*; then ten different species of primulas and seven gentians. All these Kingdon Ward has through three journeys into south-western Tibet been able to introduce into cultivation in the West. It is a great contribution to the happiness of mankind and some little set-off to the present horrors of war.

We could have wished that Kingdon Ward had that other plant-collector, Reginald Farrer's, gift of description. But Farrer was a literary genius at describing flowers such as comes only once in two or three generations; and if he could not find the exact word to describe the colour or form of a flower he would deliberately coin a word for it. Kingdon Ward lacks that gift. But he has to some extent made up for it by the beautiful photographs with which his book is illustrated and which give us a fine impression of the kind of country in which the flowers are found. This is another important part of Kingdon Ward's work: he describes in detail the physical conditions of temperature or moisture, of shade or sunshine under which the many plants he has introduced to cultivators are found in their own native habitat. F. Y.

Historic Thorn Trees in the British Isles

By Dr. Vaughan Cornish. Pp. 94+9 plates. (London: Country Life, Ltd., n.d.) 8*s*. 6*d*.

DR. VAUGHAN CORNISH in his interesting study of historic thorn trees shows that their distribution in England coincides strikingly with the areas invaded in the south by the Belgic tribes from Gaul, and in northern England, by the Parisii, an adjoining tribe. From these tribes probably originated the cult of the thorn as a sacred tree—a cult still persisting in some remote districts in England, and common in Ireland, where the fairy trees are protected with superstitious reverence. The legend of the Glastonbury thorn gathered Christian associations around the thorn.

These cherished trees planted in later times as marks for assemblies of 'hundreds' or parishes, or as forest boundaries, and in some instances—as in that of the author's own inheritance, the Salcombe Regis Thorn—maintained by replanting to the present day, trace back in their story the history of their locality. Rectors of country parishes and anyone with an interest in the past and present of their district will find Dr. Vaughan Cornish's account of the thorn trees fascinating

The English May tree speaks of our past. May Day celebrations gather round it to-day. The fresh emphasis the War has given to the value of English trees should make this history of one of the most characteristic, timely.

The Nature of the Chemical Bond and the Structure of Molecules and Crystals

An Introduction to Modern Structural Chemistry. By Prof. Linus Pauling. (The George Fisher Baker Non-resident Lectureship in Chemistry at Cornell University.) Second edition. Pp. xvi+450. (Ithaca, N.Y.: Cornell University Press; London: Oxford University Press, 1940.) 28*s*. net.

THIS book is lineal successor in a series of famous books dealing with structural chemistry from a physical point of view, the first of the line being G. N. Lewis's "Valence and the Structure of Atoms and Molecules". The first edition of Prof. Pauling's work was published two years ago. Its well-merited popularity led to the exhaustion of the first edition, and a second has now been prepared. This preserves practically the whole of the text of the original edition, but is improved and brought up to date by the inclusion of a further 20 pages, devoted mainly to the discussion of structures which have been studied by quantitative methods since the earlier edition was prepared for press. To a subsidiary extent the new matter consists of various expansions of the theoretical argument of the original work. The molecules of which the structures are discussed for the first time include the $Mo(CN)_8''''$ ion, which has the remarkable form of a triangle-faced dodecahedron, and *cis*-azobenzene; the new crystal structures include silicon disulphide and molybdenite.

Science in Peace and War

By Prof. J. B. S. Haldane. Pp. 229. (London: The Scientific Book Club, 1941.) 2*s*. 6*d*.

THE suspension of the *Daily Worker* has deprived the public of Prof. J. B. S. Haldane's weekly articles on scientific developments. The Scientific Book Club has, however, come forward and issued a new edition of his second set of collected articles. His new readers will find much entertaining material, for no one equals Prof. Haldane at casual human comment on the facts of science.

In connexion with the *Thetis* disaster, Prof. Haldane gives some very interesting details about his father's researches, which commenced with analyses of the air in the slums of Dundee in 1885 and 1886. Sometimes as many as eight persons occupied one bed in a single room, while in other cases there was no bed at all. His investigations convinced him that the high death-rate in overcrowded houses was not due to chemical causes, but to bacteria. He experimented on himself, and on his son. From the age of ten, Prof. Haldane used to accompany his father on research expeditions in mines. He tells us that his father always said that the most interesting physiological problems are those which arise in ordinary life.

J. G. CROWTHER.

INTERNATIONAL COLLABORATION AND FREEDOM OF SCIENCE*

By SIR HENRY DALE, C.B.E., F.R.S.

As we come to the end of another year we can see, as yet, no prospect for science of escape from the urgent preoccupation with the means of waging war. On the contrary, with the Union of Soviet Russia now locked in a supreme struggle for its own existence and the world's freedom, and with the United States of America rapidly directing its tremendous scientific and technical potential to the support of the same great cause, the diversion of science from its normal uses and objectives has spread right round the world. Yet even this grim necessity has brought with it some measure of compensation, in drawing closer the bonds of friendship between the men of science in the countries thus united in a common purpose. We in Great Britain received a tremendous encouragement, in the early months of this year, from the visit of President J. B. Conant and his associates to establish in London an office for the maintenance of regular and intimate co-operation between the war researches of our American colleagues and those which are here in hand. More recently, and in spite of all difficulties of communication, the sense of a common peril and a common determination is bringing us into a new and growing intimacy of collaboration with our colleagues of Soviet Russia. The organization of the science of the British Empire for war has brought to London already a number of distinguished colleagues from the Overseas Dominions, and we have heard of others who are on the way. It has been a particular pleasure to gather them here, in the house of the Royal Society, and to invite them to regard it as a centre and a rallying point for discussion of the means by which this new and closer collaboration, arising under the stimulus and the necessity of war, may be perpetuated and strengthened for the purposes of peace.

Generous gifts to the Society, during the year, from sister societies in America, have given further welcome evidence of the determination of our colleagues there to come to the help of British science in this time of need. The American Philosophical Society, founded in 1743 by Benjamin Franklin, with the Royal Society as his model, sent us ten thousand dollars "for the aid of science in Britain". They have confirmed our interpretation of their fraternal gift as betokening a desire to help us to preserve some measure of normal scientific activity in Great Britain during the War, and to keep alive the tradition of a free pursuit of knowledge for the benefit of all men. We have been able to find good use already for a large part of this benefaction, in the maintenance of a number of important researches, which war conditions had threatened to interrupt or to bring to an end. The American Physiological Society similarly sent the Royal Society five thousand dollars as a spontaneous contribution to the support of scientific publication in Great Britain, mentioning physiology as the subject to which they, as physiologists, desired us to give the first consideration. The Rockefeller Foundation, that truly international benefactor and promoter of natural knowledge, had already asked the Royal Society to be responsible for the distribution of twelve thousand five hundred dollars in aid of scientific publication in Great Britain in these difficult times.

Gifts such as these, welcome for their own intrinsic value and for the practical uses which we are readily finding for them, are even more welcome on account of the evidence that they bring of the feeling of comradeship between our American colleagues and ourselves. We can do no less, I think, than assure them of our determination that this closer sense of unity in aims and ideals, with them as with our fellow-citizens of the British Overseas Dominions, shall not be lost, but rather strengthened, when we face together the new problems which the end of the War will bring.

Though the first and imperative call on the science of all free countries is for the means of winning the war, to save the freedom without which science cannot in any true sense survive, we cannot put aside the duty of preparing for the part which science must play in rebuilding and maintaining civilization when peace returns. The Conference recently organized by the British Association on "Science and World Order" attracted more attention from the Press and the public than is usually given to scientific events and discussions; and it was, indeed, an impressive and significant fact that men of science from a dozen or more different countries, some far distant, should have found it possible now to meet, here in our war-scarred London, and to find the time and the impulse for such debate. We may offer our very sincere congratulations on the success of such an enterprise.

Many who took part in these meetings, held at a time when science finds itself conscript and organized as never before for the destructive pur-

* From the presidential address to the Royal Society, delivered on December 1.

poses of war, were clearly ready to support the view that it should be as fully organized by the Governments of a world at peace, for its proper purposes of enriching life and enlarging the opportunities of happiness for all men alike. There were not wanting voices, however, such as that of our Biological Secretary, to sound a warning of dangers which might be entailed by such fullness of association between science and government as others were advocating with conviction and enthusiasm. Freedom and opportunity, it was pointed out, rather than organization, provide the conditions for the highest types of research, and thus, in the end, for the greatest services which science can give to mankind. I find myself in sympathy with this view, and nobody here, I think, would suggest that it is usually possible to organize the researches which advance boldly into the unknown, and open new vistas to human understanding. Here we shall certainly not overlook the fact that, in the period between the two wars, important funds have been placed at the disposal of the Royal Society by a series of generous benefactors, to be administered for the support of researches over a wide range of subjects, in complete independence of any control by the State.

On the other hand, I think that it will be agreed that the remarkable development in Great Britain, since 1914, of the State support of research administered by the three Advisory Councils—the Department of Scientific and Industrial Research, the Medical Research Council and the Agricultural Research Council—normally in relation to the needs and the activities of a nation at peace, has taken place without any obvious detriment or danger to the freedom of science. The Royal Society's former function, of advising the Government directly on all scientific matters, and of organizing such systematic researches as were then undertaken in the public interest, has, of necessity, been shared and greatly diminished. We, as a Society, however, can fairly regard this development as, in many respects, a realization of the plans and the dreams of our predecessors here; and I do not think it fanciful to claim that our Society's traditions and standards have been still effective, through the influence of our fellows on the Advisory Councils and their Committees, and through the filling of their chief executive offices by men of our fellowship. As a whole-time research worker myself, since 1914, under the body which became the Medical Research Council, and the senior now in that service, I can bear grateful witness to the freedom of opportunity which can exist under an enlightened organization and control, exercised on behalf of the Government. I have no reason to suppose that the conditions are otherwise under the other Research Councils. Nor should we lose sight of the fact that a further large proportion of the free research of the country is now indebted to support from the State through grants to the universities, administered without any trace of detailed Government control.

While, therefore, the existing mechanisms for the support of science by the State are doubtless susceptible of improvement at one point or another, I find no reason to fear any threat to the freedom of science from them, or from any natural development on those lines. Nor do I fear it from a wider use of the organized application of science and scientific method to problems of public welfare; nor, again, from a more effective access of scientific knowledge to those responsible for government. A year ago Sir William Bragg told the Royal Society of the formation of the Scientific Advisory Committee to the War Cabinet, under the chairmanship of Lord Hankey, with the President and two Secretaries of the Royal Society as members *ex officio*. The representation of the Society has, indeed, been strengthened since then, and in a manner most welcome, by the fact that, though I have succeeded him *ex officio*, Sir William Bragg still gives his wisdom and experience to the work of that Committee, as an extra member.

There is one direction, however, in which I do find some reason to fear for the freedom of science. If science should become entangled in controversial politics, through the over-eagerness of its advocates and champions to invoke the sanction of science, or to claim its potentialities, in support of any special political doctrine, then indeed I believe that the threat to its freedom might become a real danger. Let there be no misunderstanding of my meaning. I am not abusing the privilege of this chair by using 'controversial' as an epithet to be applied to political opinions which I do not happen to share. I see danger if the name of science, or the very cause of its freedom, should become involved as a battle cry in a campaign on behalf of any political system, whether its opponents would describe it as revolutionary or reactionary. If science were allowed thus to be used as a weapon of political pressure, it would be impossible to protect science itself eventually from the pressure of sectional politics. If that should happen the dangers are, I believe, beyond dispute—the danger, for example, that fundamental researches, having no immediately practical appeal, would be allowed to fall into arrears through relative neglect; or the danger that the rigid standards of true science would be relaxed, by allowing the convenience of results for policy or for propaganda to enter into the assessment of their validity as evidence.

The Royal Society, with its firm and unbroken tradition of complete aloofness from political controversy, may still find it an important part of its function to keep watch and, if necessary, to stand without compromise for the right and the duty of science to seek the truth for its own sake, in complete freedom from any kind of extraneous influence. I hope, indeed, that there will never be need thus to invoke our tradition, in order to protect the freedom and the integrity of science from the enthusiasm and the advocacy of any of its friends.

PHYSICAL CONCEPTS OF THE MESON THEORY OF THE ATOMIC NUCLEUS

By PROF. W. HEITLER

DUBLIN INSTITUTE FOR ADVANCED STUDIES

A SYMPOSIUM was recently held at the Dublin Institute for Advanced Studies, at which the present state of the meson theory was discussed. The present article discusses some of the views expressed, so far as they may be of interest for the general reader. Most of the views put forward in this article—if not generally known—have been discussed in recent years between Dr. H. Fröhlich and myself.

There is at the present time a veritable jungle of literature on the meson theory of the nucleus. Quite apart from the sometimes very extensive calculations, there exist at present two or three different meson theories—they differ essentially in the value attributed to the spin of the meson—and each is claimed to have great advantages. This in itself may be sufficient to stress the very preliminary character of the theory. The meson theory is entirely based upon the principles of quantum mechanics and of special relativity. Yet it could scarcely be expected that these principles will be sufficient to solve the problem of the elementary particles; something going far beyond relativistic quantum mechanics will be needed for this purpose. Nevertheless, the meson theory has already yielded a number of very valuable results and suggestions which can be considered as safe whatever the future development may be. We may perhaps compare the situation with that obtained by applying Lorentz's classical theory of the electron to an atom, treating the latter as a classical oscillator. The most striking feature, the existence of stationary states, cannot be understood in this way, but a number of other features, such as the absorption and scattering of light, can be understood quite well. Thus we must not expect that the present meson theory can be used to calculate exactly the binding energy of the deuteron, or that it can give any other quantitative results; but we can expect to obtain a large number of qualitative results and order of magnitude relations between the fundamental properties of the elementary particles. These properties turn out to be largely independent of the particular form we choose for the theory and can be explained by using general arguments only. (This does not mean that the development of the formalism is superfluous. It has indeed its merits—and very important ones—but a discussion of this lies outside the scope of the present article.)

The meson theory originated from an ingenious idea put forward by Yukawa in 1935. In order to describe the short-range forces prevailing between a proton and neutron, Yukawa introduced a new kind of field, φ, which was thought to be analogous to, but different in nature from, the electromagnetic field. The short range of these forces requires a modification of the field equations so that the static part of the field is now described by a modified 'Poisson' equation:

$$\nabla^2\varphi + \lambda^2\varphi = 0 \qquad (1)$$

with its singular solution, $\varphi = g\, e^{-\lambda r}/r$. The range of the forces is approximately $1/\lambda$. It is an *experimental* fact that $1/\lambda$ is of the same order of magnitude as the classical electron radius e^2/mc^2. g is a new universal constant with the dimensions of a charge. It determines the strength of the nuclear field. We derive its value below.

From (1) we can go over to a wave equation describing waves *in vacuo*:

$$\nabla^2\varphi - \frac{1}{c^2}\ddot{\varphi} + \lambda^2\varphi = 0. \qquad (2)$$

(2) can also be considered as a relativistic wave equation for a particle, but in contrast to the corresponding equation in Maxwell's theory, it describes the free motion of a particle with a *finite rest mass*, $\mu = \hbar/c\lambda$. Using the fact that $1/\lambda \doteqdot e^2/mc^2$ (m is electron mass), we obtain for the new mass the order of magnitude:

$$\frac{\mu}{m} \doteqdot \frac{\hbar c}{e^2} = 137 \qquad (3)$$

Moreover, it has long been concluded from the

saturation of the nuclear forces and other facts that the forces between a proton and neutron are connected with an *exchange of electric charge*. If this is taken literally, it must mean that the electric charge is not necessarily concentrated at the position of the proton but can also be found between the two particles. In other words, the nuclear field φ must itself carry electric charge. The free particles described by (2) are consequently *charged particles*, positive and negative, as will be seen below.

Three years after Yukawa had published these ideas, particles with these properties were discovered in cosmic radiation and named 'mesons'. The actual mass was found to be about $180m$, in good agreement with (3). Secondly, the cosmic ray mesons are charged (positive and negative). The agreement of these two facts with the prediction from purely nuclear considerations is so striking that there can be no doubt about the basic correctness of Yukawa's ideas.

Next we have to determine the value of the new universal constant g. For this purpose we use two more experimental facts: (i) The size a of the deuteron is little greater than the range of the forces $1/\lambda$. This is by no means trivial. The size of a hydrogen atom is the Bohr radius, whereas the range of the Coulomb forces is infinite. (ii) It is known that in the ground state of the deuteron the kinetic energy is almost equal to the potential energy, leaving only a small fraction of the potential energy for the binding energy. According to the uncertainty relation, the kinetic energy is

$$E_{kin.} \doteqdot \frac{\Delta p^2}{M} \doteqdot \frac{\hbar^2}{a^2 M} \doteqdot \frac{\hbar^2 \lambda^2}{M}.$$

The potential energy is approximately $E_{\text{pot.}} \doteqdot g^2\lambda$. Thus we find $g^2 \doteqdot \hbar^2\lambda/M$, or

$$\frac{\hbar c}{g^2} \doteqdot \frac{M}{\mu} \doteqdot 10. \qquad (4)$$

This gives a value for g of about 4 elementary charges e. The similarity of (4) and (3) is very striking. The two dimensionless universal constants $e^2/\hbar c$ and $g^2/\hbar c$ are both equal to the ratio of the masses of two elementary particles. Both relations are deduced from experimental facts, and so far we have no deeper insight into the meaning of these relations.

We have looked upon the field φ from two different aspects. On one hand, we have considered it as a field of force, and on the other hand, as a Schrödinger wave function for the meson as a particle. The two aspects are entirely equivalent. While the Maxwell field is primarily a field of force and can only be looked upon as a wave function for light quanta in special cases, and on the other hand the Schrödinger wave function of an electron never acts as a field of force, we can consider the meson field φ from whichever point of view is more convenient. Indeed, the production of the static field $ge^{-\lambda r}/r$ by a proton or neutron is often described in the particle picture as a "virtual emission and reabsorption" of a meson. This picture can often be used with advantage.

What is the precise meaning of this expression? We have already seen that the field φ carries an electric charge. If we would carry out an experiment to find the charge at a distance r, say, from the proton (or neutron), we shall, indeed, with a certain probability, find a charged particle at that point. (The charge can, of course, only appear in the form of a particle, that is, in an integral multiple of e.) The word emission in the above expression has thus a very literary meaning. On the other hand, such an emission of a particle with a rest mass μ would be contrary to the law of conservation of energy. While all other conservation laws (charge, momentum, angular momentum, spin, statistical) are fulfilled during this emission, the word 'virtual' means that, in contrast to a real emission, energy need not be conserved. If we therefore carry out an experiment to find the charge at a distance r from the proton, this experiment will only give a positive result if the necessary energy μc^2 is *supplied by the measuring process itself*.

This argument can be used to derive the extension of the nuclear field in a direct way without referring to a particular wave equation. The argument is due to Wick, but we give it here in a somewhat modified form. We measure the position of the meson at a distance r with an accuracy Δr of the order of magnitude of r itself. The particle will then have an average momentum $\Delta p = \hbar/r$. This is connected with an uncertainty of the energy

$$\Delta E \doteqdot \frac{\Delta p^2}{\mu} \text{ (if } \Delta p \text{ is not much larger than } \mu c).$$

ΔE is also the energy supplied by the measuring process. In order that the actual finding of the particle is not contradictory to the conservation of energy, ΔE must at least be equal to μc^2. Thus the experiment can only be successful if $\hbar^2/\mu r^2 \geq \mu c^2$ or

$$r \leq \hbar/\mu c. \qquad (5)$$

This expression gives the extension of the region in which the meson can be found, in other words, the extension of the nuclear field; and is identical with Yukawa's relation.

The next question is: How big is now the probability α of finding the meson outside at a distance r from the proton? Here the limitations of the theory become apparent. α depends, of course, on r, but it is clear that r must not be chosen too small. First of all, no meaning can be attached

to a dissociation where the meson is practically at the position of the proton, since this state is indistinguishable from the undissociated state. If r is smaller than $\hbar/Mc$, the measuring process supplies energies larger than Mc^2, and pairs of heavy particles can be created. The picture of a dissociated proton then fails completely. Even if we choose $r=\hbar/\mu c$, the concept of emission of a single meson fails, since then pairs of mesons can be created. To be on the safe side, we have therefore to restrict our concept to distances not much smaller than $1/\lambda$. But these are just the distances where the physical effects are of interest. Although for many problems the theory can actually be applied to much smaller distances, the simple concepts developed in this article break down in the very region in which they are of most interest. We cannot expect any quantitative results from them, but in the region of $\hbar/\mu c$ the results will be of qualitative significance.

To find the probability of dissociation, we calculate the total energy contained in the field outside $1/\lambda$ and divide it by the energy of the meson. It is safe to conclude from the analogy with the Maxwell field that the energy density is of the order of magnitude of $\text{grad}^2\varphi \doteqdot g^2\lambda^2$ at the distance $1/\lambda$. The volume of the region where the energy density has this value is of the order of magnitude of $1/\lambda^3$; thus the total energy is g^2/λ. The energy of the meson is $\sim \mu c^2$. The fraction of time spent in the dissociated state is therefore

$$\alpha = \frac{g^2}{\lambda\mu c^2} = \frac{g^2}{\hbar c} = \frac{1}{10}. \quad (6)$$

The nuclear particles have so far been considered as point- or mono-poles, being the sources for the field around them. Accordingly, the field was spherically symmetrical. There is, however, evidence that these are not the only sources of the meson field. It is known that the proton neutron force depends essentially upon the relative spin directions of these two particles. The difference between the singlet and triplet potentials of the deuteron is of the same order of magnitude as the potential itself. It must therefore be concluded that the spin of a heavy particle acts also as a source for a meson field, the latter being no longer spherically symmetrical but having a signified direction in the direction of the spin. The dependence on angle of this field is that of a wave function of a particle in a p-state. Thus we attribute to the spin of a proton or neutron a 'mesonic dipole' $\sigma f/\lambda$ (σ is the spin of the heavy particle), where f is another constant with the dimensions of a charge. At the distances of interest $(1/\lambda)$, this field has the same order of magnitude as the field of the mono-pole if the two constants g and f are of the same order of magnitude. This assumption can account for the spin dependence of the nuclear forces.

If we look upon the dipole field from the particle aspect, we can describe it in the following way: The proton is also capable of emitting virtually a meson with *angular momentum of one unit*, the angular momentum having the same direction as the spin of the proton before the dissociation. In order to satisfy the conservation of angular momentum, the spin direction of the heavy particle in the dissociated state must be the opposite one. The fraction of time spent in this kind of dissociation is also of the order of magnitude $\alpha = f^2/\hbar c \doteqdot g^2/\hbar c$.

Considerations of this kind lead to the qualitative explanation of another very important feature, namely, the anomalous magnetic moments of the proton and neutron. It is clear that a meson with angular momentum 1 has a magnetic moment larger by a factor M/μ than 1 Bohr nuclear magneton. This contributes to the magnetic moment of the proton an amount $\alpha\, M/\mu$ (in units of the nuclear magneton) which explains why the magnetic moments have such odd values. During the dissociation, the heavy particle is a neutron and has therefore no magnetic moment of its own. The heavy particle itself contributes therefore a magnetic moment $1-\alpha$. The total magnetic moment of the proton is therefore

$$m_P = 1 - \alpha + \alpha M/\mu. \quad (7)$$

Similarly, the magnetic moment of the neutron will be

$$m_N = -\alpha - \alpha M/\mu, \quad (8)$$

where regard has been taken of the fact that the neutron emits a negative meson with the opposite sign of magnetic moment, and that in the dissociated state the neutron has become a proton with opposite spin direction. (In (7) and (8) no account has been taken of the fact that a proton can dissociate into states where the meson has no angular momentum. It can easily be seen that this does not alter the result appreciably.)

Since both m_P and m_N are of the order of magnitude unity, we see that α must be of the order of magnitude of μ/M. But this is just the relation (4) derived from the binding energy and size of the deuteron, and gives further support for the assumption that this relation is not accidental. If we insert in (7) and (8) the observed values of $m_P = 2\cdot78$ and $m_N = -1\cdot93$, we have two equations for a new independent determination of α and M/μ. We find

$$\alpha = 0\cdot075 \quad \text{and} \quad M/\mu = 20,$$

in reasonable agreement with the values previously obtained for these universal constants.

The consistency of these results suggests that the

fundamental concepts of this theory are correct. We must not forget, however, that we have restricted our considerations to distances of the order of magnitude $1/\lambda$. Little can be said at present about the contributions of smaller distances. All we can say is that their contributions to the effects considered are at most of the same order of magnitude as those from greater distances. Our results are largely independent of the particular formalism chosen to describe the meson field, so long as it conforms with what we had to postulate. Many important details, however, do depend on the value chosen for the spin of the meson (0 or 1, or both); for example, the order of the levels in the deuteron, and the behaviour of the meson during collisions with other particles and light quanta. In some cases more or less serious difficulties arise if the theory is applied to distances smaller than $1/\lambda$. In this respect no definite decision has been reached yet, and we must expect further information from future developments.

Finally, we must also mention the β-decay of the meson. This was originally a second idea of Yukawa's, quite independent of his theory of the nucleus. It was assumed that the meson can decay directly into an electron and a neutrino. The decay of the meson has since been confrmed experimentally. The great advantage of this hypothesis is that it reduces the β-decay to a much simpler form. Whereas a nucleus decays emitting the electron into a continuous range of energy, the electron emitted by a free meson can only have the energy $\mu c^2/2$ (leaving the other half for the neutrino). The β-decay of a nucleus then takes place by means of an intermediate emission of a meson but the fundamental process underlying the β-decay of a nucleus is the decay of the meson. It is clear that a detailed study of the meson decay will give us very valuable information about the most important problem of the existence of the neutrino. A detailed discussion, however, lies outside the scope of this article.

BIOLOGICAL ACTION OF VITAMINS

By Dr. Elizabeth M. Koch

University of Chicago

SOME of the outstanding developments in vitamin research reported in the symposium on the "Biological Action of Vitamins", held at the University of Chicago as part of its fiftieth anniversary celebration during September 15–17, were:

(1) The further clarification of the functions of diphosphothiamin in carbohydrate metabolism by Mr. Severo Achoa, of Washington University, in St. Louis; (2) The separation of a new B vitamin, folic acid, a yeast growth stimulant announced by Mr. Roger J. Williams, of the University of Texas; (3) The proof of the identity of biotin, vitamin H, and co-enzyme R, presented by Mr. Vincent du Vigneaud of Cornell Medical College, New York City; (4) The isolation from egg white of avidin, a substance which combines with and thus inactivates biotin, also reported by Mr. Roger J. Williams; (5) The description of a new choline deficiency effect in young rats characterized by hæmorrhagic degeneration of the kidneys, described by Mr. Wendell H. Griffith, of St. Louis University, in St. Louis; (6) The description of the symptoms of human ariboflavinosis by Dr. W. H. Sebrell, of the United States Public Health Service; (7) The extension of vitamin therapy in human nutritional diseases, reported by Dr. Norman Joliffe, of New York University, by Dr. David L. Smith, of Duke University, and by Dr. Tom Spies, of the University of Cincinnati; (8) The use of vitamin K to prevent bleeding in patients having a low prothrombin content in the blood, reported by Drs. Harry P. Smith and Emory D. Warner, of the University of Iowa.

Mr. Achoa, in his discussion of the functions of diphosphothiamin, pointed out that through its effect on the oxidation of pyruvic acid, diphosphothiamin may be expected to influence various phases of carbohydrate metabolism. This is true because of the fact that pyruvate oxidation causes the storage of a considerable amount of energy in the form of adenosine triphosphate. We may expect diphosphothiamin to be indirectly involved in the synthesis of glycogen from glucose and in the conversion of fructose to glucose, since these reactions are driven by the mobilization of the phosphate bond energy in adenosine triphosphate.

Mr. Achoa also suggested the possibility that diphosphothiamin may aid in the absorption of sugar from the intestines and in resorbing glucose in the kidney tubules. It also may be involved in the process of forming carbohydrate molecules from lactic acid or from pyruvic acid. This vitamin complex likewise hastens production by the body of acetylcholine, an agent involved in the neuromuscular mechanism.

Folic acid, so named because it is most abundant

in leaves, was discovered as an important factor in yeast nutrition. Its isolation was accomplished this year by Mr. Roger J. Williams and his co-workers, who report its presence in all animal tissues examined, as well as in leaves. The implication that it is involved in animal nutrition is obvious, although nothing is known as yet of its function in the higher organisms.

Mr. Williams also discussed the various bio-assay methods, using yeasts and bacteria which have been developed by his group for the quantitative estimation of the eight water-soluble B vitamins discovered to date: thiamin, riboflavin, nicotinic acid, pyridoxin, pantothenic acid, biotin, inositol and folic acid. These methods have proved highly satisfactory with respect to ease of manipulation and reproducibility of results.

Mr. Vincent du Vigneaud described the story of the steps by which three lines of research on vitamin H, the anti-egg-white injury factor, on biotin, one of the factors essential for yeast growth, and on co-enzyme R, which functions in the growth and respiration of many strains of legume nodule organisms—the Rhizobia—have converged to show that the three activities reside in one single substance.

In 1936 Kögl and Tönnis announced crystalline biotin. In 1939, West and Wilson suggested that biotin and co-enzyme R are probably identical. In 1940, György, Rose, Hofmann, Melville and du Vigneaud noted the similarity of the properties of vitamin H with those of co-enzyme R and biotin. They found that their vitamin H concentrates had parallel activity for the other two factors. A biotin methyl ester preparation contributed by Kögl had high vitamin H unitage. The du Vigneaud group then prepared biotin methyl ester from a vitamin H liver concentrate, and using this preparation confirmed the identity of biotin, co-enzyme R and vitamin H. Their product had a melting-point of 166°–167°, which is 18° higher than that reported by Kögl for his preparation. No explanation for this difference in melting-point has been found.

The structural formula of biotin has not been completely solved. It is probably a cyclic urea derivative with the composition $C_{10}H_{16}O_3N_2S$. By the action of barium hydroxide at 140° it forms a diaminocarboxylic acid, $C_9H_{18}O_3N_2S$. Biotin has been resynthesized from this diaminocarboxylic acid by treatment with phosgene.

Of interest in its relation to biotin was the reported isolation by Mr. R. J. Williams and his group of avidin from egg white. This is the substance which combines with and inactivates biotin, thus producing the so-called egg-white injury which develops when raw egg white is fed to rats and chicks.

The effect of choline deficiency on young rats was described by Mr. W. H. Griffith. Young rats on a low choline, low fat and low cholesterol diet exhibit an extremely toxic effect in which there is a marked hæmorrhagic enlargement and degeneration of the kidneys, a regression of the thymus and an enlargement of the spleen. The degeneration of the kidney particularly is very rapid, and may cause death in a ten-day period. The deficiency is prevented by amounts of choline too small to influence the deposition of liver fat. Supplements of cystine, fat or cholesterol increase the severity of the lesions; choline, menthionine and betaine neutralize their toxic effects. Since cystine, fat and cholesterol also increase the amount of fat in the livers of older rats, it appears that the hæmorrhagic degeneration and fatty livers are different manifestations of the same deficiency. The work of du Vigneaud and his co-workers proving that choline is involved in transfer of methyl groups indicates that the symptoms described are evidences of methyl deficiency. Griffith and his associates found that a creatine supplement lessens the severity of the lesions, but does not entirely prevent them. He suggested that while the methyl group of creatine is not available for choline synthesis, it may exercise a sparing action by making available for choline synthesis the methyl groups which would otherwise be used in the formation in the body of creatine.

As each vitamin has been made available in crystalline form, clinicians have studied its effect in the treatment of human subjects who present symptoms similar to those shown by animals that have been maintained on diets deficient in that specific vitamin. Dr. Joliffe discussed the use of thiamin for many types of polyneuritis frequently associated with alcoholism, pregnancy, gastro-intestinal disturbances and pellagra, as well as for cardiovascular disturbances, œdema, anorexia, and many other symptoms which may be manifestations of a sub-acute deficiency. He emphasized the importance of finding a means to detect early and mild vitamin deficiencies.

The history of pellagra and the final discovery that nicotinic acid is a specific for its cure long after this vitamin had been isolated, found ineffective in curing beriberi, and discarded as of no nutritional value, was related by Dr. David T. Smith. He described in detail the symptoms of nicotinic acid deficiency and the methods of treatment.

One of the most striking clinical developments in the vitamin field during the past two years has been the recognition of riboflavin deficiency symptoms. These were described by Dr. Sebrell. Dr. Sebrell and his co-workers placed eighteen adult women on a riboflavin-deficient diet. The first symptom

observed was a pallor of the mucosa in the angles of the lip. A few days later superficial fissures developed exactly in the angle of the mouth. These lesions were covered with a honey-coloured crust which could be scraped off without causing bleeding. The lips became abnormally red and shiny, and the tongue a purplish red. In addition, a fine scaly desquamation appeared about the nose and ears. The ocular lesions were equally marked. The cornea appeared inflamed, due to its invasion by capillaries. This condition was followed by corneal opacity. Patients complained of itching and burning of the eyes, a hyper-sensitivity to light, and eye fatigue.

These symptoms comprise the clinical picture known as ariboflavinosis. Dr. Sebrell has found it very prevalent among people who are not economically restricted to a poor diet. In fact, he stated, without the inclusion of liberal amounts of milk, liver and eggs, it is difficult to select a diet adequate in riboflavin.

In the case of human subjects, clinical experience has demonstrated that vitamin deficiencies are usually mixed, rather than simple, and that the administration of all the vitamins together produces more rapid and complete cures than does treatment with any single vitamin. This phase of vitamin therapy was emphasized by Dr. Tom Spies. He reported a study of "twenty-five malnourished patients with mild pellagra, beriberi or riboflavin deficiency who were becoming worse in spite of bed rest and were refusing the diet offered them. They were given a mixture of brewers' yeast powder (25 per cent), peanut butter (67 per cent) and peanut oil (8 per cent). All except two patients ate it twice a day, and all of them improved gradually." Because such a mixture is a rich source of the natural vitamins of the B complex, as well as of protein, fat, carbohydrate and mineral salts, he suggested the popularization of a sandwich of whole wheat or high vitamin bread, combined with this peanut butter – dried yeast spread as a most effective preventive or therapeutic measure.

The efficacy of vitamin K in preventing bleeding in patients with a low prothrombin concentration in the blood was reported by Drs. Harry Smith and Emory D. Warner. Hæmorrhages due to failure of the blood to clot occur in both mother and child at child-birth, in obstructive jaundice, in chronic intestinal disorders and in bile duct tumours. This failure to clot is due to the inability of the body to produce enough prothrombin. Vitamin K is an essential factor in the production of prothrombin. It is effective administered orally.

Drs. Smith and Warner recommended the inclusion of green vegetables, especially spinach, kale and tomatoes, in the diets of mothers during the last month of pregnancy, and the feeding of cow's milk to infants during the first three days of life to provide the necessary vitamin K during this critical period.

The most recently separated vitamins, pyridoxin and pantothenic acid, are already being studied clinically. Although a pyridoxin deficiency has not been described as a definite entity, the vitamin is believed to function in muscle metabolism. It was reported to cause improvement in patients having muscular weakness or suffering from Parkinson's disease. Here, again, administration with or after thiamin and nicotinic acid produces better results than when pyridoxin is given alone.

Pantothenic acid has been found in human blood. Dr. Edgar S. Gordon, of the University of Wisconsin, stated that very little is known as yet of its possible functions or of its clinical value. Spies and his co-workers found that the injection of pantothenic acid was followed by a rise in the riboflavin content of the blood. He believes that this vitamin is also essential in human nutrition, and that it is associated in its action with riboflavin.

LABOUR CONDITIONS IN WEST AFRICA

By F. W. H. Migeod

FOR countless centuries Africa had supplied labour to Eastern countries. When the American continent was discovered, an immediate demand arose for African labour for its plantations and industries. Eventually the slave trade came to an end, and Africa turned to developing the export of its own products, chiefly forestal. Progress after the change-over was slow at first. At the opening of the present century, however, mining was already well established, and plantations were started to extend the growth of economic products and secure a higher standard of quality. There ensued an increasing demand for paid labour. Nevertheless, in West Africa, the collection and preparation of forest products was still carried on by the natives in their own villages, as it still is. They traded their loads at the nearest store, or the one that offered best terms, and what they received for it was shared out between the members of the family concerned.

Labour in tropical Africa implies rather a different thing from what is understood by 'labour' in Great Britain at the present day. The native tribal organization has usually consisted of a ruling class with the rest of the population slaves, or at least dependants. Merging with the ruling class was general; and another stratum of slave population might be added below as the result of a successful war. Agriculture, the principal industry, was therefore based on slavery. On slave labour the tribe supported itself, and had a small balance of material or, in default, human goods to export. Some tribes kept no slaves; they were cannibals. Some remote hill tribes or swamp tribes may also be exceptions.

When, therefore, the European colonies or protectorates became established, the Government readily obtained the labour it required by calling on the chiefs to furnish so many men for some definite work such as building stations, making roads, railway construction, etc. The labourers would be paid if the work were beyond the chief's confines; within his own country he was responsible for it, and a money gift would usually be made to him in compensation. The Government was only concerned with the labour supplied being kept up to the number specified. Welfare conditions scarcely entered in. The labour largely looked after itself. As a result, however, of the opening up of the country to private enterprise, apart from trading, new conditions had to be met.

This is the background which it is useful to bear in mind when reading the able and valuable report by Major G. St. J. Orde Browne, labour adviser to the Secretary of State for the Colonies, presented to Parliament in May of this year*. Each of the West African Colonies, Nigeria (with British Cameroons), Gold Coast, Sierra Leone and Gambia is studied separately, and roughly the first quarter of the pamphlet contains a summary of observations and recommendations. Major Orde Browne has had long labour experience in East Africa, and in his five months in West Africa in the dry season of 1939–40 he was able by means of extensive and rapid travel to probe into labour conditions in all these colonies.

The welfare of the labourer was his first consideration. The number of instances in which he could find nothing to recommend is testimony to the generally satisfactory labour position of West Africa. It is mostly in the big Europeanized towns where improvements are called for.

It has already been said that labour questions in Africa, and more particularly in West Africa, cannot be treated in the same way as in Great Britain. The great majority of the natives are attached to the soil. This means that everyone has a home to return to whether he be of free or servile origin. He can come out periodically to work for hire, and when he has earned what he considers enough to go back home with, he departs and resumes his agricultural life. He is free so far as his wage-earning is concerned to take it up or not, just as he pleases. Where this general statement does not apply is in the large towns, where a mixed population has collected which has lost touch with home life, and either cannot, on account of distance, or for some other reason does not desire to, return to the place of their birth. Perhaps it is because he is a seasonal worker that he does not like being interfered with even for his own good, a fact Major Orde Browne refers to more than once. He has come to gain money, and will put up with inconveniences to do so. The local abundance of food is a major factor in the choice of his place of work. Often food weighs more in this choice than the actual wages paid.

This report discusses food problems very fully. The view has grown up in recent years in Great Britain that the African is generally undernourished. He used not to be. If undernourishment does exist at all widely, it is a result of economic development of the country, food-growing being subordinated to the production of sale crops or of mechanized industry. Without going deeper into the matter, it may be observed that large markets, such as are especially common in Nigeria, go a long way towards stimulating the growth and equally important distribution of food.

The migratory type of labour, that is the seasonal workers, have in some cases long distances to travel. Usually, however, they know exactly where they intend or hope to work, and travel in parties, some members of which have been over the ground before. There are, of course, cases in which some of the party fall out by the way, and one rather gets the impression from this report of large numbers of would-be labourers arriving at their journey's end worn out with the march and suffering from exhaustion from want of food. Such cases may occur. In any event, rest camps set up by the Government on the main routes are a great boon to the travellers. The mere walk of a few hundred miles is nothing very serious of itself. One has done it oneself. They are not entirely without ideas of food-provision for the journey; and food will be supplemented with saleable goods. In many cases the women go too.

Housing is a subject the migratory labourer is not too greatly concerned with. So long as he has somewhere to spread his mat, and the householder will look after his few personal belongings, he is satisfied. Except when actually asleep the house

* Labour Conditions in West Africa. Report by Major G. St. J. Orde Browne. (Cmd. 6277.) Pp. 149. (London: H.M. Stationery Office, 1941.) 2s. 6d. net.

is scarcely wanted. He especially does not like a draught, having few clothes on indoors; and so concrete houses with tin roofs do not meet with his approval. The hygienic house is not necessarily the most comfortable. However, judging by this report, living conditions in general are good on all the old-established plantations, and are equally so on the mines. Where overcrowding and bad living conditions do apply is in the towns or in the villages surrounding an industrial area; and it is with this very difficult problem that the Medical and Sanitary Department has to cope. Here, too, police problems are equally acute.

All the difficulties, however, in connexion with the labourers who come and do eventually go home, are small compared with the problems of those who do not go, either from illness or some other cause. Only too many of them unable to do regular work turn to crime. They spend their money as they receive it, and when that has become an acquired habit they will in fact never return home. There are many such. They form the body of floating labour, and it is mainly on their account that such reports as Major Orde Browne's are written.

Skilled labour figures equally largely in this report. Such labour is a product of education in some form or other. That may be either apprenticeship in the workshop, or a course of training in Government technical schools. Both systems have their values, and it is debatable whether the youth who has, say, had his training in railway workshops with a certain amount of rough-and-ready treatment, is not better equipped than one who has led a very different life in a residential college, with amenities that render him less willing to undertake any sort of work. Urbanization is, of course, a necessary preliminary to the raising of a large body of skilled artisans, and those persons necessarily become detribalized and merge into the permanent population of the large towns. The report stresses the need for more and still more technical training; and the future of the colonies would seem to lie in a good supply of all sorts of technicians being turned out.

The early trend of education was the production of clerks. Every bright youth at school wanted, and still wants, to become a clerk and wear good European clothes and not do manual work. So associated is manual labour with inferiority of social status (and not in Africa alone), and indeed with old slavery memories, that no native considered he had improved his position unless he adopted the clerical or teaching or some similar profession.

All efforts of the Government to restrict the output of persons trained as clerks have been very largely neutralized by this ambition. When clerkships are, even in their lower grades, better paid than skilled mechanics in their higher grades, and really large salaries can still further be obtained either in the Government service or in trade or the professions, it is not surprising that the youth of the country desires training for the most lucrative work; and their parents share these views. Girls qualify to be telephone operators, shop assistants, etc., but only to a small extent, as the vast body of African opinion still considers the place of the woman is in the home.

For the welfare of labour, Major Orde Browne makes many valuable suggestions, as would only be expected from a man of his experience and qualifications. There is one qualification, however, which one is not sure that he has. One doubts if Major Orde Browne has ever handled labour personally; whether he has ever had to get his labour together for some enterprise, to work it to the utmost, and yet keep it and maintain his employment at such a level of attractiveness that he is never short; also whether he has personally experienced all those repetitions of exasperation and anxiety that success in keeping his own end up implies. The trend of colonial legislation has been to reduce penalties on delinquent labour and increase them for employers; but Major Orde Browne does point out that the latter have in cases been overdone. Unless there are would-be employers with capital entering a colony, there can be no wage-earning; and because a labourer has innocence on his face it does not follow there is innocence in his heart. Trade unionism has been imposed on the colonies from Great Britain. It applies less to the seasonal worker than to the urbanized population. Since, however, in all towns natives of different tribes normally congregate together, and have a titular chief of their own tribe to watch over their interests, the necessity for trade unionism, if any exist, is limited to detribalized natives. In some pages of this report it seems as if there are two persons speaking. One is Major Orde Browne, the experienced African official; the other is someone else who has adapted himself to trade unionism and British labour ideals.

Of the numerous recommendations made, many are expensive. The report was made on conditions prevailing in the earlier period of the War. With the subsequent cessation or limitation of external trade in West Africa, it may be doubted if any more than a small proportion of the recommendations can be put into force. Indeed the necessity for many of them may have lapsed. The best thing the native can do now would seem to be to revert to his former life on his farm and, growing enough food for his family, await a time when industrial and trading activities can be profitable.

NEWS AND VIEWS

Royal Society Personal Records

THE portion of Sir Henry Dale's presidential address to the Royal Society delivered on December 1 which was of wider appeal is printed on pp. 678–80. Another section of the address, at the moment mainly of domestic interest to the fellows, dealt with a scheme which Sir Henry, with the Council's approval, has just introduced, for compiling a contemporary record of the fellows and their activities. The object is to provide the Royal Society with a complete set of personal records of all the fellows from now onwards, with annual additions to keep them up to date. So far as the more senior of the fellows are concerned, many of them, as Sir Henry pointed out, can look back over a period in which the change and expansion of scientific knowledge have been so rapid and so revolutionary that their memories of those days must be of vital interest for the history of science. The biographies of outstanding men of science provide valuable material in the form of impressions and memories of their previous generation, but such sources are relatively few in number. Sir Henry referred in particular to men like Sir J. J. Thomson and Sir Oliver Lodge, whose activities brought them into contact with many outstanding figures, and mentioned the interest—and indeed the value for posterity—of contemporary accounts which might well have been kept by fellows of the Society of their association and discussions with such outstanding figures as Claude Bernard, Louis Pasteur, Robert Koch, Carl Ludwig and others of the latter half of the nineteenth century. The proposed personal record of fellows of the Royal Society will, in Sir Henry's words, "provide a fair picture of the main currents, at least, of scientific progress in this country", which will be invaluable to the future historian who may be called upon to show the general character of this scientific age.

Martyrdom of Polish Men of Science

ON November 26 a meeting unparalleled in the history of science was held at the Royal Institution, where, in the presence of the Presidents of Poland and Czechoslovakia and General Petit (representing General de Gaulle), representatives of scientific institutions and associations from Great Britain and men of science and letters of many nations met to pay homage to the memory of the Polish professors and lecturers who had died as the result of German barbarism, and to register their protest against this crime on science and culture. Sir David Ross, vice-chancellor of the University of Oxford, who presided over the meeting, stated that the Germans are endeavouring to convert Poland into a vassal country by depriving her of her leaders, and that their brutalities fall mostly on academic life. November, 1941, is the second anniversary of the beginning of their many atrocities against science and learning, when the whole of the professorial and lecturing staff of the Jagellonian University in Cracow, the oldest in eastern Europe, was arrested and imprisoned for no other crime than that of being Poles. He described their tortures and humiliations and concluded by saying that the action of the Germans has had the opposite effect to that desired, and the suffering professors have become a symbol of martyred Poland. Dr. Gilbert Murray said that when war breaks out the first casualty is truth, but never has the lie been organized as it now is in Germany.

Prof. Antoni Jurasz, dean of the Polish Medical School in Edinburgh, spoke with an eloquence and fire which in itself was symbolic of the unconquerable spirit of his country. He described the crushing of academic life in Poland, the suppression of all learning, the pillaging of the Universities of Cracow, Warsaw, Lublin, Lwow and Vilno and the destruction of libraries and manuscripts. He spoke of many of those who have met their death, names as well known in other parts of the world as in their own country: professors of philosophy, anatomy, physiology, mechanics, literature, zoology, engineering, biology, physics, chemistry, and many others. The international character of the present meeting testified that all are united to fight the forces of darkness and that on the graves of these fine men and on the ruins of their work will be built up a new world. Prof. René Cassin, member of the "Université de France", who spoke on behalf of the Free French and also on behalf of all Frenchmen who have been reduced to silence by the invader, expressed his horror of the crimes perpetrated on intellectuals in Poland, mentioning the death of students in France who have protested against the aggressor. M. Juraj Slavik, Minister of the Interior, and Prof. Klecanda spoke on behalf of Czechoslovakia and stressed the close association between Poland and their country. Prof. Stefan Glaser, chairman, replied on behalf of the Association of Polish University Professors and Lecturers in Great Britain.

British Chemists and the U.S.S.R.

THE Chemical Society has recently sent the following message of greeting to the All Soviet Union Chemical Society. "We, the President, Council and Fellows of the Chemical Society, send greetings to you, our Colleagues in the All Soviet Union Chemical Society. We express our unbounded admiration for your Country's courage and heroic fight against the power and might of the common foe, and our deep sympathy in the suffering and cruelties inflicted on your people by the invader. Our two Countries stand together in this struggle, and we are confident that, with the united efforts of all those who realise the abyss to which Hitlerism is leading, tyranny will be overthrown and peace and justice prevail. It is our earnest hope that out of this strife and sacrifice will emerge a new order in which the prostitution of Science to the destruction of mankind will cease and men and women engaged throughout the World in the pursuit of Science will work together in amity for the benefit of the human race."

Biology and Health

At the twenty-sixth annual general meeting of the British Social Hygiene Council, the president, Sir Walter Langdon-Brown, took for his subject the relation between biology and health. This address has been printed in the current issue of the organ of the above Society, *Health and Empire*. As an introduction he described the attempts that have been made by certain countries to degrade all the standards of learning and to stultify the search for scientific truth. Quoting from this year's report of the Rockefeller Foundation, Sir Walter explained how, all over Europe, the activities of the Rockefeller Foundation have been brought to a standstill. "The conception of knowledge as an international responsibility has vanished . . . as German forces have moved from one country into another a definite pattern has been followed." Where this was resisted, faculties were sent to concentration camps and student demonstrations were broken up with machine-guns and tanks. The rest of this story is too familiar to need reiteration. In 1932, *Pflugers Archivs*, the outstanding publication for seventy years in physiological and biological research, ran to five volumes. In 1938 it appeared as one slim volume. The *Münchener Medizinische Wochenschrift*, formerly one of the leading weekly medical journals in the world, has now become the happy hunting ground of cranks and naturopaths who hope to catch the Führer's eye. Yet the lamp of learning will never be extinguished, and Sir Walter went on to deal with particular examples of the way in which biology has made for improved conditions of health. The well-known work of the Rockefeller Foundation in controlling the spread of *Anopheles gambiæ* after its introduction to Brazil from Africa in 1930, and its almost complete —if not complete—eradication by 1940 was one of the more important examples that were considered.

Later, Sir Walter described the steps that will have to be taken to combat the ravages of venereal diseases. Although the causal organisms of these diseases have been known for many years, there is still in existence the 'hush-hush' policy which refuses to admit the cleansing light of understanding. The traditional opposition of the Victorians to any mention of sex matters in polite circles initiated a conspiracy of silence which is long a-dying. But this silence is being confronted by freer and franker discussion of sex matters among all classes. In this connexion the introduction of biological subjects with its objective approach to the study of reproductive physiology, in many schools and colleges, has played a noticeable part. The three main planks in the platform of the British Social Hygiene Council were outlined as follows: (1) The study of biology as a subject of general education; (2) the education of the educator; (3) general enlightenment on the principles of social hygiene. The remainder of the address was devoted to an amplification of these three problems and an account of the manner in which the British Social Hygiene Council is trying to grapple with them. A most heartening feature of the address was the statement that there has been no sensational rise in the incidence of venereal diseases in this War as there was in the last.

The University of Liverpool

The annual meeting of the Court of the University of Liverpool was held on November 27, the Chancellor (the Earl of Derby) presiding. Lord Derby paid a high tribute to the work of the University throughout a difficult year in which the University buildings suffered considerably by enemy action. He recorded with pleasure, however, that the loss of life was fortunately slight, and that despite all difficulties, study has been maintained on a high standard. Sixty-five members of the teaching staff are now serving with the Forces or in Government Departments; the Senior Training Corps is strong; and the Air Squadron has grown considerably. The work of the Women's Training Corps has prospered, and the basic training in social service is well advanced. Thanks to the generosity and friendship of the City Council, the University is now receiving an annual grant which has reached the total of £25,000. By the generosity of Messrs. J. Bibby and Sons, the University has now been able to establish in Wirral a Veterinary Field Station under Prof. J. G. Wright.

The coming retirement of Prof. E. W. Marchant from the chair of electrical engineering was announced at the meeting. Mr. R. H. Armstrong, pro-chancellor, detailed the progress of the regionalization of the voluntary municipal hospitals, in which the University should become a focal point. He paid tribute to the research work of the University, affirming that through it, the national effort has received and would continue to receive a handsome dividend. His analysis of income and expenditure showed that the University finances are sound and that war conditions have imposed no undue burden upon student finances. The vice-chancellor (Dr. A. D. McNair) submitted his annual report, in which he emphasized the expansion of the Senior Training Corps and the part played by women students in national service. All women students were now required to engage in part-time national service.

British Standards Institution

The British Standards Institution announces that, in view of the continuing expansion of the work of the Institution and the development of its relations with the Government Departments and with standardizing authorities overseas, the General Council has appointed an Executive Committee under a permanent chairman. The Executive Committee will keep all the activities of the Institution under review and report to the General Council from time to time as may be necessary. Mr. C. le Maistre, who has been connected with the movement almost since its initiation, and who for the past twenty-five years has been its chief executive officer, has been appointed full-time chairman of the Executive Committee, and Mr. P. Good, for several years deputy director and recently joint-director, has been appointed director and secretary of the Institution.

Bracken-infested Land for Potato Cultivation

BRACKEN-INFESTED land can be made very suitable to potato growing provided the proper methods of cultivation are used. Such land is normally light and would be easy to work if it were not for the formidable amount of roots and surface trash that must first be cleared. Trials (described by I. F. Trant, *J. Min. Agric.*, 48, 109; 1941) have been carried out on three areas near Welshpool to determine the best methods for preparing this type of land for a potato crop, and much valuable information has been obtained. Autumn ploughing followed by spring cultivation and immediate planting proved to be expensive and unsatisfactory, as the bracken roots prevented the proper working of the land. Gyro-tilling in the spring after the ground had been 'pre-disked' killed off the bracken quite well, but it also was expensive and did not succeed in clearing the trash. A third method, however, though slower than the other two, gave most promising results and at considerably reduced cost. In this case the bracken was ploughed during June and July when it had attained its maximum growth and its reserve of food in the underground portions was at a minimum, a special device for burying the tall fronds being employed. The land was then worked and sown to rape, which was fed off to sheep during the autumn, thereby consolidating and manuring the ground. In the following spring, disk harrows and cultivators produced an excellent tilth, ploughing being omitted as it was likely to bring to the surface rubbish that was best left buried. Potato planting could then be satisfactorily carried out.

Electric Railways in the U.S.S.R.

IN the second of a series on "Transport in the Soviet Union", *Modern Transport* reviews the progress of railway electrification in Russia. It is stated that there were no electric railways in Imperial Russia. The Soviet began the electrification of the suburban lines in the Baku area in 1926 on the D.C. system at 1,200 v. with overhead conductors. In 1929, the 1,500 v. D.C. system was adopted with the inauguration of electric working in the Moscow suburban area, where up to 1926 electric traction was introduced on 112 route miles. In the Leningrad district, 44 miles of route underwent conversion during 1933–34. According to the *Electrical Review* of October 31, on these and certain other local lines in the Caucasus multiple unit passenger trains are employed. In 1932 a start was made with the electrification of certain main lines in mountainous and industrial areas, using the 3,000 v. D.C. system with heavy locomotives of three principal types for passenger, mixed traffic and freight trains. By 1939, electrified main lines comprised 828 route miles with an all-track mileage of 1,100 situated in the Caucasus, Ural, Donbass and Kussbass areas, and also on certain sections of the Murmansk line. Quite apart from the electrified suburban system in Moscow is the underground railway known as the Metro, which ranks not only as one of the newest, but also as one of the most lavishly carried out schemes of city transport in the world. It was authorized in 1931, and work began in 1932. By 1937 the Metro had 16·45 miles of route, and expansion was continuing.

Recent Earthquakes

ON the evening of November 25 an earthquake caused some apprehension in Lisbon and the surrounding country, though little material damage appears to have been done. Details of recordings from seismographic observatories are awaited before the exact epicentre can be determined. Several of these observatories report very large amplitudes. Fordham University (New York) reports the largest amplitudes since 1910; at Mr. J. J. Shaw's observatory at West Bromwich the recording levers were thrown out of their sockets; at Stonyhurst College Observatory the limits of registration exceeded the width of the paper; the shock was recorded at Kew and Oxford, though, according to Miss E. F. Bellamy, the amplitudes were not so great at the latter place.

On November 28 an earthquake of considerable severity was reported from Peshawar, Rawalpindi and Srinagar. No damage or casualties have been reported. Earthquakes in this district have not been uncommon in recent years and have been regularly reported by voluntary observers to J. M. Sil, representing the India Meteorological Department at Poona.

Announcements

AT the suggestion of Dr. G. Jedlewski, medical adviser to the Polish President, a special medical board has been formed in London to prepare plans for fighting epidemics which may break out in Poland at the end of the War.

A DIETETIC council has been set up in Ireland with Dr. P. T. O'Farrell to experiment on ways and means of aiding the people's nutrition under war-time conditions, paying special attention to the children's diet.

WE regret to announce the following deaths:

Dr. H. Eltringham, F.R.S., the well-known entomologist, president of the Royal Entomological Society during 1931–32, on November 26, aged sixty-eight.

Dr. Walcot Gibson, F.R.S., formerly director for Scotland, H.M. Geological Survey of Great Britain, on November 28, aged seventy-seven.

Dr. F. Stang, rector of the University of Oslo during 1921–27, president of the Nobel Committee of the Storting, who did much pioneer work in comparative research in human culture, aged seventy-four.

ERRATA. "Rigidity and Moisture Hysteresis in Gels", by W. W. Barkas, NATURE, November 22, p. 629. The following corrections should have been made in the MS.: (*a*) in equation (1), the upper limits of the integrals should read p and h_0 respectively; (*b*) in equation (2), the upper limits should read p_{k_0}, p_{n_0} and h_0 respectively; (*c*) seven lines below equation (1), for V read v.

Colour Measurement

As was recently noted in NATURE[1], an increasingly high degree of accuracy in the specification of colour in terms of C.I.E. units is now being sought as a result of the growing realization of the indefiniteness of the colour discrimination limen and the low values it can assume in quite ordinary conditions. One would normally regard such circumstances as indicating in any physical quantity to be measured an ultimate need for correspondingly higher absolute accuracy, but it should not be overlooked in this case that higher discrimination is really called for in a quantity different from the one already standardized for use in colorimetry. The latter quantity, which is defined by the C.I.E. (1931) resolutions and data and will be denoted generally below by $\chi_{\text{C.I.E.}}$, refers to (*a*) a normal observer and (*b*) normal observing conditions, including particularly (*c*) a field of direct observation of 2° to which observations were necessarily intended to be restricted in order that they should apply to a region of uniform retinal structure and thereby have analytical significance.

The present position in colorimetry is due mainly to a growing recognition of the practical effect of varying sub-condition (*c*) by increasing the field size, which results in increasingly higher powers of colour discrimination. If we imagine the so-increased retinal field to be subdivided into smaller fields, we may reasonably assume that the same *form* of colorimetric analysis would apply for each, but the exact analysis for each and the method of reconstituting without loss the 'colour' as perceived, in a synthesized physical expression of it, remain subjects for future investigation. Certain it is, however, that this reconstituted colour would provide us with a new physical concept determined by a new quantity, χ_N say.

It is in the magnitude of this quantity that the higher precision is now really required. The individual quantities from which χ_N would be synthesized, considered in terms of any acceptable common units, might, of course, differ appreciably from one another in a yet unknown way, so that the problem of exact specification of colour as such, under the new varying sets of conditions, and to the higher accuracy called for, still awaits a final solution, which prevailing circumstances may postpone. If to some the need is urgent, one may—although without much justification—adopt as an expedient a procedure which, in fact, represents present practice, namely, identify conventionally, but nevertheless falsely, the colour magnitude $\chi_{\text{C.I.E.}}$ with χ_N, and ask of $\chi_{\text{C.I.E.}}$ the accuracy actually desired in χ_N.

True it is that, providing suitable standards exist and ageing effects therein can be controlled to the necessary accuracy, the light, the colour of which may be in question, might be spectrophotometered to an accuracy corresponding in itself to the accuracy of colour discrimination sought; but as will be clear from the foregoing, this does not satisfy the conditions of the problem except as an expedient. Some further important questions have, moreover, to be considered in this connexion, and it will be seen that, to the accuracy here in question, this procedure is only ultimately valid as a method of relative differentiation of colour magnitudes. For, first, we must notice that the C.I.E. data serving to define $\chi_{\text{C.I.E.}}$ were obtained from observations made upon a 2° field. It is, therefore, no criticism of these data to say that, considered in relation to the higher accuracy now being sought, residual errors of importance may be present therein. The reduction and tabulation of the original observations as so obtained cannot therefore be regarded as affording data of ultimate accuracy. Consequently, abnormal accuracy is not *a priori* justified at present in determinations of $\chi_{\text{C.I.E.}}$ as such. What signification can we attach to a quantity so perverted from its true nature as is $\chi_{\text{C.I.E.}}$ as currently adapted to new conditions in the above way? Clearly the actual sense in which it can be employed is not the truly physical sense originally intended as applying to the accepted normal observer but only an unreal and purely conventional one. It should therefore be recognized that, however this use of the adapted $\chi_{\text{C.I.E.}}$ may be justified as a practical device, a new term, $\chi'_{\text{C.I.E.}}$ say, differing from the original $\chi_{\text{C.I.E.}}$, has in fact been introduced by the simple act of adaptation, and has been employed in practice.

Secondly, we must notice that increased accuracy as such is not really directly called for, the specific need being for higher precision, not accuracy, of individual colour measurements in order to ensure the accuracy of differences in given circumstances. Standardization could not, of course, be ultimately dispensed with, but the immediate problem is clearly one of differential colorimetry, which is technically different from that of absolute colorimetry. Given a suitable standard, for use with a differential colorimeter, known in colour to an absolute accuracy within the degree of differential accuracy, δ_1, yielded by that instrument; then measurements, in absolute terms, of $\chi'_{\text{C.I.E.}}$ could be determined to any requisite accuracy limited only by δ_1. But if such a standard is not immediately forthcoming, the measurement merely of differences of $\chi'_{\text{C.I.E.}}$ to the same accuracy would still materially assist the colorist, and, if the effects of ageing could be controlled, possibly provide him, at least in some cases, with all he needs in this respect; for his interest in the absolute measurement of colour would then enter wholly or mainly through a consideration of colour differences which generally are so large as to render practically insignificant the small differences which are important in a differential sense.

Thus the present position is not entirely dependent upon the resolution of the outstanding problems of the ultimate standardization of colour. These present an important field for physical research, and incidentally provide material for an inquiry on philosophic method. The analytical nature of physical explanation imposes upon investigation formal conditions of method which, in the present case of colour, by securing accuracy of form have lost to us the essential precision in the substance of our observations.

Although this may be inevitable in the case of a directly estimated quantity of the type here in question[2], it has the form and effect of a paradox, the influence of which upon the progress of colorimetry as a branch of physical science it will be an important problem to remove, if the underlying nature of colour is to be made clear and if colour as a physical concept is to preserve and maintain its true and proper signification in the fullest possible sense.

It may be mentioned that these considerations are not put forward with the object of indicating academic propositions without effect upon the practical development of the subject. They affect directly its practical development in a fundamental sense, and arise in a manner unusual in physical investigation merely because of the unusual types of quantities and magnitudes with which we have at present to deal in the physical investigation of colour.

Philosophy of Physical Science

THE recent discussion between Sir James Jeans and Sir Arthur Eddington [see NATURE of Oct. 25, p. 503 and earlier references], in so far as it involves the Fitzgerald-Lorentz contraction, prompts me to direct attention to an aspect of this matter which I presented recently before the American Physical Society Symposium on Philosophy and Science[1].

For many years I have maintained that the Michelson-Morley experiment has rather an illusory significance in relation to the theory of relativity and is, in fact, not fundamental to it[2]. There are, in fact, two aspects to the meaning of invariance under the Lorentzian transformation. The first, A, is a pure mathematical one and is concerned with the fact that if the equations are transformed from one set of variables to another by a Lorentzian transformation, they revert to the same form. The test of this is a pen and paper affair. The second aspect, B, implies all that is contained in the first and, in addition, the postulate that the second set of variables is that which an observer, moving with velocity v in relation to the origin of co-ordinates of the first system, would automatically use.

Suppose that in a system S I have a rod to which I impart a velocity v. In this process, all sorts of acoustical vibrations are set up. These die down in time, but how does the rod decide that it must settle down to a new length determined by the Fitzgerald-Lorentz contraction? The acoustical vibrations cannot be dismissed lightly, since they are part and parcel of the whole mechanism by which the rod received its motion. It seems that the quantum theory, if relativistically invariant in form, possesses the power to give the necessary answer.

According to the quantum theory, the form and stability of the rod at rest in S are determined by its being in a 'ground state'. Now if the equations are invariant in the sense A, we know that if we have, in S, one solution for, let us say, the Ψ function, satisfying the usual conditions of continuity, etc.; then associated with this solution we have an infinite number of other solutions obtainable from it by a Lorentzian transformation, and *these are all possible quantum states in the systems*. (It is quite true that on the aspect B any one of them would also be a quantum state in a system S' of measurements moving in relation to S with velocity v. I wish to make no use of this fact, however.) Any one of these states presents, of course, as one of its aspects, the picture of the rod moving along with a velocity which, measured in S, is equal to the value of v which occurs in the transformation, and the state can, therefore, by the quantum theory, be a possible state for such a rod. The ground state for the rod moving with velocity v is the state obtainable by a Lorentzian transformation from the ground state of the rod before the motion was imparted. It is, therefore, the state which the moving rod may be expected to assume unless the perturbation forces involved in the production of the motion are so large as to have produced the kind of quantum transitions of finite and, in general, large magnitudes which are associated with what we may call non-reversible changes in structure. In general, we may say that the kind of forces which are associated with the determination of structure are those characteristic of molecular affinity, and the quantum transitions necessary to produce non-reversible changes in structure are such quantum transitions as would be involved in molecular quantum transitions.

It thus appears that a relativistically invariant quantum theory, or something closely analogous to it, is a necessary supplement to the general principle of invariance of equations if we are to provide for the Fitzgerald-Lorentz contraction and for the customarily accepted form of the theory of relativity symbolized by what we have called the form B.

Sept. 23.

[1] Held at Providence, R.I., June 21, 1941. The address and a special amplifying paper concerning the specific point in question are published in *Rev. Mod. Phys.*, 13, 190 and 197 (1941).
[2] Swann, W. F. G., *Phys. Rev.*, 35, 336 (1930); *Rev. Mod. Phys.*, 2, 243 (1930).

I HAVE terminated my correspondence on the philosophical controversy; but since Dr. Swann's letter deals with a purely scientific question regarding the relations of relativity theory and quantum theory, I venture to offer some remarks.

As Swann points out, the Lorentz transformation is no more than a mathematical change of variables unless it is coupled with a theory of the 'similarity' of the fixed and moving systems. I would remark, however, that the problem of similarity arises in physics at a much earlier stage, namely in defining a standard of length. Swann's question, how a rod decides its extension when it is given a different motion, is only part of the general question how it decides its extension when it is given a different location in space and time. Surely the answer is given by the law of gravitation, which definitely expresses the fact that the rod decides its extension by measuring itself against the local space-time curvature—that being the only linear characteristic available for comparison[1].

Dr. Swann's conclusions are reached in a general form if we adopt a more elementary starting-point. When we make statements about lengths in a remote star or at a remote epoch, it is implied that there

and then a physical standard (with the desired orientation and velocity) could be constructed 'similar' to a corresponding terrestrial standard; and the statements have no meaning unless we define the criterion of similarity. This is discussed rather fully in "The Philosophy of Physical Science" (pp. 73–85). It is concluded that the two standards must be constructed from a common specification; and the quantitative part of the specification must consist of *pure numbers* only, since it is required to precede the definition of length and all other physical quantities. This means that the specification must be a quantum specification; because it is only in quantum theory that a method has been developed of describing material structure by pure numbers—numbers of elementary particles the mutual arrangement of which is specified by quantum numbers. Thus appeal must be made to quantum theory for the definition of the interval ds, which is the starting-point of relativity theory.

Naturally the quantum theory must harmonize with relativity theory, and Dr. Swann is no doubt technically correct in saying that it must be relativistically invariant in form. But, as I have recently pointed out[2], this condition has been widely misunderstood and misapplied in quantum theory. It is often understood to mean that the equations should be Lorentz-invariant in form. But Lorentz invariance (or, more strictly, covariance) is no more than a special formula applicable when two systems, though considered in conjunction, are physically isolated—a condition rarely, if ever, arising in quantum problems. There is no more value in employing Lorentz-covariant equations in treating the internal structure of an atom or nucleus than in treating the internal structure of a star. 'Structural equations' are relativistically invariant as they stand, since they remain true whatever the motion of the body possessing the structure.

To come back to the original problem, if we suppose the fixed and moving rods to be calibrated by reference to the dimensions of hydrogen atoms sharing their respective motions, the rods will equally obey the Lorentz transformation whether the atoms are Dirac atoms or Schrödinger atoms. We have to go much more deeply into the general principles of relativity theory to obtain any useful guidance as to the form quantum theory must take.

Physiology and Ecology of Cuticle Colour in Insects

THE interesting article in NATURE of October 11, p. 428, by Dr. Hans Kalmus requires comment upon a number of points, but first a protest must be entered against the use of the word 'frequently' in evidence for a 'rule'. Other vague statements might well be given more precise definition, such as 'pale' or 'dark'. The complications of pattern introduce great difficulties: Is an insect (non-lepidopterous, to fall in with Dr. Kalmus's excision of this group from most of the argument) with strongly contrasted areas of dark and light, conforming to the type of disruptive pro-cryptic, or of aposematic, coloration, to be considered 'dark' or 'pale'? Dr. Kalmus's criteria would seem to be applicable only to unicolorous examples, or those of which the pattern gives a fairly uniform result, and thus must exclude immense numbers of insects.

The difficulties of applying Dr. Kalmus's 'rules' are great. For example, in the dry Ngamiland country of South Africa, I found large scavenging black Tenebrionid beetles running about in the hottest sun: equally large black and active predatory Carabids appear after dark, but another large predatory beetle, the black Cicindeline Manticora, hunts by day, as do a great number of its more brightly coloured relatives.

Among weevils, the hardness of many is proverbial, and experimental evidence by the late C. F. M. Swynnerton showed it to be decidedly of protective value. Yet some are 'pale', others 'dark'; some may be found freely exposed by day, others conceal themselves until night.

Among aquatic insects the Coleoptera might, on the whole, reasonably be classed as 'dark'. The much softer Hemiptera (Notonecta, Corixa, Naucoris) are 'pale', but the equally soft Nepa is very dark, or black. All may be found in the same pond. The explanation that dark cuticle is less easy to wet seems rather weak.

As regards the darkness of eggs, much more evidence is required. Contrast the dark eggs of the puss moth on willow leaves with the bright yellow eggs, on cabbage, of the cabbage white. The eggs of stick-insects (Phasmidæ) are notorious for their degree of cryptic resemblance to seeds in shape and colour: seeds are very often dark, and so are these eggs.

One would like to see figures in support of the statement that most non-black insects are found in the tropics: Are we to conclude that out of all non-black insects a majority occurs in the tropics, or that, of all insects in the tropics, a majority is non-black?

In connexion with the interesting point about liquid food, surely most aphids are not pale? One thinks of the black bean and dock aphids, and, at the moment, of a large bed of reed-mace, of which the leaves and stems are blackened with Aphis.

An interesting test of whether predators are darker than phytophagous species could be provided by a statistical study of two not widely separated families of Hemiptera—the predaceous Reduviidæ and the plant-sucking Coreidæ, which may be found side by side all over the world. Dr. Kalmus writes of the dark colour of the tse-tse fly. There are some twenty species of Glossina, and while some, such as *palpalis*, may be called 'dark', this term can scarcely be applied to *morsitans*. The former, inhabiting rain forest, can scarcely be said to be subject to the conditions of a dry region, while *morsitans*, in such a dry area as the Nuba mountains in southern Sudan, should be the darker species.

G. D. HALE CARPENTER.

University of Oxford.

I AM pleased that my article should have aroused the interest of such a well-known authority on adaptative coloration as Prof. G. D. Hale Carpenter. Before answering in detail, I should like to deal with his first general protest. He objects to the word "frequently" in formulating a rule and calls this a "vague" statement. It is interesting in this context to quote from a letter which I received from Dr. B.P. Uvarov, of the Imperial Institute of Entomology,

which he kindly permits me to use: criticizing the wording of these same rules he writes: "The dogmatic character of your rules . . . is the first weakness of your paper." So I think I have on the whole kept well between extremes such as formulating rigid laws or merely making "suggestions for observation" as suggested in the letter quoted above.

If I understand Prof. Hale Carpenter's second sentence, he also thinks it vague to describe an insect as "pale" or "dark". In particular he thinks that the "complications of pattern introduce great difficulties". Actually I think it is quite feasible to assess the total brightness of an insect, for example, by using a photo-cell, and it is usually very easy to say which of two related forms is the darker one. Species with light and dark areas of cuticle are very useful for study. They provide the best material for a comparison of the properties of light and dark cuticles. I have been informed that such an investigation is in progress in a physical laboratory in Great Britain.

My article did not deal with pattern, but only with colour. Radiant heat, desiccation, or any of the five physical factors mentioned in my article do not have very different effects on an insect, whether homogeneously coloured or speckled, provided it has the same total brightness.

Many of Prof. Hale Carpenter's points seem to me to be the kind of exceptions which prove the rules. I think the beetles of Ngamiland provide quite good examples for Rules 12 and 14 (drought and vagility). They are mostly conspicuously black, and the more brightly coloured Cicindelids may well show a metallic colour. A comparison of the colour and life-habits of weevils may be worth while, but as both the light and the dark forms are very hard, a different process of hardening seems to be at work.

I think Rule 11 can only be understood to mean that the proportion of non-black insects is greater in the tropics. Similarly, Rule 13 means in respect of the aphids that a high percentage of them is light. The cuticle of the black aphids, mentioned by Prof. Hale Carpenter, is quite light; only the body contents and the epidermal cells are pigmented. This can easily be demonstrated by pressing a black aphid (for example, the chrysanthemum aphid, *Macrosiphoniella sanborni*) between two bits of filter paper. The result is two dark spots and a hyaline cuticle. The colour of the Reduvidæ and Coreidæ would not seem to have much bearing on the problem, since they are also hemimetabolic insects (Rule 5) and probably most of their coloration is not situated in the cuticle. It would be interesting to find out whether the same is true of Nepa.

It is difficult to see what selective advantage can be ascribed to the notorious resemblance of the eggs of Phasmidæ to seeds. On the other hand, I think it is not surprising that an embryo, whether plant or insect, which has to resist the vicissitudes of a very similar environment, should show similar features. To my knowledge the humidity on a willow and a cabbage leaf have not yet been compared; but perhaps the fact that the puss moth has only one generation a year, whereas cabbage whites have several, could be interpreted by means of Rule 9.

I used a dark tse-tse fly merely as an example to show the difficulty in some cases of detecting the controlling factor in coloration, and I quite agree with Prof. Hale Carpenter's remark in his second paragraph, that the difficulties in applying my rules are great. However, they are not greater than in any other new ecological subject. That the "ecogenotypical colour variation" of insects is indeed beginning to attract the interest of biologists appears not only from correspondence on the subject, which I receive almost daily, but also from a paper, which reached me after my article had been written, and from which the term "ecogenotypical" is taken (W. Hovanitz, *Ecology*, July, 1941). It deals precisely with the group of insects which I thought would offer the greatest difficulties for the application of my rules, namely with butterflies. Although in disagreement with some of my rules, Hovanitz concludes from the study of many species that "contrary to established dogma the adaptiveness of animal coloration need not only be 'protective' but may only be a secondary product of a more fundamental function in the physiology of the animal". He thinks further that the geographical centres of pigmentation "are shown to be centres of certain physical conditions such as aridity, high temperature, etc., though they might more specifically have been said to be centres of low precipitation, low humidity, high temperature, high solar radiation, fast animal development and light coloured soil".

Number of Primes and Probability Considerations

IN the first sentence of Lord Cherwell's communication[1] occurs the phrase "a number chosen at random"; and the applicability of the theory of probability surely depends on the possibility of random choice. Now an integer can be chosen at random from any finite set, but there is no way of choosing one at random from the infinite set of all positive integers. Thus if Lord Cherwell chooses an integer "at random" it will certainly be less than $10^{10^{10}}$, as otherwise he will not live long enough to write it down. But the probability that an integer chosen at random is less than $10^{10^{10}}$ is zero.

Hence, though we may use probability theory heuristically in the theory of numbers, and although it sometimes gives correct results, we have no logical grounds for supposing it will do so. Perhaps a set of axioms could be produced which would enable us to apply probability theory, but such a set would not, I think, include the phrase "a number chosen at random". Until this is done it is not obvious where to look for the weak link in the chain of reasoning when probability theory gives an incorrect result. We can, of course, apply probability theory to everywhere-dense infinite sets, such as the real or algebraic numbers in an interval, but in this case we never deal with an individual number, but only with a sub-interval. We biometricians have our difficulties, but at least the number of men, or even of bacteria, is finite, so biometrical sampling theory can be given a comparatively secure logical basis.

J. B. S. HALDANE.

Department of Biometry,
University College, London;
at Rothamsted Experimental Station,
Harpenden, Herts.

[1] NATURE, 148, 436 (1941).

IN NATURE of October 11, p. 436, Lord Cherwell calculates, by considerations of probability, the number of primes in an interval Δ and finds that the correct answer is about 11 per cent smaller than his results.

Having myself calculated the number of primes by the probability method some time ago, I think I can give an explanation of the difference.

The probability for a number to be prime

$$\bar{\omega}_n = (1-\tfrac{1}{2})(1-\tfrac{1}{3})(1-\tfrac{1}{5})(1-\tfrac{1}{7})(1-\tfrac{1}{11}) \ldots \left(1-\frac{1}{p_n}\right)$$

is valuable only for the whole interval between p_n and $(p_{n+1})^2$. But Lord Cherwell applies it—or one derived from it—to an interval which is only part of the preceding. And the different parts of the $p_n-(p_{n+1})^2$ interval are not equally rich in primes. The higher parts are comparatively poor in primes. Thus, applying to the higher parts of the interval a formula which is valuable only for the comparatively richer whole interval, Lord Cherwell very naturally finds a number of primes which is slightly too great.

On the contrary, when the formula is applied to the correct interval [p_n to $(p_{n+1})^2$] the agreement becomes rapidly very good as p_n increases, as is shown by the accompanying table.

Prime numbers		Interval	Probability of being prime for a number in the interval Δ_n	Number of primes in the interval Δ_n		Difference %
p_n	p_{n+1}	$\Delta_n=(p_{n+1})^2-p_n$	$\bar{\omega}_n = (1-\frac{1}{2})(1-\frac{1}{3})(1-\frac{1}{5}) \ldots \left(1-\frac{1}{p_n}\right)$	Calculated by $N = \bar{\omega}_n\Delta$	Actual	
2	3	9 − 2 = 7	0·5	3·5	3	+16·7
3	5	25 − 3 = 22	0·3333 . . .	7·333 . . .	7	+ 4·6
5	7	49 − 5 = 44	0·2666 . . .	11·733	12	− 2·2
7	11	121 − 7 = 114	0·2286	26·055	26	+ 0·2
11	13	169 − 11 = 158	0·2078	32·830	34	− 3·4
13	17	289 − 13 = 276	0·1918	52·936	55	− 3·8
17	19	361 − 17 = 344	0·1805	62·097	65	− 4·5
19	23	529 − 19 = 510	0·1710	87·216	91	− 4·2
23	29	841 − 23 = 818	0·1636	133·80	135	− 0·9
29	31	961 − 29 = 932	0·1579	147·20	150	− 1·9
31	37	1369 − 31 = 1338	0·1528	204·50	202	+ 1·2
37	41	1681 − 37 = 1644	0·1487	244·02	244	+ 0·008
41	43	1849 − 41 = 1808	0·1455	263·01	262	+ 0·4
43	47	2209 − 43 = 2166	0·1421	307·77	307	+ 0·25
47	53	2809 − 47 = 2762	0·1391	384·10	385	− 0·25
53	59	3481 − 53 = 3428	0·1364	467·71	461	+ 1·5
59	61	3721 − 59 = 3662	0·1341	491·18	491	+ 0·03
61	67	4489 − 61 = 4428	0·1319	584·18	580	+ 0·7
67	71	5041 − 67 = 4974	0·1300	646·43	646	+ 0·07
71	73	5329 − 71 = 5258	0·1281	673·70	673	+ 0·1
73	79	6241 − 73 = 6168	0·1264	779·47	777	+ 0·3
79	83	6889 − 79 = 6810	0·1248	849·70	848	+ 0·2
83	89	7921 − 83 = 7838	0·1233	966·18	966	+ 0·02
89	97	9409 − 89 = 9320	0·1219	1136·0	1129	+ 0·6

Of course the probabilities of divisibility are strictly independent and it cannot be any question of a mysterious tendency of the factors to avoid each other.

A FREE FRENCH SCIENTIST.

October 13.

"A FREE FRENCH SCIENTIST" appears to use the word 'probability' in an unconventional sense. The probability that a number in the neighbourhood of a large number A should be a perfect square tends to $\frac{1}{2\sqrt{A}}$; this is an obvious property of numbers in the neighbourhood A; it is not a matter of intervals. A "Free French Scientist's" expression does not give the probability of a number in the neighbourhood of a large number N^2 being prime, but the average value of the probabilities between p_n and $(p_{n+1})^2$.

The agreement he finds is unfortunately spurious. According to well-established theory the number of primes in his interval would be approximately $\mathrm{li}\,(p_{n+1})^2 - \mathrm{li}\,p_n$. In the region he has examined in his table this happens to be about 10 per cent bigger than $\frac{p_{n+1}}{2 \log p_{n+1}}$ and therefore nearly equal to $\frac{p_{n+1}}{e^{\gamma} \log p_{n+1}}$. But this is because he chanced to stop at 97. If he had proceeded to larger numbers the agreement would vanish and he would find a discrepancy just as serious as the one to which I directed attention.

Incidentally, my use of the word 'avoid' seems to trouble the "Free French Scientist" unnecessarily. Perfect squares avoid one another more and more the further we go, but there is nothing mysterious about this.

While I can sympathize with Prof. Haldane's very human wish to begin a metaphysical discussion, I had not expected him to reveal the urge quite so soon after his letter extolling utilitarian studies as opposed to pure science. Unfortunately, I do not feel I ought to indulge him, since his difficulties are quite irrelevant to the point at issue. The discrepancy to which I directed attention can be derived perfectly well by choosing a number at random from a finite class.

CHERWELL.

Christ Church,
Oxford.

Penetration of a Water-soluble Sulphonamide, Sodium Sulphacetamide (Albucid-soluble) into the Eyes of Rabbits

RECENT work has shown that the local application of sodium sulphacetamide can control the development of experimental corneal ulcers in rabbits (Robson and Scott[1]). This sulphonamide is also being used clinically in concentrations up to 30 per cent for the treatment of various ocular infections, and especially of hypopyon ulcers, and it became of interest to determine the concentration attained in the various ocular tissues, when solutions are applied locally to the conjunctival sac.

Experiments were performed on twenty-eight mature rabbits. Under ether anæsthesia, celluloid

funnels were put into one or both eyes and kept in position by means of purse string sutures through the lids (see Fig. 1). The funnel was so designed that its aperture had a diameter greater than that of the cornea. The flange therefore lay against the conjunctiva overlying the sclera, and no part of the funnel was in contact with the cornea. The solution of sodium sulphacetamide (2·5 or 30 per cent) was poured into the funnels and allowed to remain in contact with the eye for periods ranging from 5 to 30 min. The eyes were then removed, washed in saline and rapidly dried on blotting-paper. The aqueous humor was then withdrawn and the tissues dissected off, washed in saline and rapidly dried on blotting-paper.

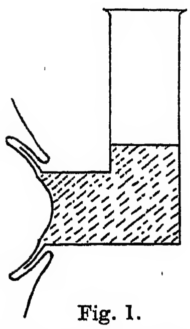

Fig. 1.

DIAGRAM TO SHOW POSITION OF FUNNEL IN CONJUNCTIVAL SAC.

The sodium sulphacetamide content of the tissues was then determined colorimetrically by the method of Marshall and Litchfield[2], with slight modifications. The results are shown in Figs. 2 and 3.

Each point on the graphs represents the mean of the values obtained in 5–10 experiments. There was considerable individual variation but certain facts nevertheless stand out quite clearly.

The concentrations in the cornea and conjunctiva are very similar and much higher, as was to be expected, than that found in the aqueous. The values for the iris were still smaller. The drug penetrates into the cornea and conjunctiva very rapidly

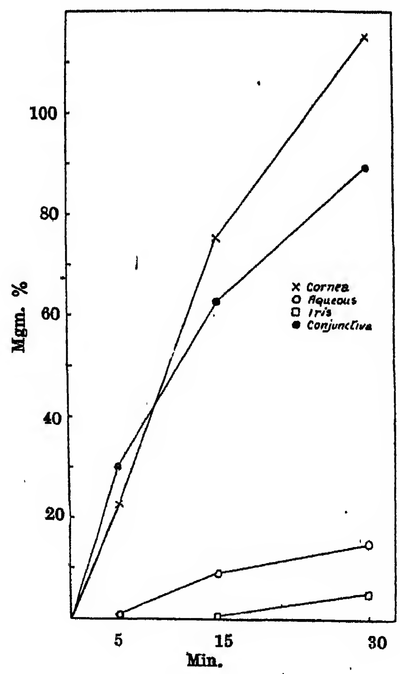

Fig. 2.

CONCENTRATIONS OF SODIUM SULPHACETAMIDE (MGM. %) ATTAINED IN OCULAR TISSUES AT VARIOUS PERIODS AFTER THE BEGINNING OF APPLICATION OF A 2·5 PER CENT SOLUTION OF THE DRUG TO THE CONJUNCTIVAL SAC.

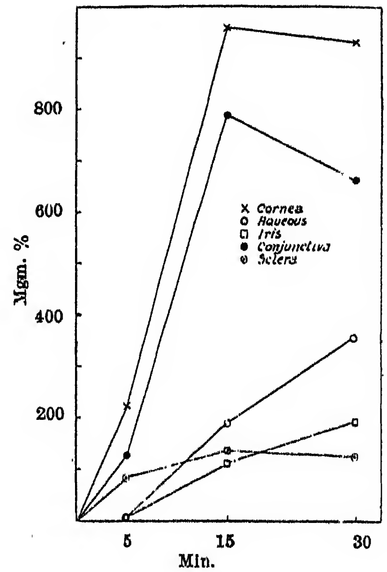

Fig. 3.

CONCENTRATIONS OF SODIUM SULPHACETAMIDE (MGM. %) ATTAINED IN OCULAR TISSUES AT VARIOUS PERIODS AFTER THE BEGINNING OF APPLICATION OF A 30 PER CENT SOLUTION OF THE DRUG TO THE CONJUNCTIVAL SAC.

and very high concentrations can be produced, either by applying the 30 per cent solution for a short period, or by applying the 2·5 per cent solution for longer periods.

Application of the 30 per cent solution (which is hypertonic) for fifteen minutes or more produced some degree of œdema of the cornea, and this may be responsible for the failure of the concentration of the drug in the cornea to rise any further.

Only small amounts of the drug were found in the vitreous humor and there was practically no penetration of the drug into the lens. In a number of experiments the concentration of the drug in the blood was determined. The highest value obtained was 7 mgm. per cent after the application of the 30 per cent solution for 30 min.; but in most cases it was much smaller. These low values show that direct penetration of the drug was responsible for the high values found in the ocular tissues.

These results, like those of P'an[3], suggest that local application of sulphonamides is the method of choice for the production of adequate concentrations of the drug in the ocular tissues and for the treatment of certain ocular conditions by sulphonamides.

The expenses of this investigation have been defrayed by the W. H. Ross Foundation for the Prevention of Blindness. We are greatly indebted to Mr. Edwards of British Schering Ltd. for the supply of a 30 per cent solution of albucid soluble.

RESEARCH ITEMS

Ancient Indian Cultures

AN article by M. E. and D. H. Gordon (*J. Roy. Asiatic Soc. Bengal*, 6, No. 2 ; 1940) contains interesting information concerning their studies in the Indus valley. The prehistoric cultures exemplified by Harappa and Mohenjo-daro are not necessarily isolated from those of the early historic period, as certain objects have been found in mounds in Peshawar and other neighbouring districts which appear to carry on the ancient traditions. Moreover, painted pottery such as is found in these mounds is made in all the same localities to this day. This does not mean that there is no distinction between the present-day painted pots and those of the early historic periods; but there are certainly similarities, which, with the other evidence put forth, tends to show that there is no hiatus of 2,000 years in these Indian cultures. Ancient metal and stone workings in the eastern portion of Chota Nagpur have been excavated by E. F. O. Murray and described in "The Ancient Workers of Western Dhalbhum" (*ibid.*). The ethnology and geology of the district are dealt with briefly and a description given of the very interesting finds of pottery, beads and stone implements. The old mines are also described. The author concludes that they belong to an ancient culture of a higher level than that attained by the present inhabitants of the region.

Nicotine Accumulation in Reciprocal Grafts of Tomato and Tobacco

THE distribution of nicotine between stock and scion in reciprocal grafts of tomato and tobacco was described by R. F. Dawson at the Autumn Meeting of the U.S. National Academy of Sciences held during October 13–15. When tobacco scions were grown upon tomato stocks no appreciable amounts of nicotine accumulated in the tobacco leaves or stems. In fact, the nicotine which was originally present in the scions remained in the lower leaves and stems, and the leaf and stem tissues which afterwards developed were nicotine free. When tomato scions were grown upon tobacco stocks nicotine was found in appreciable quantities in the tomato stems and fruits, and large quantities of the alkaloid accumulated in the leaves. Nicotine accumulation in the leaves of the tomato scions was sectoral when tobacco stems were decapitated and inserted into the tomato stems unilaterally. Nicotine was isolated from the xylem and the xylem exudate of the stems of intact tobacco plants. The evidence indicates that the presence of nicotine in tobacco leaves is due to (*a*) the synthesis of the alkaloid in the tobacco roots, (*b*) the translocation of the fully formed base (and not its precursor) to the leaves by way of the xylem, and (*c*) the continued accumulation of this nicotine in the leaves.

Microscopic Structure of the Wool Fibre

A SERIES of twenty-seven microphotographs forms a special feature of a study of the fine details of structure of wool fibres by C. W. Hock, R. C. Ramsay and M. Harris (*J. Res. Nat. Bur. Standards*, Washington, D.C., 27, 181 ; 1941). Special attention was given to constituent scale and cortical cells. The individual cells were released by treating chemically modified wool with pepsin. The striated appearance of the cortical cells is due to the presence of many fibrils which can be separated with microneedles. Between crossed nicols the fibrillar part of the cortical cells appears birefringent whereas the nucleus does not. The scales show little internal organization and appear non-birefringent between crossed nicols. A comparison of root and shaft of the fibre reveals many differences in reaction to microchemical colour tests as well as differences in cellular structure. The paper can be obtained also as Research Paper *R.P.* 1412 [10c] from the Superintendent of Documents, Washington, D.C.

Heat of Sublimation of Carbon and Absorption Bands of Three Mesomeric Hydrocarbons

SPECTROSCOPIC analysis of the CO spectrum, together with thermochemical measurements on the burning of carbon in oxygen, lead to the conclusion that L, the heat of sublimation of carbon, is either 124 or 170 kcal./mol. G. J. Kynch and W. G. Penney (*Proc. Roy. Soc.*, A, 179, 214; 1941) have made an estimate of L by calculating the energies of excited states of benzene, butadiene and hexatriene. Various values of L were assumed and the calculations were compared with experiment. Almost exact agreement was found for all three substances by assuming $L = 170$, and no agreement was found by assuming $L = 124$. The theory used is similar to that developed by Eyring for estimating activation energies. The equilibrium internuclear distances in the excited states are found, and the potential function controlling some of the vibrations about these positions is determined. The excited state of benzene has the regular hexagon configuration, with the carbon-carbon internuclear distance 1·45 A., compared with 1·39 A. in the ground state. The carbon-breathing frequency in the excited state is calculated to be 920 cm.$^{-1}$, compared with the experimental value 940 cm.$^{-1}$.

Preparation of Deoxycholic Acid

THE preparation of deoxycholic acid from cholic acid was described by T. F. Gallagher and W. P. Long at the Autumn Meeting of the U.S. National Academy of Science held during October 13–15. When methyl cholate is oxidized at low temperatures with chromic oxide, the principal product is the methyl ester of 3-12-dihydroxy-7-keto-cholanic-acid, hitherto undescribed. A method for separation of this compound is given. Upon reduction by the method of Wolff-Kishner it is converted smoothly to deoxycholic acid in excellent yield.

Structure of Soap Curd Fibres

SOME interesting photographs of the curd fibres of sodium laurate have been obtained by L. Marton, J. W. McBain and R. D. Vold (*J. Amer. Chem. Soc.*, 63, 1990 ; 1941) by means of the electron microscope with direct magnification up to 19,000 diameters. The results confirm previous conclusions based on less direct evidence. The curd is shown to consist of a mass of fibres which are thin ribbons with widths tending to be integral multiples of approximately twice the length of the sodium laurate molecules. In order that the carboxylate groups and methylene groups, respectively, may be adjacent to one another

in the manner found by X-rays for the monoclinic crystals, it would be expected that the fibres should be much wider than they are thick, and this agrees with the microscopic result. The fibres branch to form a felt, which accounts for the rigidity of the curd. The fibre junctions are also seen to give rise to many capillary spaces of variable diameter in which water can be retained, even at very low relative humidity. Some of the sodium laurate apparently is not a part of the fibrous structure but is present in granules 100–200 A. in diameter irregularly spaced along the fibre. These were perhaps formed by rapid dehydration, during exposure of minute drops of solution, or may be related to aggregates pre-existing in the soap solution.

Effect of Ions on the Liquid Structure of Water

G. W. Stewart, in a paper read at the Autumn Meeting of the U.S. National Academy of Sciences held during October 13–15, discussed the effect of ions on the liquid structure of water. Water is unique in its liquid structure, and the influence of ions in solution on this structure becomes important experimental evidence. The results represent a considerable extension of an earlier report, and the conclusions therefrom are as follows: (1) With 41 strong electrolytes (so named in I.C. tables), out of a possible of approximately 200, the alteration in the X-ray diffraction pattern indicated that the ions caused an increase in the co-ordination bonds of the solvent water with a contraction in its volume. (2) With 37 of these, there was a rough but striking correlation between the rate of change of apparent molal ionic volume with concentration and the rate of change of the X-ray structure with concentration, the latter being determined in a somewhat arbitrary but consistent manner. The number of electrolytes was limited by the desirability of using only the lighter atoms. (3) With 3 of the strong electrolytes the rate of change of the apparent molal ionic volume occurred in the opposite direction although the change in water structure was similar to that with the others. The conclusion is that there are other factors in these special cases (the total number is only 6 in 200) which have the effect of decreasing the apparent molal ionic volume. Quantitatively, ionic temporary pairing might be such a factor. (4) There is a rough correspondence between the solubility of these electrolytes and their effect upon the structure of the water, the less the effect on the structure the greater being the solubility. (5) All these results are consistent with and seem to emphasize the tetrahedral structure of water changing with increasing temperature, this structure and these changes accounting for some of the unique characteristics of water.

New Compounds Fluorescent to X-Rays

New compounds fluorescent to X-rays consisting of pure isomorphous mixtures of the sulphates of barium and lead, have been discovered in the research laboratories of Ilford Limited by F. F. Renwick and H. S. Tasker, and form the subject matter of a recently issued British Patent No. 540,252. These materials, it is claimed, emit a strong violet and ultra-violet fluorescence, without afterglow when excited by X-rays, but show no fluorescence under ultra-violet light illumination. Being insoluble and inert towards photographic emulsions, they are likely to prove valuable, not only for the manufacture of X-ray intensifying screens, but also in composite units embodying both screen and emulsion on a single support. They appear, moreover, to be unique in that they can be prepared by double decomposition in an active micro-crystalline form by the simple interaction of a solution containing salts of barium and lead with a solution of a sulphate, without the necessity for a subsequent firing treatment, as is essential in the preparation of all the well-known fluorescent salts, such as calcium and other tungstates, zinc sulphide and zinc silicate. When a firing operation is also employed, their fluorescence is stated to be considerably enhanced, and products rivalling the most highly fluorescent calcium tungstates are said to be obtainable. This addition to the list of useful fluorescent compounds will doubtless interest not only radiologists but also those research workers who make a special study of fluorescence phenomena.

Bombardment Experiments with Protons on Boron

When boron is bombarded with protons, two groups of α-particles are found, one a group with continuous distribution in range and maximum range of 3·7 cm., the other a group with homogeneous range of 4·4 cm., according to A. Ellet and J. Jacobs in a paper read at the Autumn Meeting of the U.S. National Academy of Sciences held during October 13–15. The excitation function of each group was studied in the range 100–200 kev., and in each case showed a resonance at 158 ± 3 kev. The resonance for the continuous group had not been previously found. The distribution in angle of each group at resonance and of the continuous group just above resonance (175 kev.) was measured. Both groups showed asymmetry at resonance (in agreement with previous reports); but the continuous group was observed to possess spherical symmetry above resonance (in contradiction to previous reports). The resonance yields of the α-particles of each group are presumed to have a common origin, a p- or d-proton capture. The non-resonance yield of the continuous group is presumed to arise from an s-type capture. The results are in agreement with certain theoretical considerations.

Maxima of Absorption Lines in Stellar Spectra

The maxima of absorption lines in stellar spectra were described by P. C. Keenan at the Autumn Meeting of the U.S. National Academy of Sciences held during October 13–15. The accurate spectral types recently determined at the Yerkes Observatory for a large number of stars provided the basis for improved estimates of the spectral types (and corresponding effective temperatures) at which the stronger atomic lines and molecular bands reach their maximum intensity. In giant stars the neutral iron lines of *e.p.* 1·5v. show a maximum at type $K5$ ($T_e = 3600° \pm$) while those with *e.p.* 2·4v. are strongest near $K3$ ($T_e = 3850° \pm$). In dwarfs the behaviour of these lines is similar but less clearly differentiated. Among the lines of ionized elements which persist to low temperatures, the K-line of Ca^+ shows no marked falling off in strength through the coolest observable giants (type $M5$ with $T_e < 3000°$), but has a maximum for the dwarf stars near $K5$. Bands of CN are strongest at $K1$ in giants and at $G7$ in supergiants, while remaining weak in dwarfs at all temperatures. The $\lambda 4300$ band of the CH molecule behaves similarly, but has maxima about five spectral subdivisions earlier than those of CN.

MEDAL AWARDS OF THE ROYAL SOCIETY*

COPLEY MEDAL

THE Copley Medal has been awarded to Sir Thomas Lewis.

Lewis's life's work, still in vigorous progress but for interruption by war duties and war conditions, has been the application of precise and controlled methods of experimental research to problems of clinical medicine. This has enabled him to achieve a detailed analysis of abnormalities of function produced by disease, injury or hereditary defect; and so far his attention has been centred upon the circulation of the blood and its disorders. Being attracted through the work of the late Sir James Mackenzie to the study of abnormal rhythms of the human heart-beat, Lewis recognized, about 1908, the great opportunity for a closer investigation of them offered by the then recent introduction of the string galvanometer by Einthoven. With its aid Lewis had soon made a number of clinical and laboratory studies, such as those in which he finally identified auricular fibrillation as the cause of a particular kind of complex irregularity. He was thus led to undertake, and to extend, with a succession of collaborators from many countries, the remarkable series of investigations, carried through in logical sequence between 1910 and 1923, in which he passed from the laboratory to the clinic and back again as the occasion demanded.

It is fitting that special mention should here be made of the series of experimental studies published in the *Philosophical Transactions* during 1914–1916, and presented in brilliant summary by Lewis in his Croonian Lecture to the Society in 1917. In these were traced, with an astonishing precision of measurement and timing, the point of origin and exact course of the rhythmical waves of excitation and contraction in the normally beating heart of the dog, and, finally, for comparison, in the hearts of other classes of vertebrate animals. Considered by itself, this work ranks as one of the outstanding achievements of experimental physiology in our times, and it has given to physiology a large part of its present detailed knowledge of the nature of the heart-beat. For Lewis, however, its greater importance lay in giving to clinical medicine the background for an accurate picture of disturbances of the normal mechanism, therewith a new security of diagnosis and prognosis in dealing with disordered actions of the heart, and ultimately a rational basis for their treatment. A new phase of cardiological thought and practice spread rapidly from Lewis's clinic round the world.

Meanwhile he had begun in 1917, and was to maintain with a series of collaborators for more than another decade, a separate series of investigations, dealing by direct experiment with the blood vessels of the human skin. Thus were elucidated the means by which the resistance of these vessels to the flow of blood is maintained and varied, including their complex reactions to chemical substances akin to histamine, which he proved to be released from the cells of the epidermis by injuries or irritant stimuli. These methods of investigation were later developed and extended to vascular disorders of the limbs, and the experiments of still more recent series have dealt with pain and functional defects in muscles and nerves, due to interruption of the blood supply. Apart from the separate accounts of items and stages of those lines of research, as completed, in papers which have issued from his department in steady sequence, Lewis has assembled and discussed the results, in their appropriate connexions, in a succession of comprehensive monographs. He has been the inspiring leader of a group of younger workers in clinical research as an experimental science, has founded a Society for such studies and has devoted to their use a journal which he had started with a more limited scope.

The work of Thomas Lewis, which we honour today with the highest recognition in the gift of the Royal Society, is renewing and carrying forward, with a special directness, the great tradition which William Harvey created, before this Society was founded.

ROYAL MEDALS

A Royal Medal has been awarded to Prof. Edward Arthur Milne.

Milne is distinguished for his work on planetary and stellar atmospheres, on the internal constitution of the stars, and on the theory of relativity. An early paper on various properties of the earth's atmosphere, up to high levels, led later to a valuable improvement of the theory of the escape of planetary atmospheres by the passage of the faster moving molecules out of the range of the gravitational field. Thence he passed on to a long series of investigations on radiative equilibrium and the theory of the atmospheres of the sun and stars.

Next, partly in collaboration with R. H. Fowler, he improved and extended Saha's theory of the absorption lines in stellar spectra, obtaining a relation between the maximum strength of a line and the mean pressure and temperature in the atmosphere. Afterwards Milne generalized this theory, providing a rational foundation for the astronomers' empirical method of determining stellar parallaxes from the spectra.

Later he considered the equilibrium of the calcium chromosphere of the sun, and also discovered a method by which outward-moving atoms capable of absorbing radiation in the region of the chief absorption lines can be accelerated and pass beyond the range of the sun's attraction, attaining a limiting speed of about a thousand miles a second. This theory also has an application to 'new' stars.

Milne then considered the deeper layers of the atmosphere (for example, in the case of the sun, the photosphere), which in 1929 he took as the subject of his valuable Bakerian Lecture. He has also given a theory of the structure of sunspots and of the circulation associated with them.

In 1929 he began a new series of researches on the radiative equilibrium of gas spheres, designed to improve the theory of the internal constitution of the stars. His work in this field was specially important in focusing attention on the properties of degenerate matter.

In 1932 Milne began an altogether different series of investigations, bearing on the largest topics of astronomy and cosmogony, and providing an alternative

* From remarks made by Sir Henry Dale in presenting the medals for 1941.

to the general theory of relativity developed by Einstein and his followers. He has made a valuable analysis of the concept of time, and his kinematical theory of gravitation has some promise of a possible extension to include also electromagnetism.

Milne's later work has been the subject of much controversy: but the originality and boldness of his attack seem certain to promote our understanding of these great problems.

A Royal Medal has been awarded to Prof. Ernest Laurence Kennaway.

Kennaway is the director of the Chester Beatty Research Institute of the Royal Cancer Hospital, and has been engaged for the past twenty years in investigations on the production of cancers by the continued effects of chemical agents. The long-known liability to skin cancer of men whose work involves regular contact with soot, coal tar, or pitch, and the more recently demonstrated production of such cancers in animals by painting the skin with tar, had raised the question whether a specific chemical agent was concerned, or only a sufficiently persistent irritation. The fractionation of coal tar, in search of a substance revealing its action only after tedious months of experiment, was an undertaking to daunt any but a devoted investigator. Kennaway embarked on this quest, and after years of labour the fluorescence studies of his co-workers Mayneord and Hieger made it possible to isolate a pure substance from tar with intense carcinogenic activity, and ultimately to identify it as benzpyrene. This identification and its confirmation by synthesis were due to J. W. Cook.

Meanwhile, the observation that active fractions of the tar had ultra-violet fluorescence spectra resembling those of hydrocarbons of the phenanthrene type, led to the synthesis of substances with carcinogenic activity. The first of these was a dibenzanthracene, and was found to be almost as active as benzpyrene. Substances of still greater activity have since been obtained, and some of these have a close structural relationship to naturally occurring sterols. A characteristic nuclear ring-complex thus, surprisingly, provides a link of structural community between these carcinogenic agents and a number of natural substances having intense but widely different biological activities—the D vitamin, a number of hormones concerned with sexual functions, and the highly toxic but remedially important glucosides of the digitalis series. One of the most fascinating chapters in organic and biological chemistry has been opened. Identification of these provocative agents does not tell us how they act, and the causes of seemingly spontaneous cancers remain as yet obscure. It cannot be doubted, however, that, when further advances of knowledge enable a correct account to be written of the nature and mode of origin of the malignant tumours, the pioneer work of Kennaway and his able group of co-workers will provide one of the important chapters.

DAVY MEDAL

The Davy Medal has been awarded to Dr. Henry Drysdale Dakin.

Dakin began his researches in the field of biochemistry early in the present century. At that time, in comparison with knowledge of the end-products of metabolism, relatively little was known about the chemical activities of the living cells of the animal body. His work has made very important additions to knowledge of the intermediary changes produced by these activities, and also of the chemical structure of natural components of the tissues.

One side of Dakin's work has dealt with enzymes of the animal organs. He was the first to show that such an enzyme will attack at different rates the two optical isomers in a racemic mixture. With Kossel he discovered the enzyme arginase, with its important role in the production of urea from arginine. Later he discovered the enzyme glyoxalase, the wide distribution of which in the tissues must indicate some important though still undefined function in carbohydrate metabolism.

In connexion with the intermediary metabolism of fatty acids, Dakin produced the first convincing evidence of oxidation at the β-carbon atom as the first stage of their utilization by the body, and showed that this type of oxidation can even be reproduced *in vitro* by the action of hydrogen peroxide.

Dakin's work on the chemistry of the proteins has included a method of partial racemization, bringing subtle differences of molecular pattern into view, which could be related to specific antigenic differences. He also introduced a method of separation which enabled new hydroxyamino acids to be recognized, and raised much nearer to unity the proportion of a protein molecule accounted for as known amino-acids. At a wide interval of years, Dakin has made two notable contributions to the chemistry of hormones. In 1905, he was rosonsible for the first published artificial synthesis of a hormone, adrenaline. In 1936 he described the isolation from liver of a substance which is, at least, a principal factor in the important effect of liver extracts on pernicious anæmia.

Working in France during the War of 1914–18, Dakin introduced the use of a buffered hypochlorite solution for irrigating infected wounds. Later, on a ship bringing the sick and wounded from Gallipoli, he made a similar solution by direct electrolysis of sea-water. Another war is reviving the use of such preparations to meet the same and other needs.

Though Dakin has worked in a private laboratory, with but rare collaboration and no pupils, his work has exercised a wide and powerful influence on the growth of biochemistry and on the strengthening of its links with organic chemistry.

HUGHES MEDAL

The Hughes Medal has been awarded to Prof. Nevill Francis Mott.

Early in his career Mott's work in the field of atomic collisions attracted widespread attention. He was the first to show that Rutherford's scattering law holds in quantum mechanics, and to give an accurate theory of the effect of symmetry in scattering problems. When he took up his present post as professor of theoretical physics in the University of Bristol, he abandoned this subject for that of the theory of metals and alloys. Within a few years he was recognized as one of the leading international authorities in this field, to which he contributed a number of important papers on electronic bands in metals and on the electrical conductivity of alloys and its temperature coefficient. In establishing a close association between theoretical and experimental workers he has no superior. He also contributed to the important problem of metals under strain; under his direction Fuchs has calculated the elastic constants of certain metals and obtained good agreement with known values.

Later Mott turned to semi-conductors and insulators, throwing light on the physical processes involved in the formation of oxide films, and in the electrical conductivity which can be induced by various means in polar crystals. His theory (with Gurney) of the formation of the latent image in a photographic emulsion has found general acceptance, and has stimulated fresh experimental work in research departments of the industry.

This striking record of published work was achieved between 1928 and 1939.

When war broke out Mott found that his activities as a quantum physicist had no direct application to the War. It is a tribute to his versatility and flexibility of mind that he could turn so quickly to a new field in classical physics, and make important contributions to the practical problem in connexion with which he now holds an important post.

ABORIGINAL AUSTRALIAN STRING FIGURES

As time goes on, more and more attention is given to primitive man in his physical, mental and cultural aspects, and among the last-named may be classed that singularly fascinating and complicated pursuit known to us as string figures. It is now nearly forty years since the first collection of string figures was made and described from Torres Straits by Rivers and Haddon, and since then there has been a steady interest in the subject and a mounting number of collections made in different parts of the world. The latest is embodied in an article by D. S. Davidson (*Proc. Amer. Phil. Soc.*, 84, No. 6; Aug. 1941) in which he sums up our present knowledge of the subject and adds a most interesting collection made by him from the Australian aborigines.

That a goodly store was to be collected there was evident from Roth's illustrations of numerous Queensland figures, unfortunately without directions for their making, published in 1902; from some collected by myself from a few restricted areas in 1914, and from Stanley's collections, again from north Queensland, in 1926. Mr. Davidson's studies form a much-needed addition to our knowledge of the subject and are the more valuable in that he traces the possible connexions of these Australian figures with those occurring in other parts of Oceania. According to his conclusions, string figures are of comparatively recent introduction into Australia from Melanesia, as they are found in greatest numbers in north-west Queensland, whereas in Western Australia they are almost lacking and what exist are of recent introduction.

Mr. Davidson considers that Australia, Melanesia, Micronesia and Polynesia comprise a major string-figure area, and from the evidence of the string figures themselves suggests the possibility that they were brought into the Pacific by the Polynesians or Micronesians, and spread from the west into New Guinea and western Melanesia late in the pre-Polynesian period. He suggests also that the diffusion of string figures into the New World and Africa from some Asiatic point of origin might have taken several thousands of years, but he does not appear to consider their possible spontaneous generation in unrelated areas. This is known to have occurred recently among the Brahmins in India and seems likely to be an explanation of their world-wide distribution, seeing that string—or its equivalent—is co-existent with man.

Mr. Davidson has described and illustrated some seventy string figures and in addition gives a comparative chart of their distribution; there is also a bibliography. If one might venture a criticism of one of his descriptions, taking a loop off a digit would seem to indicate removing it, whereas in "Movement Z" it means making the loop common to right and left thumbs. But this is a detail and in no way impairs the interest and value of the contribution.

K. Rishbeth.

THE MOA IN NEW ZEALAND

A recent valuable contribution to the natural history of New Zealand by Dr. G. Archey dealing with the moa* fully maintains the high reputation of the ornithologists of that country, and both the author and the Council of the Auckland Institute, who sponsored the work, merit our congratulations.

Almost from its inception the study of the moas has been accompanied by considerable confusion and uncertainty owing to the insufficient definition of types, and to the frequently erroneous association of different parts of the skeleton, an unsatisfactory state of affairs which Dr. Archey determined to remedy. After much patient work involving the examination of types and other specimens both in New Zealand and in England he has produced this excellent monograph of the moas.

Perhaps the most urgent need was for a knowledge of the associated skeleton in the various forms, and in accumulating material for this the author tells how greatly he was helped by many enthusiastic field workers who, since 1930, have discovered and collected in different parts of the North and South Islands no less than fifty fairly complete skeletons, and more than a hundred partial sets of bones of individual birds. Among the facts revealed by this mass of authentic associated material is the hitherto unsuspected occurrence of parallelism in one division of the moas. The author writes ". . . that two subfamilies with widely differing skulls, sterna and phalanges have independently embarked upon identical courses of development of shorter and heavier

* The Moa: a Study of the Dinornithiformes. By Gilbert Archey. Bulletin of the Auckland Institute and Museum, No. 1. Pp. 119+15 plates+9 tables of Measurements. (Auckland: Auckland Institute and Museum, 1941.)

leg-bones" (p. 8). Good evidence is supplied in support of the claim that from the characters of both skull and skeleton the moas can be separated into two natural divisions: "the tall Dinornithidæ, with flattened broad skulls and the normal number of phalanges, are regarded as standing apart from the others." The second division absorbs the remainder, which thus includes a considerable number of genera and species. These two sections are the equivalent of Dr. Oliver's Dinornithidæ and Anomalopterygidæ. Careful diagnoses and descriptions are given of the genera and species, and these greatly help to bring order into this rather unwieldy group. In habits these birds appear to have been tolerant of different climatic conditions, vegetarian in their diet, and dwellers in open scrub and grassland. Dr. Archey refuses to credit the great Dinornis with a maximum height of twelve feet, and thinks that it cannot have exceeded a normal walking height of ten feet. The phylogeny of the moas is of paramount interest, being related to the problem of the origin of all the large flightless birds, but the author does little more than review this subject, although he seems inclined to cling to the belief in a loss of flight through degeneracy. Dr. Percy Lowe's brilliant anatomical researches, coupled with the discovery of an ever-increasing number of large fossil flightless birds in nearly every region of the globe, forces this old belief to appear in a somewhat fantastic light.

The last section of the book, entitled "Development and Extinction", includes much diverse information. The author concludes that the evidence all points to the "final extermination of the Moa by the earliest Polynesian immigrants a considerable time ago, first in the North Island and later in the South, and probably before the arrival of the immediate ancestors of the present Maori tribes in the Fleet migration of 600 years ago" (p. 97). There are also new and interesting details about the occurrence of the remains, notes on recent geological happenings affecting the moas, and so forth. The volume is completed with a comprehensive bibliography, a series of tables of measurements of limb bones, and fifteen plates. This brief notice should serve to show that this is a volume which will be indispensable to every serious ornithologist.

D. M. A. BATE.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

SATURDAY, DECEMBER 6

INSTITUTE OF PHYSICS (LONDON AND HOME COUNTIES' BRANCH) (at the South-West Essex Technical College, Forest Road, Walthamstow, London, E.17), at 2.30 p.m.—Dr. W. G. Wearmouth: "Physical Problems in the Plastics Industry".

MONDAY, DECEMBER 8

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 3 p.m.—Lieut. L. G. Trorey: "Photographic Survey by High Obliques; the Canadian Plotter and Crone's Graphical Solution".

TUESDAY, DECEMBER 9

CHADWICK PUBLIC LECTURE (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 2.30 p.m.—Mrs. Blaise Gillie: "Post-War Housing in the Light of War-Time Experience".*

ILLUMINATING ENGINEERING SOCIETY (at the E.L.M.A. Lighting Service Bureau, 2 Savoy Hill, London, W.C.2), at 2.30 p.m.—Mr. R. Maxted: "Infra-Red Radiation and Equipment, their Application to Industrial Processes".

INSTITUTION OF MECHANICAL ENGINEERS (Joint Meeting with the Institutions of Civil and Electrical Engineers) (at Central Hall, Westminster, London, S.W.1), at 10.45 a.m.—Conference on "Air Raid Precautions and the Engineering Industry".

ROYAL INSTITUTION OF GREAT BRITAIN (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Prof. J. C. Drummond: "Recent Advances in the Science of Nutrition and their Significance in War-Time".

WEDNESDAY, DECEMBER 10

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Miss Elizabeth Denby: "The Post-War Home—Its Interior and Equipment". 2: "Using Space to Advantage".

PHYSICAL SOCIETY (COLOUR GROUP) (at the Electric Lamp Manufacturers' Association, 2 Savoy Hill, London, W.C.2), at 2.35 p.m.—Dr. F. H. G. Pitt: "Colour Blindness and its Importance in Industry".

THURSDAY, DECEMBER 11

PHARMACEUTICAL SOCIETY (at 17 Bloomsbury Square, London, W.C.1), at 2.30 p.m.—Mr. Thomas Tickle: "The Influence of Analytical Chemistry on Pharmacy" (Harrison Memorial Lecture).

FRIDAY, DECEMBER 12

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at the Mining Institute, Newcastle-upon-Tyne), at 6 p.m.—Dr. A. Caress: "Plastics and Engineering".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

PROFESSOR OF AGRICULTURE—The Principal, University College of Wales, Aberystwyth (January 15).

JUNIOR ASSISTANT DRAINAGE AND IRRIGATION ENGINEER by the Government of Sierra Leone—The Ministry of Labour and National Service, Central Register Branch, Queen Anne's Chambers, Tothill Street, London, S.W.1 (quoting E.330).

FIRST ASSISTANT PORT ENGINEER for the Basrah Port Directorate, Government of Iraq—The Ministry of Labour and National Service, Central Register Branch, Queen Anne's Chambers, Tothill Street, London, S.W.1 (quoting E.340).

SECOND ASSISTANT PORT ENGINEER for the Basrah Port Directorate, Government of Iraq—The Ministry of Labour and National Service, Central Register Branch, Queen Anne's Chambers, Tothill Street, London, S.W.1 (quoting E.341).

SENIOR ASSISTANT DRAINAGE AND IRRIGATION ENGINEER by the Government of Sierra Leone—The Ministry of Labour and National Service, Central Register Branch, Queen Anne's Chambers, Tothill Street, London, S.W.1 (quoting E.345).

ASSISTANT ENGINEER (CIVIL) for the Gold Coast Government Railway—The Ministry of Labour and National Service, Central Register Branch, Queen Anne's Chambers, Tothill Street, London, S.W.1 (quoting E.346).

NATURE

SATURDAY Dec. 13, 1941

HEALTH AND SOCIAL WELFARE

ALTHOUGH the health of the nation in war has recently been debated in both Houses of Parliament, the attention paid to the subject has scarcely been commensurate with its importance; indeed it might be held that in this matter Government action is in advance of public opinion. Upon the standard of health depends very largely the volume of production and also the quality of the Fighting Services, yet in the concern over absenteeism, as a report of the Select Committee on National Expenditure indicated, there has been little appreciation of the health factor as the result of excessive hours of work. The precious and vital asset of the good health of the industrial worker is yet to be fully appraised, even if we are more awake to the value of civilian health generally as a result of last winter's experiences.

A further encouraging picture of the nation's health generally has been given by the Chief Medical Officer of the Ministry of Health, while in the recent debate the Minister himself showed that the nation is entitled to congratulate itself on the avoidance of serious epidemics during the second as well as the first year of the War. This second year, moreover, included a period of intense air attack when large sections of the population lived in shelters, often insanitary, and in which material damage coupled with a large re-distribution of the population undoubtedly caused some overcrowding. That the public health has remained so good may well be more a matter of good fortune than of a well-planned policy for the health services, and there can clearly be no relaxation of vigilance. The Minister himself pointed out that good housing is the indispensable foundation of public health, and housing policy is necessarily in suspense.

It should be our first aim, therefore, to utilize this breathing space to adapt our health services to the harder conditions which may lie ahead, and two broadsheets issued by Political and Economic Planning (P E P) are welcome for their contribution to this end. The first of these, on "Health in War-time", points out that the problems of civilian health are potentially far more serious than in the War of 1914–18, mainly because the development of aerial warfare has made the wrecking of civilian community life and services a major objective in the attack on Britain. This is due not merely to the actual damage to public services, such as gas, water, electricity or sewers and consequent deterioration of public hygiene, or to hospitals and clinics, but also to the widespread existence of conditions making for fatigue and loss of satisfactory sleep, and to the indirect effects of the black-out in homes and work-places in reducing the supply of light and air and assisting the spread of air-borne infections.

The two major problems, however, are, as in 1914–18, how to ensure adequate nutrition and how to combat fatigue. The nutrition situation is still much better than in 1917–18, and the measures being taken by the Ministry of Food, of which the new scheme for extending the supply of meals and milk for school-children announced by Lord Woolton is a recent example, encourage the hope it may never deteriorate to the same extent. Confidence in this respect is strengthened by the evidence of co-ordinated policy and close collaboration not merely between the Ministry of Food and the Board of Education but also between the Ministry of Food and the Ministry of Transport, as indicated in a subsequent announcement regarding the rationalization of transport to eliminate avoidable cross-hauls and the control of transport of foodstuffs by the Ministry of Food.

The problem of fatigue is probably much more serious. It is estimated that the average adult has lost one hour's sleep a night, and in the bombed areas his sleep is less satisfying than in peacetime. Moreover, hundreds of thousands miss most of their sleep on a number of nights each month because of Home Guard, fire-watching or other civil defence duties. The ratio of civilian food intake to energy output has so far been reduced more from the output and less from the intake end than in 1914–18. Whether this will in the long run reduce physical resistance so as to lead to outbreaks of infection on a large scale is impossible to say. The situation is clearly fraught with long-term dangers and calls for the utmost vigilance, as well as fully justifying all the attention that Lord Woolton is able to give to the variety of diet and the character of nutrition as well as to its amount.

In such circumstances it is of the utmost importance to avoid any unnecessary taxing of health and strength whether in home life or in industry. For this reason alone the recent report of the Chief Inspector of Factories makes somewhat disquieting reading. The Senior Medical Inspector, it is true, finds no evidence that in general the health of the industrial worker has materially suffered in spite of all the adverse circumstances. Night work in itself is not lowering his physical standard, and the effect of long hours on production has led to some relaxation before it has had any real effect on the general health of the worker. Moreover, there is no evidence pointing to any appreciable number of accidents due to nervousness or jumpiness caused by air raids. The evidence is all the other way of courage and spirit in overcoming intense handicaps.

What is disturbing in this report is the evidence of close vigilance that is still required in respect of hours of work, and the alarming wastage of man-power and woman-power through preventible accidents. The question of long hours recurs throughout the report, and while many managements have learnt the lesson that excessive hours diminish production and that proper breaks and rest days are of great importance from the point of view of output alone, there is far too much evidence that other managements have forgotten or appreciate insufficiently the lessons of the War of 1914–18. The observations of the admirable report of the British Association for Labour Legislation issued last year on welfare and health in relation to hours of work and output in wartime remain pertinent. They are supported by a special report on the subject issued by the Industrial Health Research Board, as well as by evidence in the reports of the Select Committee on National Expenditure.

It is clear that in this matter greater stiffness in enforcing good labour conditions would promote production and efficiency as well as morale and health ; and a like observation applies to the question of accidents. Fatal accidents rose last year by 24 per cent and non-fatal accidents by 20 per cent over 1939, the figures for which were already 17 per cent and 7 per cent, respectively, higher than in 1938. This increase is attributed to relaxation of care, and particularly the neglect of training in accident prevention among the new industrial workers. While inspectors have to meet some criticism that accident prevention is rather an unworthy subject for consideration in war-time, when men in the Forces are taking every kind of risk, the criticism is unsound ; further, as the Chief Inspector points out, the Services are carefully trained not to take unnecessary risks.

What has yet to be realized by management, and sometimes also by workers, is the serious loss of output directly due to accidents caused by lack of reasonable care. This is a matter of increasing importance as the difficulty of replacement of workers and of parts increases. We cannot develop our full man-power and productive capacity until everything that foresight and sound management can suggest has been done to eliminate waste of this character.

This emphasis on the crucial importance of management in regard to health and efficiency is reflected in two other matters bearing on the health of the industrial worker to which reference is made in the same report. The Senior Medical Inspector stresses the need for the extension of a medical service in factories. Much yet remains to be done under the Factories (Medical and Welfare Services) Order of July 1940, and the increasing appointments of medical officers to factories will fail of their full effect without the goodwill and co-operation of both employers and employees. The

services of fully trained nurses have been greatly extended and they are entering industry in increasing numbers, and if the development of a comprehensive medical service in factories is a long-term policy which cannot be fully achieved in war-time, very considerable advances are none the less possible where managements are alive to the possibilities and realize the opportunities which are theirs through the responsibilities imposed in part under the necessity of civil defence.

The second matter which is one of the responsibilities of management is that of the provision of works canteens. To this subject a special section of the report is devoted. Rationing troubles, two- and three-shift working, travelling hardships, billeting, and bombed homes have made the works canteen an essential in war-time. The difficulties in regard to construction and equipment appear now largely to have been overcome, though resort to mobile canteens may be desirable where a policy of dispersal has aggravated the difficulties. Particularly among the smaller employers, conservatism remains an obstacle, and the factory inspectorate sees no alternative but the extension of communal feeding under the local authorities.

The question of canteens indeed illustrates the way in which the health of the industrial worker is linked up with that of the civil population. The extensions of the selective distribution recently announced by the Ministry of Food should in themselves give a direct impetus to the canteen movement, and the policy of redressing the grievances or inequalities which are inseparable in a uniform rationing system in this way is unquestionably sound. Before the end of the year, eighty-five per cent of miners will be receiving supplementary rations served out at the pithead, and the issue to heavy workers of special rations in their canteens or other catering establishments is sound from the health as well as from the production point of view.

These may be described as a short-time programme, but whether they and the long-term programme for the adequate feeding of children will prove effective depends on other factors—continued success in the Battle of the Atlantic, the rigorous elimination of waste, effective administration of the policy itself, and not least the progress of our own efforts to increase food production. The marriage of health and agriculture which is being realized under our eyes is one good thing that has come out of the War, like the fuller utilization of our rapidly advancing knowledge of nutrition. The P E P broadsheet rightly lays stress upon the great asset we possess in this respect compared with 1914, particularly through advances in chemotherapy, in blood transfusion techniques, in radiology, in the understanding of problems of industrial health and fatigue and of the mechanisms of the spread of air-borne infections, and other branches of medical science.

This linking up of nutrition and health with agriculture is a noteworthy example of the way in which provision for war-time needs is serving those of long-term policy or reconstruction after the War. The hospital services themselves provide yet another outstanding example; air warfare has already forced upon us a transformation of our medical services. The admirable analysis of the Emergency Hospital Scheme contained in the second P E P broadsheet, on "Hospitals in War Time", not only reviews the scheme in action, but also makes constructive proposals for the improvement of this highly centralized organization.

The first of these proposals is the development of the Emergency Hospital Scheme into a National Hospital Service. The estimates of expected casualties should be reviewed, but the State should continue to pay full treatment costs for Service cases and air-raid casualties, and also for all children, as well as residual costs for full-time civil defence workers, Home Guards, etc. A direct State subsidy to hospitals to maintain their working efficiency is proposed. Changes in central administration involve transforming the E.H.S. Division of the Ministry of Health into a National Hospital and Medical Services Division, and the Ministry would have to play a more positive part to ensure that hospital services everywhere are brought up to an adequate level for the needs of the whole population.

These proposals involve greater regional autonomy and co-ordination. They can only be carried out if the Ministry's regional staffs are strengthened and greater powers delegated to them. The regional and group officers must be carefully selected for administrative ability and be vigorously backed by the Ministry. Other proposals relate to the further development of services: for example, out-patient departments and specialist clinics at appropriate base hospitals, pædiatric services in all reception areas, regional courses on the structure of the E.H.S. and its experiences in action, on war surgery in general, on blood transfusion, poison gas, rehabilitation of the injured and the nursing of war wounds.

Finally, the broadsheet proposes machinery for the planned use of medical man-power, including the transformation of the Central Medical War Committee into a War Medical Service Committee, representing all the interests involved, to determine priorities, to allocate medical men to the various civilian and military services, and to plan their geographical distribution and full employment. Working through regional committees, incorporating the machinery of the existing local

medical war committees, which register local medical men for national service and recommend how they should be allocated, this proposal might not only facilitate the transference of private practitioners to correspond with the movements of population, but also assist in the use for civilians of medical men in the armed forces who are not fully utilized at present—a question already much discussed by practitioners and social workers and one which may soon become an urgent general question.

Since the broadsheet appeared the Government has announced the broad principles on which its post-war policy will be based. The partnership between the local authorities and the voluntary hospitals is accepted, not merely as the existing basis of the hospital services but as the necessary basis, supplemented by sufficient Government support to ensure that as soon as possible after the War appropriate treatment should be readily available to all in need of it through a comprehensive hospital service. The Government proposes to lay on the major local authorities the duty of securing, in co-operation with the voluntary agencies, the provision of hospital services, and that the service must be designed to serve areas substantially larger than those of individual local authorities, so as to avoid wasteful multiplication of equipment and accommodation. The Government also proposes to secure the provision of the more highly specialized services at teaching hospitals and other selected centres.

These proposals, though less detailed, are clearly in line with the general ideas underlying the recommendations of the P E P broadsheet. Both sets of proposals visualize the construction of the new hospital service on the experience of the past, and the synthesis of traditions and techniques, previously separate, in the service of a wider movement. Nowhere indeed are there wider possibilities in the building of a healthier social order than in this field of public health, if we but utilize aright the new knowledge and experience of nutrition and healing, of regional organization and administration which lie at our command as a result of research and development, in part through the impact of the War. Social habits, both of diet and of occupation, have been broken down, giving us immense opportunities of raising the whole standard of life and health, if we are ready to seize those opportunities after the War. Nor need we wait until after the War. As Lord Horder has reminded us, in this matter of food and fitness, health and education, child welfare and agriculture, we can begin now in the very service of our war effort.

WORLD ECONOMICS AFTER THE WAR

Economic Peace Aims: a Basis for Discussion
By Oswald Dutch. Pp. 280. (London: Edward Arnold and Co., 1941.) 12*s*. 6*d*. net.

MR. DUTCH begins his book with an excellent destructive account of the muddle which was made, especially from the economic point of view, of the settlement of European affairs after the War of 1914–18. This encourages the hope that he will be equally successful in making practical proposals for the settlement after this War. But this hope is disappointed. Mr. Dutch wavers continually between an almost Utopian optimism —as when he proposes that the world shall become practically a free trade area without any barriers in the way of free exchange within about a twelvemonth of the conclusion of hostilities—and a contrasting pessimism which causes him to harp on the dangers of over-production and the need for a universal system of quotas, which are somehow mysteriously to be prevented from operating in the same restrictive fashion as capitalist monopolies have by his own admission been operating in recent years. Again, Mr. Dutch is so haunted by the fear of totalitarianism in all its forms that he appears unable to recognize anything of value in the achievements of the Soviet Union, which he continually brackets with Nazi Germany and Fascist Italy as a horrible example of the destruction of every kind of human liberty.

Mr. Dutch is, in effect, an advocate of controlled capitalism as the instrument of post-war reconstruction over all the world. "The primary and most important fundamental for fixing the status of capital in a new economic plan must be that property remains untouched. There must be no capital levy, no expropriation, no breaking up of landed property, and no abolition of hereditary rights." In view of this sweeping statement it is not surprising to find that, in spite of his devotion to the cause of liberty, he has no hesitation in recommending the conscription of labour for the work of reconstruction. "It will be advisable not to demobilise these men [the armed forces, except those who have definite jobs to go back to] but to put them to work in groups, under army discipline but at full rates of pay." I fancy that, in all countries, the returning conscripts will have

something to say about this simple plan, especially if Mr. Dutch's views about the immunity of capital are carried into effect.

The truth is that Mr. Dutch very simply identifies democracy with capitalism. He recognizes that capitalism will need to accept a large element of State planning in the post-war world, but he assumes that ordinary men and women will be quite content to accept a military discipline that will compel them to work for controlled capitalism acting as the agent of public policy. "This work" [the work of reconstruction], he says, "will not of course be carried out by the State directly but by private firms commissioned by the State." Very possibly it will, but the human beings whom the State is to send to work for these private firms' profit will in that case be disposed to ask a good many questions to which Mr. Dutch neither provides nor attempts any answers.

For the rest, Mr. Dutch shares the projector's habit of specious particularity in prescribing measures for the post-war world. He is at home when he is neatly classifying things, and saying categorically that this and that will be done. But sometimes his particularity conceals a real confusion of mind. It is, for example, quite impossible to extract from his various statements any clear notion of the position which he expects Great Britain to occupy in the economic or political structure of post-war Europe. Sometimes it appears that Great Britain is to be an integral part of a unified European system, and at others that Great Britain, linked to the British Empire, is to stand outside, but related to, a Continental system in much the same way as the United States. He recognizes clearly the part which the United States will be called upon to play, not only in the immediate tasks of relief but also in the long-term reconstruction and development of the European continent and of the backward countries of Asia and the rest of the world. But in relation to Great Britain he shows a marked desire both to eat his cake and to have it, by treating Great Britain both as a part of the European system and as a partner with the United States in reconstructing a European system to which she will not completely belong. "Resolutions taken by the Parliament and Government of the Commonwealth will be restricted to Continental affairs and Great Br tain will be excluded from the territorial sovereignty of the Commonwealth Government. Great Britain will have to share in much of the responsibility for Continental affairs, especially in matters of defence, finance, and economic problems. On the other hand, the European Commonwealth will have no responsibility for British affairs." This, and the chapter from which it is taken, seem to me merely muddled. I have no conception of what Mr. Dutch really means.

I do, however, understand what he means when he writes that "the masses of the peoples must be transferred from war to peace work at once without giving them time to organize themselves elsewhere or to carry out any extremist plans". I think Mr. Dutch's conception of democracy is that of a society in which, on one hand, there is "no capital levy, no expropriation, no breaking up of landed property, and no abolition of hereditary rights", and on the other hand, the peoples are compulsorily driven to labour "without giving them time to organize themselves elsewhere or to carry out any extremist plans". This is not my conception of democracy; and I find it, to speak plainly, quite infuriating in one who appeals to his readers in democracy's name. I suppose Mr. Dutch believes himself to be a democrat, and is not pulling his readers' legs. But I sincerely hope no one will take him as a guide to the foundation of our economic peace aims, and at the same time greatly fear that many people will; for he presents just the sort of muddled eclecticism which is calculated to appeal to those who wish to believe that the new world can be at once altogether different from the old and a secure repository of all the ancient values which they personally would like to preserve.

G. D. H. COLE.

A REVIEW OF THE ALGÆ

An Introduction to the Study of Algæ
By V. J. Chapman. Pp. x+387. (Cambridge: At the University Press, 1941.) 18*s*. net.

THERE has long been a need for a short general account of the Algæ, for the various works published during recent years are either detailed treatments, often dealing only with certain aspects, or specialized taxonomic works. The book under review aims at supplying this need and endeavours to deal briefly with the study of Algæ from every point of view. The task that the author has set himself is no light one, and for its successful accomplishment both considerable experience and a judicious handling of the subject-matter are requisite. Despite diverse defects, Dr. Chapman's book will undoubtedly prove of value to those wishing to obtain an outline knowledge of the range of form and reproduction and of the manifold roles that Algæ play in Nature. The author has shown great industry in assembling the wide range of

matter that is covered, but one cannot help feeling at the outset that he has detracted seriously from the value of his work by endeavouring to include too much and by the manner of presentation, which lacks continuity. It is difficult at various points to get away from the impression of rather hasty compilation, and diverse sections would have profited from a more carefully considered and balanced treatment.

Rather more than two thirds of the book is taken up by the taxonomic and morphological matter, and here the Chlorophyceæ and Phæophyceæ occupy the bulk of the space. The sections on Cyanophyceæ, Xanthophyceæ and Rhodophyceæ are brief, while all other classes receive little more than mention. In each main section, after a short introduction, a series of 'types' is described. Apart from the question whether such separate consideration of genera is the most suitable method of introducing the reader to an acquaintance with the Algæ, too many examples are often selected. This has the disadvantage of confusing the picture, the more so as individual descriptions are commonly so inadequate that one may doubt the value of their inclusion. As examples, Chordaria, Elachista and Corallina may be mentioned, while the account of Sporochnus gives no conception at all of the structure of this remarkable form, so fully studied by Kuckuck and Sauvageau. The choice of 'types' does not always appear to be very appropriate. Among the true desmids, for example, the only genus considered is Closterium, which is divergent in various respects. It is difficult to understand why Martensia is brought in on p. 230, when the multinucleate character of the tetraspore mother-cell is equally well shown by the British *Nitophyllum punctatum*. Nemalion is referred to at the end of the description of Batrachospermum because of the division of the spermatium-nucleus which is also recorded in the latter, while more important features, such as the fusions in the carpogonial branch of Nemalion, are not mentioned.

The subject-matter is in general up to date, but if the author had delved rather more deeply into the Continental literature, he would have avoided several misstatements or omissions. Thus, the unilocular sporangia of *Ectocarpus virescens* (p. 134) were described by Sauvageau in 1933, and Papenfuss described the gametophytes of Spermatochnus (p. 148) in 1935. Under Sphacelaria prominence is given to the rather inconclusive work of Clint, while that of Papenfuss which, together with that of Schreiber on Cladostephus (1931), sheds considerable light on the nature of the life-cycle in Sphacelariales is afforded a rather casual mention. A perusal of Nienburg's work (1913) would have contributed to a clearer presentation of the development of the conceptacle in Fucales. The account of cell-structure of Cyanophyceæ is scarcely in accord with the present state of our knowledge. A number of erroneous statements, for example, the reference to Phacotus as a colourless form, that relating to the orientation of the flagella in Dinophyceæ, and the development of the cystocarp-wall in Polysiphonia, should have been avoided. There are other inaccuracies. For example, red snow (p. 33) is due to a species of Chlamydomonas and not of Sphærella, as was shown long ago by Wille, the 'trumpet-hyphæ' of Laminariales are almost certainly for the most part neither connecting threads nor hyphæ, while the account of the mature Thalassiophyllum plant accords ill with the familiar figure of Postels and Ruprecht.

Statements are made in various parts of the book that appear to lack any sound foundation; examples are the suggestion of homoplasy between Merismopedia and Prasiola, that the original centre of distribution of Laminariales was in the North Pacific, and that there is an affinity between Trentepohlia and Phæophyceæ. The chapter on reproduction and evolution is in my opinion a definite backward step, and the matter is presented in such a form that the student will find difficulty in following it. A scheme such as that given on p. 261 has no support whatever in fact and is contrary to all modern teaching, while the value of phylogenetic trees like that on p. 262 may be questioned. The final chapters dealing with physiology and ecology contain a considerable amount of useful though not very thoroughly digested matter. The account is, moreover, marred by too much tabular presentation, and the treatment is in part rather one-sided. Why, for example, should a range of salt-marshes be considered, while the account of lake communities is restricted to Windermere? Why should freshwater and marine plankton be almost entirely ignored and yet several pages given to a tabulation of various classifications of life-form among the Algæ?

The brief citations of literature at the end of each chapter are perhaps intentionally rather one-sided, since reference is often made mainly to British and American papers. A considerable number that are included are, however, rather paltry and might with advantage have been omitted to make place for others of greater importance. One is surprised, for example, to find no mention of Killian's paper on Laminariales, of Sauvageau's classical memoir on Sphacelariales, and of Kylin's more recent contributions to Floridean morphology. The copious illustrations occasionally suffer from too much reduction or from crowding.

F. E. FRITSCH.

VEGETABLE PRODUCTION IN THE TROPICS

Vegetable Gardening in Malaya

By J. N. Milsum and D. H. Grist. (Malayan Planting Manual, No. 3.) Pp. xviii+215+52 plates. (Kuala Lumpur: Department of Agriculture, 1941.) 2 dollars.

IN recent years British Colonial policy has been largely directed to matters of nutrition, and the health and well-being of the native inhabitants have been matters of particular concern. In many Colonies the development of export crops had, for long, been the main interest, and such research and experiments as have been undertaken were largely devoted to these crops. Latterly, however, the need for the investigation of the food crops of the people has received increased attention, and new discoveries in the realms of human nutrition have brought to light the unbalanced ration on which so many of the people have had to subsist, and more particularly the need for the increased consumption of those foods containing the so-called 'protective elements'.

The book under review deals with vegetable gardening in Malaya and is a sequel to two previous publications on the same subject published by the Department of Agriculture of the Straits Settlements and Federated Malay States. The senior author of this edition has been associated with all three publications. This one includes and brings up to date much of the information incorporated in the previous volumes.

The present book is a complete compendium of vegetable gardening in Malaya. It includes detailed accounts of the most important of the native vegetables grown, and also some of the newer introductions of foreign origin. So many of the gardening books of the tropics have included the cultivation of fruits and flowers, that they are somewhat unwieldy, and as a result the section devoted to vegetables has often been too scanty. A similar mistake has not been made in this instance where the work is confined strictly to the cultivation of vegetables. Useful chapters describe the methods of preparing the land, and the common insect pests and diseases and ways of controlling them. There is also an account of the vitamin contents of the different kinds of vegetables, written in popular language, which is a novel and welcome addition. The description of the cultivation of European vegetables in the highland area is all too brief and might with advantage have been expanded. These high plateaux in the wet tropics present particular difficulties. The temperature is cool enough to suit vegetables from the temperate regions, but the heavy rainfall and the high humidity make matters difficult, and doubtless special varieties will need to be bred to meet these special conditions. These difficulties appear to have been overcome to some extent in the Cameron Highlands by raising the plants under glass-topped frames. An account is given of this method, which may well be worthy of trial in other similar regions in the tropics, but one is inclined to wonder whether the capital cost of such installations might not prove too heavy.

The chapters on economics are of particular interest. A comparison with the neighbouring island of Java shows that the latter country with a teeming population of more than fifty millions is able not only to supply its own needs, but also to export vegetable products to Malaya to the value of half a million dollars. Malaya is in fact largely dependent on outside sources of supply and obtains large quantities of vegetables from China and India. One of the reasons for this state of affairs is the comparatively infertile nature of the soils. In Java the soils are rich, being derived from rocks of modern volcanic origin, but in Malaya, the underlying strata belong to geologically ancient formations and the soils have been leached of their mineral salts by hundreds of years of tropical rainfall. Another contributing factor is the different character of the population. In Java every person is an agriculturist and skilled in the cultivation of the soil, but in Malaya this is not the case, and the Malay was, until recently, accustomed to seek his livelihood on the sea or in the jungle, and did not take kindly to the settled life of a farmer. It is for this reason that we find that even at the present time nearly all the vegetables produced in Malaya are grown by the Chinese, who have settled in the country in comparatively recent times. The Chinaman is the gardener *par excellence* of the tropics. One may not admire all his methods from the strictly hygienic point of view, but he does produce the goods. Further, as is clearly brought out in this book, he thoroughly understands the art of watering and the necessity for abundant supplies of humus and organic fertilizers. He invariably adopts mixed farming methods to supply these needs, and for this reason he combines the keeping of pigs and poultry with his gardening, and is able to convert most unpromising sites, such as the tailings of a tin mine, into flourishing market

gardens. He imports much of his seed from China, and there is no doubt that the varieties of certain cruciferous, leguminous and salad plants which he grows—and they are numerous—would well repay the critical survey of seedsmen from Western countries. It would be fairly safe to prophecy that such a detailed examination would result in the discovery of additions to our present list of cultivated vegetables, which would be of great value to the plant breeder.

Efforts are now being made by the Department of Agriculture to persuade the Malays to emulate the example set by the Chinese. The latter seem to have the trade for the supply of vegetables in bulk to the towns in their hands, but there is no reason why the Malay cultivator and the estates should not do more towards growing sufficient for their own requirements. The efforts that are being made in this direction are well described, and the drive is being stimulated by existing war-time conditions, which have resulted in a shortage of shipping and thus of imports.

The book is illustrated with photographs of the more typical vegetables and is well worthy of the study of all people interested in tropical gardening.

GEOFFREY EVANS.

THE NEW PHARMACOLOGY

The Pharmacological Basis of Therapeutics
A Textbook of Pharmacology, Toxicology and Therapeutics for Physicians and Medical Students. By Prof. Louis Goodman and Prof. Alfred Gilman. Pp. xiii+1383. (New York: The Macmillan Company, 1941.) 50*s*. net.

In the past, most important pharmacological discoveries have been made in German universities and German commercial laboratories, but in recent years the work of American pharmacologists has been growing rapidly in importance. "The Pharmacological Basis of Therapeutics", by Profs. Goodman and Gilman of Yale, is a valuable review of this American work.

The authors must be warmly congratulated on this remarkable book. It is written from the clinical point of view; experiments on man are described more fully than experiments on animals, the results of which are given without detailed discussion, so that the book is a work of reference for the intelligent medical practitioner rather than an exposition of the methods which have led to such remarkable advances in pharmacology in recent years. In this respect the book resembles many recent text-books of pharmacology, which have tended to concentrate on the applications of the results to man. This tendency is in many ways a good one, but there is a danger that it may go too far, and that the student may never learn that pharmacology is a living experimental science, which has had great practical effects.

Most medical students will find this book too long, but it will be very valuable for teachers and experimentalists. It contains thousands of references to recent work, a large proportion of them to papers published in 1940. It opens with 100 pages on anæsthetics, and there are 180 pages on cholinergic and adrenergic nerves, more than 100 pages on sulphanilamide and related drugs, 88 pages on hormones and 60 pages on vitamins, with equally complete sections on other branches of pharmacology.

All this wealth of information is apt to have a humiliating effect on anyone who has tried to keep abreast of pharmacological literature, and to stimulate a search for omissions. The clue to success in such a search lies in the fact that the European literature has been less well covered than the American literature. For example, in the section dealing with emetin cathartics, it is stated that the time required for the drugs to traverse the small intestine, and the necessity for a chemical liberation of the active principle, delay the cathartic action, but there is no discussion of the work of Straub, which showed that delay in the small intestine played no part in the time of action of senna, which was not affected by tying the small intestine so that the drug could only act through the blood stream.

The release of histamine in anaphylaxis is dismissed as if it were a dubious speculation rather than a well-proved fact, while the release of histamine by the exposure of sensitive individuals to cold is thought to be established by the isolated observation that an acid gastric juice is secreted.

The section on sympathomimetic drugs contains no mention of perovitin (or methedrine) which has aroused interest in Great Britain because it has been said to have been used to increase the endurance of German parachute troops.

In spite of a few such omissions, the text as a whole is very full and up to date, and gives a very fair account of controversies still raging. It is the kind of work that might have been the fruit of the collaboration of a team of authors, and it is difficult to think how two men did it.

J. H. GADDUM.

The Physical Examination of Metals

By Dr. Bruce Chalmers and Dr. A. G. Quarrell. Vol. 2: Electrical Methods. Pp. viii+280+8 plates. (London: Edward Arnold and Co., 1941.) 20*s*. net.

IN Vol. 1 (reviewed in NATURE, 145, 660; 1940), Dr. Chalmers described optical methods of metallurgical investigation. In the present volume, he unites with Dr. Quarrell, a pioneer in the development of electron diffraction research in metallography, to deal with electrical methods, thus completing a work which will be a boon to the research worker and an indispensable part of students' reading.

The scope of vol. 2 is reviewed in its first chapter. It is logically planned, commencing with magnetic properties and their measurements. Electric measurements and thermo-electric effects are then discussed. X-ray diffraction technique, as applied to metallurgy, is then dealt with and electron diffraction methods follow. The present position of electron microscopy is then examined. The final chapter deals briefly with radiography. Appendixes are devoted to electrolytic polishing and X-ray crystallographic data.

This book successfully combines theoretical treatment with practical outlook. The authors have certainly succeeded in their attempt "to indicate the scope and limitations of the various methods . . . by reference to successful applications". One application, hitherto unpublished, is a very pretty microthermal analysis (p. 108), for which Dr. Chalmers managed to do without any gramophone needles.

Perhaps because it is regarded as engineering rather than metallurgy, stress analysis is not dealt with in the discussion of X-ray diffraction methods.

Modern Assembly Processes

Their Development and Control. By J. L. Miller. Pp. xii+168+28 plates. (London: Chapman and Hall, Ltd., 1941.) 13*s*. 6*d*. net.

IT is possibly strange that engineers have had to wait so long for a book dealing specifically with jointing methods used in the large-scale production of small parts. So far as Great Britain is concerned, it is probable that everybody has waited for Mr. Miller to write it. Those readers who have not the good fortune to know the author personally, will learn from this book that he is a first-class engineer of very long practical experience and gifted with the intelligent curiosity and enthusiasm which most people lose when they gain years of discretion. Those who do know him will enjoy meeting him again in these pages, packed with common sense, and will take particular pleasure in the simple logic with which each point is explained.

The processes dealt with are riveting, soft soldering, hard soldering and brazing, hydrogen furnace brazing, pressure and shrinkage fits, fusion welding by gas and arc methods and electrical resistance welding. The advantages and limitations of each method of jointing are clearly stated and the fundamental principles, on which a choice should be based, are admirably stressed. The chapters on hydrogen furnace brazing and projection welding are unique, since the author has had unique experience in developing and applying these processes; but there are few chapters in which the most up-to-date engineer will not find something useful, and the wisdom of Chapter 14, "Testing, Inspection and Trouble Hunting", is worth every penny of the book's purchase price.

Polynesian Paradise

An Elaborated Travel Journal, based on Ethnological Facts. By Donald Sloan. Pp. 288+15 plates. (London: Robert Hale, Ltd., 1941.) 12*s*. 6*d*. net.

THIS book is a departure from the usual type of story from the South Seas in that it contains quite a lot of information that will interest an anthropologist. The author lived for several months on Manu'au, an isolated group of three volcanic islands inhabited by Polynesians of Samoan stock. These islands are off the usual routes and their isolation has been jealously guarded by the United States of America, to whom they belong, in order to preserve their integrity. This is the more easily done as the Manu'ans themselves are a conservative race and cling to their old ways of life.

By living among them as he did, the author was able to enter freely into their daily life, and he obviously made good use of his opportunities. As a personal guest of the chief he was present, and partook of, all the important feasts and ceremonies, including those for the burial of the chief and the marriage of the village virgin. He gives full accounts of these as well as of the daily life of these unsophisticated people, with whom he was evidently on excellent terms. While there he learned, among other things, to fight with and kill a shark single-handed and armed only with a sharp knife: dealing thus with a seven-foot man-eater provides a truly Homeric contest.

Natives such as those Manu'ans who dwell in isolated parts and live out their lives in the old traditional way are always an interesting study, and although this book is perhaps more adventurous than deeply scientific, it may be none the worse for that as it is likely to interest a wider circle of readers in an extremely important study—that of the unspoilt native peoples.

Introductory Foods

By Oseo Hughes. Pp. vii+522. (New York: The Macmillan Company, 1940.) 12*s*. 6*d*. net.

THIS book will be regarded as throwing interesting light on the impact of nutritional science on cookery practice in the United States. It shows how the American housewife has become 'food-conscious' and 'vitamin-conscious', and why she has been diverted from the straight and honest path of Mrs. Glasse and Mrs. Beeton. The author has given quite a good scientific background to the hundred and one cooking problems he discusses. Vitamins, viscosity, surface tension, denaturation, crystal form are only a few of the scientific problems dealt with.

FOOD FROM THE GARDEN

By DR. H. V. TAYLOR
MINISTRY OF AGRICULTURE
AND
DR. J. C. DRUMMOND AND DR. M. PYKE
MINISTRY OF FOOD

IN peace-time, gardening was merely a hobby to a great many people. In consequence it was common to have a superabundance of vegetables in the summer and insufficient in the winter. Very few people before the War gave any thought to the food value of the crops they grew in their gardens. Nowadays, however, it is essential that vegetables should be produced in a systematic sequence throughout the year and that those vegetables should be grown which will provide in greatest abundance the food constituents most needed in the war-time diet.

The method of cropping described in 1939 by the Ministry of Agriculture in Bulletin No. 1, "Food from the Garden", was designed to fulfil these requirements. The Bulletin contained a cropping plan of the area to be devoted to each crop, the time of sowing and the period of use of each crop. Gardens and allotments were planted in this way during 1940 in most towns of England and Wales. Ninety-eight gardens and allotments, each of ten perches in size, planted in this way were selected and records were made daily of the weight of the crops and the time of gathering. From the complete records set out in the accompanying tables it will be seen that the yield averaged for all these gardens for the year was 411 lb. of potatoes and 1,085 lb. of other vegetables.

Although potatoes and some other vegetables can be stored for considerable periods, it is essential for any plan to be satisfactory in war-time that it ensures a continuous supply of fresh vegetables throughout the year and especially during the winter period. In each of the four quarters of the year at least a dozen different vegetables were available from the planned allotments. In the summer period, for example, there were broad beans, runner beans and dwarf beans, cauliflowers, carrots, peas, lettuce, spinach and turnips. The weekly supply of vegetables other than potatoes during each season was approximately that shown as follows:

	Gross weight lb.	Edible weight lb.
Summer	19	12·4
Autumn	19	14·8
Winter	26	19·7
Spring	17	11·2

From these figures it can be seen that not only has the continuous weekly supply throughout the year been achieved, but also that an increased supply is available during the winter when it is most needed.

When the Ministry of Agriculture cropping plan was devised it was known that the field supplies of potatoes would be more than sufficient. In consequence the garden and allotment crop was planned only to provide the household with potatoes until Christmas. In actual fact the gardens from which records were taken gave 82 lb. during the summer period and 330 lb. during the autumn months. This represented a weekly supply of 6 lb. of new potatoes during July–September and 24 lb. a week of main crop potatoes during October – Christmas.

According to Orr and Lubbock[1] the amount of vegetables eaten per week during the period 1937–1939 was 4·2 lb. of potatoes and 1·66 lb. of other vegetables. These authors recommended that the desirable consumption during war-time of veget-

ables other than potatoes should be 2·6 lb. a week. On this basis the vegetable supply from each of the ninety-eight gardens was sufficient for a family of five people for the whole year and in each season of the year.

Nutritive Values

Although potatoes supply a substantial proportion of carbohydrates, and thus of calories, to the diet and they and other vegetables provide a certain amount of protein, vegetables are primarily of importance for their 'protective' value, that is to say, the vitamins and mineral salts contained in them.

For an adult a good daily allowance of vitamin A is about 5,000 international units and of vitamin C about 50 mgm. These are the two vitamins which vegetables can primarily supply. Vitamin B_1 is derived from wheatmeal bread and other cereals and to a less degree from potatoes, pork and meat, although green vegetables make some contribution.

It will be seen from the accompanying tables that the vegetables produced according to the Ministry of Agriculture cropping scheme provide the full dietary needs of vitamin C throughout the year for from 8 to 12 people. Considerable losses due to wastage, cooking and other causes may be expected, so that it would be conservative to consider this equivalent to the true requirement of a family of 4 or 5 people. This is a most valuable contribution to the national diet and one which can only be achieved by planning vegetable production with a clear appreciation of the object in view. This contribution of vitamin C made to the diet by vegetables is particularly noteworthy at a time when fruit is difficult to obtain. The amount of vitamin A provided in the form of carotenoid precursors, mainly β-carotene, while not so ample as that of vitamin C, is nevertheless a most substantial proportion of the family requirement. The loss of vitamin A in cooking is very much less than that of vitamin C.

Examination of Table 2 in detail shows the contribution made by each vegetable. For example, carrots, which are available throughout the year, provide the major proportion of vitamin A. It would therefore be inadmissible to substitute any other crop for them. Similarly, savoys, which are available in the period January–March, maintain the supply of vitamin C at that time. The amounts of such minor crops as beets, shallots or turnips may be varied to some extent according to taste, but alteration in the quantities of winter greens, for example, and particularly carrots, will weaken considerably the whole plan of a continuous supply of 'protective' nutrients.

Beside their primary role in the diet as sources

* Figures based on carotene analyses of vegetable groups.

of vitamins A and C, the vegetables produced from an allotment provide a useful percentage of the mineral elements in which war-time food is likely to be deficient. Calcium particularly, which is important for growth and the structure of the bones in children and for adult well-being, is present in substantial amounts in green vegetables such as kale, sprouting broccoli and turnip tops, and in appreciable quantities in many other vegetables.

Conclusion

The results of a critical assessment of the produce grown during 1940 on ninety-eight gardens and allotments show that, under the system of cropping recommended by the Ministry of Agriculture, a fairly even supply of vegetables is secured, with the larger quantities being available during the winter months. These vegetables can probably supply the vitamin C requirements and a substantial proportion of the needs for vitamin A for a family of five people throughout the year, taking into consideration losses due to cooking and other causes. In addition, they provide substantial contributions of other vitamins and of minerals, particularly calcium and iron. The importance of cropping gardens and allotments in this way cannot, therefore, be stressed too strongly.

[1] "Feeding the People in War-Time", by Sir John Orr and David Lubbock, Macmillan (1940).

APPLICATIONS OF PARTICLE SIZE ANALYSIS

By Dr. E. G. Richardson
King's College, Newcastle-upon-Tyne

Many methods are available for the delineation of the size-frequency curve of a substance in amorphous form, but most of those in current use are adaptations of the microscope or of sedimentation technique. Each of these has certain disadvantages. The microscope—whether it employs a beam of light or a beam of electrons—demands the careful selection of a representative sample, and much tedious measurement of the cross-section of individuals, setting aside problems of optical resolution and distortion. Rather similar criticism applies to the X-ray method, though this seems only to have been applied to a system having particles of nearly equal size. A method in which the powder is allowed to settle in a suitable fluid medium, either in a gravitational or centrifugal field, or alternatively is held stationary or driven against such a field by a suitable upward fluid current, on the other hand, demands an assumption of Stokes' Law or one of its recent modifications, and also requires that the powder is not so concentrated in suspension that neighbouring particles interfere with each other's movements, and that temperature gradients may not give rise to convection currents. It is also necessary to see that the estimation of the 'weight of a sample'—using the words in a statistical and not in a literary sense—which is taken from time to time as the powder settles does not spoil the course of the sedimentation. Probably, the 'photo-extinction method', in which the weight of a sample is estimated by casting a beam of light athwart the settling tank to fall on a photo-electric cell, is the most accurate as well as the most convenient of these, particularly as it will work with quite small amounts of the powder.

It is not, however, the purpose of this article to discuss the methods themselves[1], but rather to direct attention to the increasing number of applications of the technique in the spheres of applied physics and chemistry.

Applications to Powders

One of the difficulties that trouble the employer of this technique is to ensure that the degree of dispersion which exists in the sample chosen for analysis persists during the examination itself. For example, if particle-size analysis is chosen as one of the fundamental physical factors in describing soil properties, as it undoubtedly should be, how can the state of aggregation and relative positions of the grains be preserved during their transfer to the microscope or sedimentation tank? Indeed, since in either apparatus the particles must be separated or diluted to a certain extent, the purist would say that the analysis ought only to be done *in situ*, which in the present state of the technique is impossible.

For some materials, sedimentation at low concentration is favoured, with the addition of a reagent like ethylene glycol to the liquid, into which the powder is vigorously stirred, short of causing actual abrasion. If it is intended to study the effect of such deflocculating agents on the results as well as to obtain a set of results representative of the original sample, the unfortunate operator has indeed been set a difficult problem.

It is evident that each industry must work out its own dispersion technique in international collaboration if results in different laboratories are to be comparable, though the agreed results may still not represent the powder in its natural state.

Particle-size analysis is constantly being used to determine the efficiency of grinding and milling processes and to estimate to what extent equality of fineness may be produced in similar mills when used by different operatives or in different factories. The problem presents itself as that of deciding how a certain property depends on the granularity of the powder or material in which it is incorporated, and then of finding to what extent a specified degree of fineness can be reproduced in practice.

Thus in the baking industry, particle size is one of the chief features which discriminate those flours which are suitable for cake-making from those which will form a good bread dough. In the accompanying table are shown the results of some analyses of different types of commercial flour. It will be noticed that there is not much difference in the two commercial bakers' flours, but the flour made from the Irish wheat, being softer to the touch, has a greater percentage of fine particles. On the other hand, the strong imported flour from Canada tends in the other direction and has more large grains than the British-milled commercial flour. The speciality cake flours are all finely ground, but there are differences between them, those with the maximum of fine particles being found most useful for special cake processes[2].

Occasionally, there seems to be a critical size which is most effective in a given process. A specific size is often mentioned in connexion with the dust problem in mines, whether as causing explosions or in diagnosing the cause of miners' silicosis. Pigment colours reach a maximum brilliance for a certain grain size probably associated with the wave-length of the light absorbed or reflected. On the other hand, certain light-influencing factors such as the brilliance of fluorescence in phosphor powders continuously increase as the particles causing it get smaller, apparently because on a given covered area the total surface of the exposed grains increases as they get smaller[3].

In those cases where the physical property which it is desired to influence depends on pore space, the size of the units which make up the texture of the material is equally a determining factor. The insulating plasters used as acoustic absorbents form an example. For a given total volume of grains in contact, the most open structure is obtained by securing that they are of uniform size. On the other hand, the concrete industry looks for a polydisperse mix to get a better conglomerate. These two extreme types of distribution curve are readily resolved in a sedimentation apparatus.

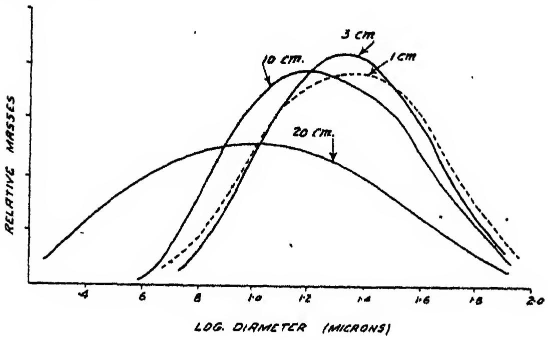
APPLICATIONS TO LIQUID PASTES AND SUSPENSIONS

It is well known that many liquid suspensions show anomalous flow behaviour, so that it becomes difficult to compare their viscosities unless measurements are made at equal shearing rates. There is often the added complication of hysteresis and other memorials of the previous history of the suspension. Nevertheless, it is generally found that viscosity rises as the aggregates break down. In monodisperse systems certainly, fine particles in themselves promote high viscosity, but many factors may obscure this effect, since the addition of coarser grains and the noted effects of thixotropy —reversible sol-gel transformation—and electrokinetic potentials on the state of aggregation may influence the flow behaviour of the suspension. When the grains are in the main large but are interspersed with very small, albeit, colloidal particles, the colloidal filling seems to act as an effective lubricant. In this way a stubborn soil becomes easy to plough and an erstwhile firm sand is turned into a quicksand. Such suspensions form valuable muds for oiling the drilling tool during the excavation of a bore hole. The phenomenon is usually explained by saying that the colloidal adulterant confers thixotropic properties on the specimen, whereby it is easily made to flow under a sufficient pressure, but partially 'sets' when the pressure is released.

By a similar process, fine particles confer cohesion on a modelling clay, and allow a cast to fit the mould more perfectly while not preventing it from being shaped under manual pressure.

Pigments in a liquid medium present similar light-dispersing characteristics in the paste form to those in the dry state. In addition, the manufacture of a liquid paint involves considerations of brushing and wetting properties which are again largely a question of granularity. The paints with finer pigments have better covering

power, which means that less paint will be required per square inch of that colour which has the greater specific surface. It has also been suggested that one could discriminate in this fashion between a medium which is a wetting agent—one that lowers the surface tension of water without altering the state of aggregation—and a true dispersoid which not only increases the number of fine particles at the expense of the aggregates but also imparts resistance to flocculation, an important factor in the conferment of good brushing or spraying properties in paints[4,5].



An interesting case in which two desiderata require size-frequency curves having peaks at opposite ends of the granularity range is to be found in the spinning of rayon. To control lustre the manufacturer adds titanium oxide in amorphous form to the cellulose acetate before it is spun. If this powder is too coarse, the jets from which the mixture is squirted become choked. On the other hand, the presence of fine particles raises the viscosity (*vide supra*) and involves greater pressure to force the rayon through the spinnerets.

APPLICATIONS IN NATURAL PHENOMENA

Recently, useful information has been acquired from measurements of the granularity of sediments put down by natural agencies such as winds and rivers. Sometimes these studies are made during the actual process of silt transport and deposition in rivers in spate or during desert storms[6,7], a field in which much still remains to be done in correlating the scale of turbulence to the silt-carrying propensities of the flow, which varies with the mean size of grain involved and the size-frequency distribution in a way not properly understood.

In fluid motions over a rough surface, it is the size of the rugosities which determine the character of the flow. This has been brought out by experiments in which a uniform sand has been glued to a smooth board set edgewise to the stream while its hydrodynamic resistance is determined. If, however, the sand is free to move, it will be transported whenever the velocity gradient at the boundary exceeds a critical value and redeposited at a lower critical value, which can be determined for each grain size. In mixed sands, these critical values are less certain, but their significance from the point of view of natural phenomena like the raising of desert storms or of the silting up of river estuaries is obvious.

Some preliminary work has been done on the analysis of cores drawn from lake beds, using an apparatus described in an earlier issue of NATURE[8]. These cores consist of recent deposits of semi-liquid mud overlying more compact stratified layers of clay in which fine and coarse particles often alternate, representing successive climatic stages in the history of the lake.

The accompanying figure represents analyses into size-frequency curves of the upper layers of the bed of Esthwaite Water, Lancs, in which only recent depositions are represented in the graphs for various depths. The whole extract is loosely compact and semi-fluid. The shifting of the mean towards finer particle size as the depth of sampling increases may be the result of chemical and bacteriological action breaking down the aggregates, which are formed of silt and organic detritus deposited on the lake bed in the absence of circulating currents, or it may mean no more than that the fine grains during the natural process of sedimentation penetrate through the interstices between the larger crumbs in the ooze until brought to a standstill lower down. The change in mean size goes rapidly at first with depth and then more slowly; in fact, a good straight line is obtained by plotting the logarithm of the most frequent size in the curves shown on the figure against the depth. A similar law is not, however, found for the hardened cores representing historical deposits. Bands of colour in the core and sudden changes in size-frequency distribution probably represent geological catastrophes in the bed formation or of the seasonal inflow of silt from rivers in spate.

It must be appreciated that many of the applications here outlined are in the early stages of their development, but it is hoped that sufficient examples have been given to show that the accurate measurement of granularity will be increasingly used to supply data without which the exploration of many phenomena, both in the laboratory and in the field, will be incomplete.

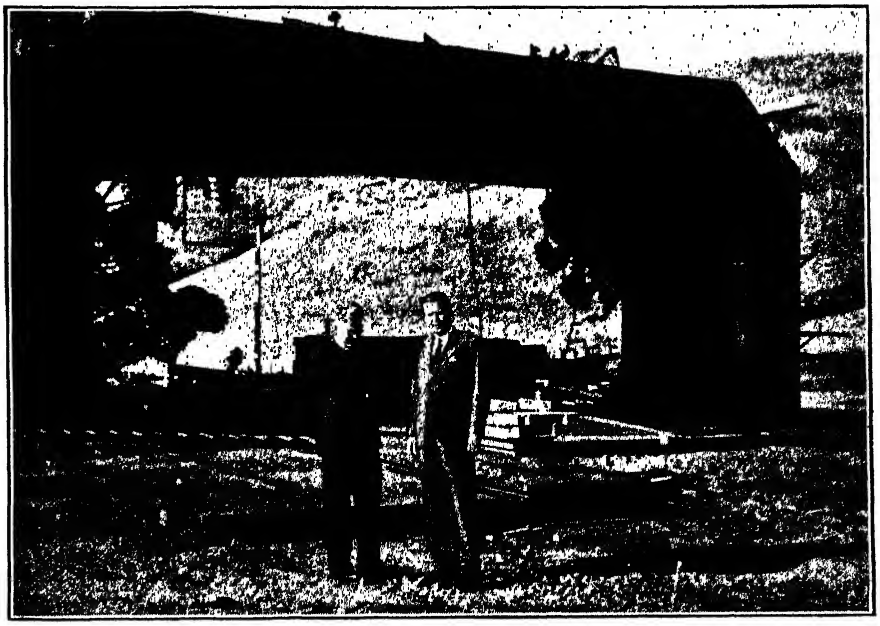
THE 184-IN. CYCLOTRON AT BERKELEY, CALIFORNIA

By Prof. M. L. Oliphant, F.R.S.

During a recent trip to the United States in an official capacity, I was fortunate to be able to repeat for a few hours a visit I made first in 1938 to the Radiation Laboratory in Berkeley, California. The earlier visit was made with the object of obtaining information which would enable me to build in Birmingham a large cyclotron. The 60-in. monster in the Crocker Laboratory was almost complete, and Lawrence had already begun to think of trying to push the cyclotron technique to its limit. We discussed in detail the difficulties of such a scheme, but these proved small obstacles in the path of Lawrence and his great band of co-workers. The theory of the cyclotron had recently been worked out, and it had been shown by the 'prophets' that existing apparatus which delivered 8–10 million volt deuterons was in fact the largest which could be made to work, owing to loss of resonance between the particles and the electric field due to relativistic change of mass. The Berkeley group under Lawrence promptly increased greatly the voltage applied to the electrodes of the new 60-in. cyclotron and showed that no such limit need in fact exist.

In the realms of nuclear physics the cyclotron is by far the most powerful tool which we possess, and in its present form in Berkeley it provides curies of activity of artificially radioactive elements and weighable quantities of transmuted elements. The possibilities for medical and chemical investigation are only now being realized, and the chemistry of carbon itself in complex organic and biochemical changes is being studied by use of the short-lived active carbon isotope now available in large quantities. Elements as heavy as bismuth can be transmuted by bombardment with the existing apparatus.

The giant cyclotron now under construction contains enough steel and copper to build two large destroyers, and is designed to push the cyclotron technique to the extreme limit. It will be capable of providing particles with energies approaching those of cosmic rays, and we can expect with confidence that these will open up fresh fields in atomic physics. The Rockefeller Foundation and the United States are to be congratulated on the vision displayed in enabling the inventor of the most remarkable apparatus used in scientific investigations the opportunity himself to direct the building of this great machine. Lawrence is assisted by a brilliant team of workers who have been associated with his work in the past. With Lawrence himself, many of these men are now doing work of more immediate national importance, but the project itself is proceeding under the guidance of Dr. Donald Cooksey, Lawrence's enthusiastic lieutenant.



MAGNET OF THE 184-IN. CYCLOTRON UNDER CONSTRUCTION AT BERKELEY, CALIFORNIA. In the foreground are Prof. E. O. Lawrence (right) and Prof. M. L. Oliphant (left). Photograph by Dr. Donald Cooksey, assistant director of the Radiation Laboratory.

It is certain that, when completed, the giant cyclotron will attract physicists from the whole world, and Lawrence expresses himself as the director of a piece of apparatus which will in happier times be shared by all who have the wish and the ability to do so. In front are the blue waters of San Francisco Bay; and behind, the warm hills scented by groves of eucalyptus trees. A physical centre of such importance in so beautiful

a part of the earth will draw scientific workers from every country. In Berkeley with Lawrence there is much of the spirit of the Cavendish, and in Lawrence there is one who, like Rutherford, can gather round him a team of men and inspire them to do great things.

Dr. Donald Cooksey, who has forwarded the photograph reproduced herewith, showing Prof. Ernest O. Lawrence (right) and Prof. M. L. Oliphant (left), has sent the following particulars of the cyclotron and the laboratory which is being built to house it.

The magnet is 56 ft. long, 30 ft. high and 184 in. wide. It rests on 1,200 tons of concrete, contains 3,700 short tons of steel and 300 tons of copper. The pole diameter will be 184 in., and the gap between the poles 40 in. The steel construction is complete except for the upper core and the pole tips.

The laboratory enclosing this magnet, which is about to be erected, will be a 24-sided building, on a spur overlooking the Berkeley campus and the whole of San Francisco Bay; in fact, it is directly opposite the Golden Gate, the elevation above sea-level being 881 ft. The views involved probably make it the most spectacular site for any physics laboratory in the world. The construction work has now been under way for about a year, and it is estimated that approximately two more years will be required for its completion. This cyclotron is being designed to give 100 million electron-volt deuterons.

OBITUARIES

Mr. H. M. Wallis

Henry Marriage Wallis died on November 10 at the age of eighty-seven in Reading, where he had resided since 1872. He was a member of a well-known Quaker family from Ipswich. He had travelled widely in Europe and North Africa, spending each winter in and around the Mediterranean. He was 'father' of the Reading Museum and Art Gallery, with which institute he had been associated for half a century as the honorary curator of vertebrates.

As the result of a deep passion for, and love of, Nature, Wallis became known for his multitude of observations, especially on birds and mammals. His knowledge (based on first-hand experience) was profound and was passed on to his fellows by contributions to a number of scientific and other journals and to the Press and by lectures—the latter covering many branches of science and history.

Wallis corresponded with Darwin on the subject of the hair upon the ears of new-born babies. Wallis also did research work on ancient breeds of pigs, having been stimulated by those he saw in Bulgaria and those depicted on Greek coins.

He was responsible for the acquisition of specimens of the British deer—red, fallow and roe (male, female and young of each)—from the herd of the late King George V at Windsor, which now make the magnificent groups in Reading Museum. The birds of prey of the Pyrenees were a special study of his, and I am indebted to him for minute guidance to the avi-fauna of that region. Besides his study of local birds and mammals, Wallis took a leading part in the experiment in 1930 of introducing a colony of large copper butterflies in the Kennet valley.

He was a founder member of the Reading and District Natural History Society and was president during 1891–93. He was also a member of the British Ornithological Union, the British Trust for Ornithology.

H. M. Wallis was a lovable and humble man and will be sadly missed by a multitude of friends, both personal and scientific. W. A. Smallcombe.

Mr. Richard T. Baker

We regret to record the recent death in Australia of Mr. Richard T. Baker. For thirty years Baker was curator of the Technological Museum, Sydney, and for thirteen years lecturer in forestry at the University of Sydney. He is perhaps best known to botanists for his comprehensive work on the Conifers of Australia, published in 1910, in which he was assisted by Mr. H. G. Smith, assistant curator and economic chemist at the Technological Museum, Sydney. Mr. Smith also collaborated with him in his valuable researches on the genus Eucalyptus, especially with reference to their essential oil, and the results were published in 1902. The conifers were profusely illustrated by numerous photographs of the trees *in situ* and of herbarium specimens, as well as photomicrographs showing anatomical structure, some of them in the colours with which they had been stained.

Baker also published a large number of small papers on various Australian economic plants, and these are scattered through the volumes of the *Journal and Proceedings of the Linnean Society of New South Wales*. Nearly all of them are accompanied by first-rate black-and-white drawings by the author, with full details of the structure of the flowers and fruit.

Baker was a fellow of the Linnean Society of New South Wales and served on the Council during 1897–1922. In 1922 he was awarded the Clarke Medal of the Royal Society of New South Wales, of which he was elected a fellow in 1894.

NEWS AND VIEWS

The World at War

IT is one of the conditions of the existence of a group of individuals as a society that certain rules for the guidance of the individual be obeyed. This applies as much to nations in their association with other nations as to individuals. A fundamental rule in international relations is that no nation should carry out an act of war against another without giving notice of its intentions. In spite of all the facilities of modern means of communication, Japan has thought fit to ignore this elementary procedure in its attack on the United States, thereby aligning its foreign policy even more emphatically with those of Germany and Italy in its total disregard of international law. It is yet another demonstration of the Nazi 'new order' of the supremacy of armed force, and of the worthlessness of any pretensions on the part of the totalitarian nations of conceding any rights or liberties to other nations. Japan is a relatively young nation which chose deliberately to model its future on that of the Western world. She has chosen bad mentors, and it must be a source of grief and despair to those Japanese men of science of international reputation like Honda and Yukawa, as it would have been to those of the older generation such as Kitasato, Noguchi, Omori, and Jogi Sakurai, that the nation should have allowed itself to be carried away by the machinations of the military party.

With the extension of war to the Pacific, Japan's so-called "China incident" becomes now a part of a vast conflagration which has girdled the earth. The greater part of Europe, Africa, Canada and the United States, most of the States of South America, the myriad isles of the Pacific in the hands of the United States, Great Britain, Australia and New Zealand, the eastern sea-board of Asia from Siberia to Singapore, the Dutch East Indies, Australia and New Zealand—all are directly involved; and it is safe to add that no nation or people at present at peace is unaffected. When the totalitarian powers have been finally broken, the Allies, who are pledged to democracy and freedom, must go forward with a world programme for reconstruction, the fundamentals of which will be based on the Atlantic Charter. President Roosevelt put the position bluntly in his radio address on December 9: he said that Americans "must begin by abandoning once and for all the illusion that we can ever again isolate ourselves from the rest of humanity . . . there is no such thing as security for any nation, or any individual, in a world ruled by the principles of gangsterism. . . . We are now in the midst of a war not for conquest, not for vengeance, but for a world in which this nation and all this nation represents will be safe for our children. . . . We are going to win the war, and we are going to win the peace that follows."

Dr. V. K. Zworykin: Rumford Medallist

THE American Academy of Arts and Science has awarded the Rumford Gold and Silver Medals to Dr. V. K. Zworykin for his invention of the iconoscope and other television devices. Dr. Zworykin was born in Russia, and educated in Petrograd, Paris and Pittsburg. Since 1929 he has been connected with the Radio Corporation of America and has been associate director of the research laboratories of that Corporation since 1934. Zworykin's name is world-renowned for his far-reaching researches in electronics and photo-electric cells, culminating in his invention and development, with a group of associate workers, of the iconoscope or 'electric eye', which forms the basis of the television system adopted in Great Britain and still in active development in the United States.

The iconoscope is a special form of cathode ray tube in which the fluorescent screen is formed of a mosaic of tiny photo-electric cells, on which is focused the television picture to be transmitted. The electron beam of the tube is caused to scan this screen, and the resulting fluctuations of potential, depending upon the relative illumination of different parts of the screen, are used as the source of the picture modulation signals for the television radio transmitter. Zworykin's work has also led to the electron-multiplier, for amplifying the signals produced by a photo-electric cell, and to other devices used in television transmission and reception. All this work is described in a number of papers by him and his co-workers published principally in the *Proceedings of the Institute of Radio Engineers*, New York, and in the *Journal of the Institution of Electrical Engineers*, London.

Training of the Disabled

AN interim scheme for the training and re-settlement of disabled persons, which is for the benefit of women and girls as well as of men and boys, is described in a leaflet issued by the Ministry of Labour and National Service. In addition to members of the Fighting Services, the Merchant Navy and the Civil Defence Services disabled on war service, the scheme is intended to cover civilians injured through air raids, factory accidents or in other ways, and is open to all persons above the age of sixteen. Some degree of preference may be given to those whose disablement is due to war service or to enemy action, but foreigners who have been disabled since the beginning of the War are also eligible. Training will be given in occupations connected with munitions work such as draughtsmanship, fitting, instrument making, machine operating, welding, inspecting and viewing, and for this purpose the courses of training will be similar to those in the existing schemes of the Ministry, but modified to suit disabled persons or particular types of disablement. It also will be given in other

occupations specially authorized for the scheme. The training will be provided at certain Government training centres administered by the Ministry of Labour, at special centres with experience in training disabled persons for industry, at technical colleges and similar institutions and at works. A maximum period of twenty-six weeks training will probably be sufficient. Throughout the training, in addition to proper medical supervision, weekly allowances varying from 42*s*. to 17*s*. for men and boys and 33*s*. to 15*s*. for women and girls will be paid, and each trainee will also receive a dinner meal or 5*s*. per week in lieu, daily travelling expenses, when necessary, and dependants' allowances. These allowances will be independent of any pension or other payment the trainee may receive in respect of his or her disability.

Evaluation of Individual Adjustment

"AN Evaluation of Adjustment based upon the Concept of Security" by Mary D. Salter has been published in the University of Toronto Studies (Child Development Series No. 18. Toronto: University of Toronto Press; London: Oxford University Press, 1940. 3*s*. net) as the first part of a larger study designed to provide an evaluation of important aspects of an individual's adjustment by means of a series of scales based upon the common concept of security. The technique used in this investigation utilizes the principle of internal consistency to construct an extra-familial and a familial scale of security designed to throw light on relations outside and inside the family, respectively. The results indicate that social insecurity appears most frequently with those who are dependently secure in the family and with those who are insecure and independent in the family. Tolerance is much more frequent with independence than it is with dependence, both for the socially insecure and the socially secure groups. Those who are socially secure and dependent tend to intolerance and familial insecurity.

Familial security in the early stages is of a dependent type and forms a basis from which the individual can work out gradually, forming new skills and interests in other fields. In its absence the individual is handicapped by the lack of a secure base from which to work, and at the college age such insecurity is at least partly due to friction on the issue of emancipation. Independence of the family is true independent security if the individual has formed requisite skills and dependencies outside the family without being involved in conflict with the family. Continued dependence on the family may make for inadequate adjustment if it seriously interferes with the development of skills in other fields. Extra-familial security is based partly upon social skills and partly upon dependencies on friends, both apparently being necessary and interrelated. Insecurity is due to a lack of skills or of friends or of both. Intolerance is a common form of compensation which may contribute to social security during the acquisition of skills, and is most effective if the individual has dependent security also or at least a fairly satisfactory basis of skills already formed. Lacking both these, compensation either becomes ineffective resulting in insecurity, or must be exaggerated to avoid insecurity, leading to the unusual forms of behaviour which characterize serious maladjustment.

University Staffs in the British Empire

THE "Yearbook of the Universities of the Empire" is an invaluable reference book, the last issue of which is dated 1940. In view of the numerous changes, probably mostly due directly to the War, which have occurred during the past eighteen months or so in the staffs of universities, this issue quickly lost much of its value. When, however, the Universities Bureau had to consider the preparation of the issue for 1941, it was found that, on account of the destruction of the Bureau's premises, the delays in obtaining information from overseas and the shortage of paper, it was possible to prepare only a Supplement to the existing volume (Supplement to the Yearbook of the Universities of the Empire, 1940. Published for the Universities Bureau of the British Empire. Pp. xxxi+255. London: G. Bell and Sons, Ltd., 1941. 3*s*. 6*d*. net). In this book, which is of the same format as the well-known Yearbook, the officers are given for each university followed by a list of changes of staff. The list is carefully set out to facilitate easy reference, and there is an index of names at the end of the volume. The Yearbook for 1940, with the Supplement, provide as up-to-date a record of university staffs in the British Empire as is feasible in these times. The Bureau is to be congratulated on its enterprise.

Tar Oil Washes

THE introduction of tar oil washes in Great Britain about 1921 resulted in the greatest advance in the control of fruit pests that has been made during the present century. With extension in their use came the demand for their standardization, as differences in source and process of manufacture had led to uncertainty in their performance. After a study of the insecticidal properties of the various components of the washes and their behaviour under different conditions had been made both at the research stations and the research departments of insecticide manufacturers, a small joint committee of representatives of the Association of British Insecticide Manufacturers and the Ministry of Agriculture was set up to consider the available information, and, if possible, to prepare specifications. After still further investigation, specifications and methods of analysis for both the miscible oil (black fluid) type and the stock emulsion (mayonnaise) type were successfully drawn up, which have been accepted by the Association and the Ministry, with the concurrence of the Government Chemist. The full data are available in Bulletin 122 of the Ministry of Agriculture (H.M. Stationery Office, 6*d*.). Members of the Association and most of the manufacturers of tar oil washes have agreed that their products shall conform to these standards, and purchasers are strongly advised to take advantage of this by requiring that any washes they obtain shall comply with the specifications.

Public Health Education in Mexico

THE August issue of the *Boletin de la Oficina Sanitaria Panamericana* contains an instructive article by Dr. Angel de la Garza Brito, director of the School of Hygiene of Mexico, on the present and future of education in hygiene in his country. The old preparatory school in public health which was reorganized in April 1938 gave instruction to 130 medical men, 184 nurses and 70 health officers, as well as to an auxiliary staff consisting of statisticians, laboratory assistants and social workers for venereal diseases. In 1941 the first regular course for medical officers of health was opened. Difficulties which have been encountered are due to an almost complete lack of modern text-books and special literature on preventive medicine and public health, the scarcity of full-time teachers and the absence of basic training in preventive medicine and hygiene. These defects have been partly remedied by the preparation of synopses on each subject, and by encouraging the study of foreign languages, especially English. It has also been suggested that hospital instruction should be supplemented by a sociological approach.

Urea Formaldehyde Glue for Plywood

PLYWOOD is made to one of two specifications, either D.T.D.427 or B.S.S.5.V.3, requiring resistance to three hours immersion in water at 60° C. (140° F.) and 100° C. (212° F.) respectively. At present urea formaldehyde resins are used for D.T.D.427 plywood, and Tego film (paper impregnated with a phenol formaldehyde resin and used in a dry state) for the 5.V.3 plywood. Although modified urea formaldehyde glues meet the requirements of B.S.S.5.V.3, they cannot be used in the manufacture of very thin plywood because of the swelling caused in the thin veneers by the wet glue, and because of the penetration that takes place after pressing. The phenol formaldehyde film type of glue is, of course, immune from these troubles.

To meet this difficulty, and to reduce costs, Messrs. Aero Research, Ltd., of Duxford, Cambridge, have introduced a foamed modified urea formaldehyde glue. The amount of glue applied by any ordinary means (glue spreaders or brushes) is in excess of the optimum amount ; by using the glue in the form of a foam an extremely thin uniform spread is obtained in terms of pounds of glue per square foot, although the glue layer has an appreciable thickness. Actually the volume of the glue is about doubled by a special beater machine before it is poured into the glue spreader. Under ordinary factory conditions it is possible to get a spread of 1·35 lb. of glue per 100 square feet. This foamed-up glue, known as Aerolite F.67, gives plywood meeting the requirements of specification 5.V.3. Because of the nature of the foam, it can be used with thin veneers. The press temperature required is 90° C., so that steam-heated presses are unnecessary and the older type of press common in Great Britain, with hot-water heating, can be used ; the use of pressing temperatures below 100° C. obviates any risk of over-heating of the wood with its attendant troubles. Messrs. J. M. Steel and Co., Ltd., of Kern House, 36–38, Kingsway, London, E.C.2, are the distributors of Aerolite glue, and all inquiries should be addressed to them.

Forests of British Honduras

THE annual report of the Forest Department of British Honduras for the year ending December 31, 1940, is an illustration of the failure on the part of responsible administrators to understand the principles of a true forestry management. Mahogany has been exported from the country for a couple of centuries and more. The report commences with the statement that "British Honduras is essentially a producer of raw materials for export, of which in the last eighteen years an average of 79·6 per cent has been derived from the forests. In 1940 there was continued improvement in the export trade, and particularly so for forest produce, in spite of war conditions." There was but slight disruption of communications with North America to which a considerable proportion of these productions goes and the United Kingdom Timber Control Department purchased the whole of the lumber output. The Conservator writes: "the work of the Department in 1940 was concentrated on the most important aims of the forest policy." This policy is apparently to develop the forest estate by the maintenance of the chief export, mahogany, and chicle, etc. This is not forestry. A timber merchant can do this ; nor can it be termed a 'forest policy'. The exploitation of the forests is apparently done entirely by licensees who set up their own mills.

That the forests so worked and the amounts of valuable timber they contain is to a great extent unknown is obvious from the statement in the report that "shortage of staff has, for years, made it impossible to do much exploration in advance of exploitation" ; there appears to be an idea that by giving longer terms to the licences issued, licensees will plan their work economically. In the history of forest lumbering this hope has ever remained a dead letter. The superior staff of this Department consists of a conservator and two assistant conservators. Both these latter were absent for a greater part of the year; and yet we are told that 79·6 per cent of the raw material exported from the Colony comes from its forests. It would have been interesting had the report told us the direction in which the sums obtained from this produce went. Do they go into the exchequer of the Colony and are they spent in the improvement of the conditions of the people ? If the answer is in the affirmative, how long will the forests stand the drain upon them in the absence of the introduction of a true conservative management which could solely be enacted and maintained by an adequate forest staff ? According to the report, the latter can only be considered to be present in name.

British Association Seismological Committee

THE report of the British Association Seismological Committee for 1941 has just been received. It shows that some progress is being made in spite of

war conditions. The new-type electrically driven recording drums for the Milne-Shaw seismographs are proving satisfactory in India. The rotation of the drum is particularly uniform and there is no 'backlash'. This result has been achieved by pivoting the electric motor eccentrically on a spindle, and permitting it to fall by gravity into mesh with the gear attached to the drum. It may be described as a 'floating' contact in place of the usual fixed centres. Difficulties in connexion with the International Seismological Summary are being successfully overcome at Oxford. Jeffreys has investigated the deep earthquake of June 29, 1934, and has obtained from it helpful readings of the receding (*DE*) branch of *PKP*. The table of *PKP* has thus been improved and a table also constructed for *sP*. Stoneley makes some very helpful and pertinent remarks concerning the integration of seismograms in connexion with the long-wave phase of earthquakes. There need now be no hesitation in accepting the usual identification of the early part of the long-wave phase (apparent velocities 4·4–4·0 km./sec.) as Love waves.

Compounding in Locomotive Design

MR. W. A. STANIER delivered the presidential address to the Institution of Mechanical Engineers on October 24, when he discussed "The Position of the Locomotive in Mechanical Engineering". Although a standard feature of marine reciprocating design, compounding has not found extensive favour in Europe except in France. In England it has been the subject of repeated trials—no less than 12 per cent of the papers ever read before the Institution are on compounding—and in theory it has obvious advantages over simple expansion. These advantages are specially marked at working pressures higher than 300 lb. per sq. in. Attempts in Great Britain have contained defects, condensation causing serious loss, and lack of understanding of the principles of steam flow have often rendered the engines more sluggish than their simple expansion contemporaries. Superheating, which brought fresh life to the compound engine on the Continent, has only been applied to any scale to one British type, the 'Midland' compound; within the limits of its size, good work has been done and is still being done by this class. It has, however, never been modernized as regards its cylinder and valve-gear design, so its actual efficiency is below that of the present-day simple expansion engine. It is also possible to understand now why the French De Glehn compounds, imported by the Great Western Railway in 1903 and 1905, did not give results superior to the simple-expansion designs of Churchward. It is impracticable to combine within the British loading gauge, however, both the large low-pressure cylinders required, and the bearing and crank dimensions required by compound locomotives.

Northern Ecological Association

THE Northern Ecological Association was founded by the late Mr. R. J. Flintoft, of Goathland, Yorks, who organized workers in various fields of natural science in their own localities in the north of England. Valuable work had been done in this way, and it was felt that the organization should not be allowed to lapse, but should be placed on a permanent basis. Accordingly a special meeting of the Association was held at York on November 23, and it was decided to re-enact the existing constitution and to adopt the existing name. The officers of the Association are as follows: *president*, Dr. W. Collinge; *secretary and treasurer*, Mr. J. L. Forrest, Eversfield, Goathland, Yorks; *editor*, M. Dallman.

Dr. E. N. Miles Thomas

DR. E. M. DELF, Department of Botany, Westfield College, London (at St. Peter's Hall, Oxford) writes: "Dr. E. N. Miles Thomas, who is widely known amongst botanists for her contributions to the study of seedling anatomy, retired from her position as head of the Department of Biology at University College, Leicester, in 1937. Thereafter she occupied a research room at Westfield College (University of London), and for a time continued her many professional activities. Her health, however, was already seriously impaired. The evacuation of the College to Oxford and other difficulties in connexion with the War situation probably added greatly to the overstrain from which she was suffering. Early in 1940 she was found to have lost almost completely her power of memory, a condition which is now unfortunately regarded as permanent, although her general health has somewhat improved. Her research effects are housed at the Jodrell Laboratory, Kew."

Recent Earthquakes

IN addition to being recorded on all the seismograms at Kew Observatory, the earthquake of November 25 was recorded on the electrometer record of the rain electrograph. This earthquake, which affected Lisbon, gave very large amplitudes at Kew. The real ground amplitude caused by *P* (18h. 08m. 22s. U.T.) exceeded 300 μ, the amplitude caused by *S* (18h. 13m. 45s. U.T.) exceeded 800 μ and the maximum may have exceeded 2 mm. A tentative interpretation of the records shows a compression from the south-west (azimuth 233°) and an epicentral distance near 3,600 km. The epicentre may thus have been near 28° N., 29° W., in the Atlantic Ocean south of the Azores. On December 4 an earthquake of considerable severity was felt at Rangoon though no damage is reported. On December 6 earthquakes were reported from Santiago and from San José in Costa Rica. Considerable damage was reported though full details are not yet available.

The United States Coast and Geodetic Survey, in co-operation with Science Service and the Jesuit Seismological Association, has found the epicentres of the earthquakes of October 3 and October 5. The earthquake of October 3 at 16h. 13·2m. U.T. had its epicentre near lat. 40·6°N., long. 124·6°W., which is in northern California in the neighbourhood of Cape Mendocino. On the basis of instrumental reports from seven seismograph stations, the epicentre of the earthquake of October 5 at 10h. 11·2m. has been calculated to be lat. 15° S., long. 173° W., which is in the Pacific Ocean between the Islands of Samoa and the Fiji Islands. All interpretations and calculations are tentative.

Linkage of Physico-Chemical Processes in Biological Systems

IT is a truism of general physiology that living organisms are *actively* co-ordinated systems, that is, systems in which there is co-ordination of action as well as of structure. It would be no exaggeration to say that the discovery of the *quantitative* correlation of processes is the major task of modern general physiology, a correlation which, in the present state of science, can be exactly expressed only in terms of the existing concepts of physics and chemistry. Failure to recognize the linkage of intracellular *chemical* processes with *physical* diffusion processes involving unequal distributions of ions between the living cell and its fluid environment has often given rise to misunderstanding. The following simple example will serve to illustrate the point.

In Fig. 1, (I) represents the interior of the cell,

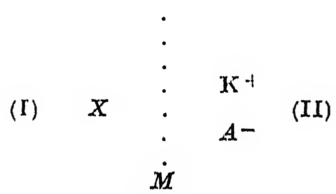

Fig. 1.

(II) the fluid environment, M the semipermeable cell-membrane. Within the cell is a dissolved *impermeable* neutral substance X, while in the extracellular fluid there is the ionized salt K^+A^-, where (for example) K^+ denotes the potassium ion and A^- a certain univalent negative ion, the membrane M being freely permeable to both. Fig. 1 represents an *initial* state.

We now make the supposition that the *practically irreversible* chemical reaction

$$X + A^- \longrightarrow Y^-, \quad . \quad . \quad . \quad . \quad . \quad (1)$$

occurs within the cell, where Y^- denotes an *impermeable* 'complex' ion (using the word 'complex' in its widest sense). The chemical reaction (1) may involve the elimination of one or more water molecules and the active co-operation of an enzymatic system, but the simple formulation given in (1) suffices for the present purpose. The final state of the system is represented by Fig. 2, where we assume that there has been present in the system more than sufficient A^- to convert practically all the X originally present into Y^-.

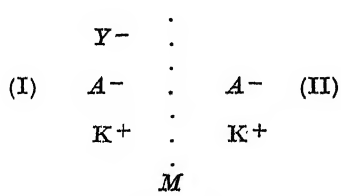

Fig. 2.

For simplicity (that is, for the sake of illustrating the ideas involved), we now assume (*a*) complete ionization of the salts KA and KY, and (*b*) applicability of the laws of very dilute ideal solutions. We have then the following relations (where C denotes molar concentration):

$$C_K = C_A + C_Y, \quad . \quad . \quad . \quad . \quad (2)$$
$$C_K C_A = C'_K C'_A, \quad . \quad . \quad . \quad . \quad (3)$$
$$C'_K = C'_A; \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

whence follows:

$$C_K = \tfrac{1}{2}\left(C_Y + \sqrt{C_Y^2 + 4\,C'^2_K}\right) \quad . \quad . \quad . \quad (5)$$

(the accented letters denote quantities referring to (II)).

Equation (5) shows that at equilibrium $C_K > C'_K$, and gives a quantitative expression for 'the accumulation of potassium ions in the cell against a concentration gradient'. In the present case such an accumulation is rendered possible by the occurrence of the reaction (1). This reaction involves *per se* a decrease of free energy, but this decrease of free energy is not directly and quantitatively correlated with any diffusion of potassium ions against a concentration gradient (and across an electrical potential difference). There is no mysterious 'energy-pump' at work, 'pumping' the potassium ions against a concentration gradient. The situation is simply such that the occurrence of the intracellular chemical reaction (1) produces a *down* concentration-gradient of A^- ions from (II) to (I), and the free-energy changes associated with the *down-gradient* diffusion of A^- offset (when necessary) those associated with the simultaneous, linked, and equivalent *up-gradient* diffusion of K^+. If the reaction (1) be sufficiently rapid, we may divide the process of passage of K^+ and A^- from (II) to (I), into two phases; the first is complete when the reaction (1) is (practically) complete and (I) contains only the salt K^+Y^-, while further diffusion of K^+ and A^- from (II) to (I) occurs in the second phase and completes the equilibrium.

Although not necessary for the preceding argument, it may be noted that at equilibrium we have also the osmotic pressure equation (ignoring for the present purpose all constituents in (I) and (II) except those already considered):

$$P_I - P_{II} = RT\,\{C_K + C_A + C_Y - (C'_K + C'_A)\}$$
$$= 2RT\,(C_K - C'_K) \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

where P_I and P_{II} denote the hydrostatic pressures in (I) and (II) respectively.

Generally, we may suppose that, as the cell grows, fresh X is constantly being produced and as constantly converted into Y^-, there being always a sufficiency of KA in the fluid environment.

The foregoing simple example, though somewhat different, has been suggested by the recently published remarkable work of P. J. Boyle and E. J. Conway[1] on potassium accumulation in muscle and associated changes. It must be stated, however, that the highly simplified considerations of the present note

touch only the fringe of the ideas involved in the extensive investigation of the authors mentioned. Nevertheless, the present brief communication will serve a useful purpose if it directs attention to an important investigation which throws much valuable light on the difficult problem of the quantitative correlation of linked physico-chemical processes in a living system.

Role of Potassium in Yeast

IN our previous communication[1] it was described how ammonia could entirely replace potassium in yeast under suitable conditions. It became then a question of interest as to how the 'ammonia yeast' functioned compared with the normal or 'potassium yeast' when both were maintained under strictly similar conditions, except that the ammonium ion replaced potassium. The rate of fermentation of glucose, the reproduction in suitable media and the resting metabolism were examined.

Preparation of the yeast for examination. Two 5-gm. samples of the same baker's pressed yeast were taken, one immersed in Ringer-Barkan fluid (as described in ref. 1) containing $N/5$ NH_4Cl and no potassium, and the other in a similar solution, K being replaced by NH_4 ions. The mixture was bubbled with 3 per cent carbon dioxide and 97 per cent oxygen, the medium being changed every twenty-four hours. After four days there was no measurable amount of potassium left.

The 'potassium yeast' after centrifuging contained 205 m.eq. K/kilo moist yeast and no appreciable amount of ammonia, and the 'ammonia yeast' contained 248 m.eqs./NH_3–N and no potassium.

Fermentation. 1-gm. samples of the centrifuged yeasts were suspended in 10 c.c. of water and allowed to act on an equal volume of 6 per cent glucose. It was found that the mean rate of carbon dioxide production by the 'ammonia yeast' was 40 per cent of that for the 'potassium yeast'—this latter being 0·26 m.eq./hr./c.c. yeast suspension.

Growth and reproduction. Small platinum inoculations were made into 100 c.c. of sterile medium containing 2·5 gm. glucose, 0·5 gm. K (or NH_4) acid phosphate, 0·1 gm. $MgSO_4$, and 20 ml. of boiled 1/5 water extract of 'potassium (or ammonia) yeast'. A curious difference appears between the two yeasts. The 'potassium yeast' grows much faster at first, but reaches an upper limit after twenty-four hours. The 'ammonia yeast' is considerably slower at first, but after two to three days exceeds the 'potassium yeast' and passes on to a far higher level (about four times the number of cells). The early upper level of the 'potassium yeast' is not due to an exhaustion of the glucose by fermentation, as shown by the use of higher glucose concentrations leaving much unfermented sugar after twenty-four hours, but no appreciable change in the number of yeast cells. It appears to be related to an exhaustion of some substance in the yeast extract added.

Resting metabolism. The oxygen uptake at 30° C. was examined in the Warburg apparatus, 3 ml. being taken of a 1/100 suspension in a medium consisting of 0·095 gm. Na_2HPO_4, 0·080 gm. NaH_2PO_4 and 0·60 gm. NaCl made up to 100 ml. ($pH = 6·7$). The Q_{O_2} for 'potassium yeast' was found to be $-5·35$ and that for the 'ammonia yeast' was $-6·36$. Thus the resting metabolism of the 'ammonia yeast' is *higher* than that of the 'potassium yeast'.

Experiments such as described in the previous letter and in other communications[2,3] show that potassium exists in cells in the ionized form, and it would appear that the main biological reason for the accumulation of potassium in cells (at least those with distensile membranes) is a necessary process for the accumulation of appreciable non-diffusible material or such as the cell can retain[4]. At the same time, the potassium ion even in one-celled organisms, such as yeast, may exert some specific ionic effects, though the above experiments indicate only a difference between the ammonium and potassium ion without it being possible to say which, if any, plays a merely passive role. They show, none the less, that potassium (at least over 0·1–1·0 mgm./100 gm.) is not essential for fermentation, growth or resting metabolism of the living yeast cell.

Nature of the Disturbed Calcium Metabolism in Thyrotoxicosis and Myxœdema

VARIOUS theories have been put forward to explain the excessive calcium output in thyrotoxicosis including an increased metabolism *per se*[1], neutralization of acid products[2], direct stimulating catabolic action of thyroxin on bone, and a co-existing hyperparathyroidism[3]. For reasons to be given later, all these theories are unsatisfactory. As a result of direct experiments and observations[4] on normal subjects and cases of thyrotoxicosis, myxœdema and parathyroid tetany, a new theory has been formulated. It is believed that in thyrotoxicosis, an excessive secretion of thyroxin acts directly on the kidneys, stimulating them to increase their output of calcium. This may be achieved either as a result of the increased metabolism *per se* or by lowering the renal threshold for calcium.

As Aub *et al.*[1] have shown that an increased metabolism *per se* does not increase the calcium output, the excessive calcium loss would appear to be due to a lowering of the renal threshold for calcium. This leads to a fall in the serum calcium, and as a result there is an increased mobilization of calcium from the bones. In other words, the decalcification in thyrotoxicosis is due to a *vis à fronte*. In myxœdema there is the converse picture, where a diminished thyroxin secretion raises the renal threshold for calcium and causes the calcium output to fall.

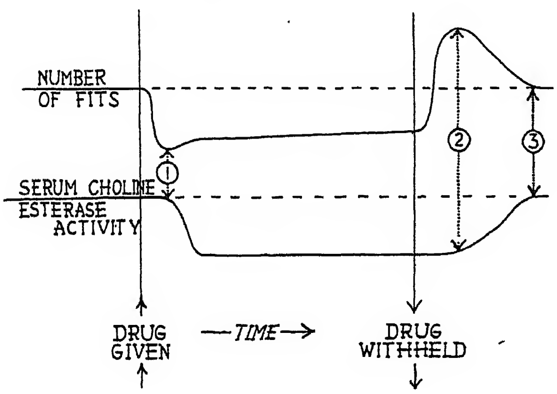
Mechanism of Drug Addiction and Drug Tolerance

It has been found that prolonged administration of 'luminal' (and other barbiturates) to human beings (for example, epileptics) and animals greatly reduces the cholinesterase activity of the serum, so that it reaches 10–2) per cent of what it was before the treatment with the drug. No change in cholinesterase activity was found, however, when the drug was added to serum *in vitro* (2·5 mgm./c.c.). It appears that the barbiturate does not act directly on the enzyme as in the case of eserine and other anticholinesterase substances. The pronounced decrease in cholinesterase activity which was found *in vivo* might be interpreted as a counter-adaptation, the activity of the cholinergic system being reduced by the narcotic, reducing thereby the demand for cholinesterase, which, consequently, slowly decreases.

It is known that when the drug is withheld from epileptic patients to whom it has been given for many months the number of epileptic fits rises sharply. They become much more frequent than they were during the drug treatment and before the treatment was started. After some time, however, the fits appear with very much the same frequency as before the treatment. In the accompanying figure both cholinesterase activity and frequency of fits have been plotted against time.



The peak in the number of fits when the drug is withheld may be compared with the great demand for drug when withheld in cases of drug addiction. The number of fits, however, is a conveniently more measurable quantity than the expressed desire for the drug in the latter case. It is suggested that the increased number of fits (at 2) is due to the fact that the narcotic effect of the drug, which diminishes the fits, wears off more rapidly than the counter-adaptation, namely the reduction of the cholinesterase activity. It should be noted that when the fits reach their maximum (at 2) the cholinesterase activity was still low. The fits, however, return to their 'normal' number at about the same time that the cholinesterase activity reaches its former level (at 3). Accordingly the optimal effect of the drug (greatest reduction of fits as at 1) is observed when the direct narcotic effect of the drug, as indicated by the number of fits, has already taken place, and the counter-adaptation (reduction of cholinesterase activity) has not yet adjusted itself. The best effect of the drug is thus observed when an apparent strong narcotic effect (few fits) is combined with a high cholinesterase activity (at 1). At 2 there is little or no narcotic effect (many fits) combined with a low cholinesterase activity.

These observations, apart from suggesting that the cholinesterase should have a therapeutic effect on the number of epileptic fits, might also explain the development of drug tolerance.

In the case of barbiturates one may therefore distinguish between a direct (D) and an indirect effect or counter-adaptation (C). In our case both could be estimated, D from the number of fits, C from the reduction of the cholinesterase activity. The velocity with which these two effects develop and wear off respectively is greatly different. If in other cases a drug should prove to produce two such similar effects, the condition for an increased demand for a drug after it is withheld (addiction), or that higher doses are gradually needed to obtain the same effect (tolerance), might generally be expressed thus: $\frac{dD}{dt} > \frac{dC}{dt}$, where t is time, and both $\frac{dD}{dt}$ and $\frac{dC}{dt}$ are positive in drug addiction, immediately after the drug is withheld, and negative in drug tolerance, immediately after drug is given.

Drug Prophylaxis against Acute Anoxia

In the course of some oxygen-lack experiments, an opportunity occurred to test the prophylactic effect of ethylene-diamine theophyllin ('Cardophylin') against acute anoxia.

Mixture breathed	Time	Tension in mm. mercury of alveolar carbon dioxide	oxygen	Minute volume in litres.
Air	11.48	41·1	95·3	6·8
11·4 per cent oxygen	12.00	29·1	56·1	9·0
	12.05	0·4 gm. of 'Cardophylin' taken orally.		
Air	12.35	36·9	98·9	6·7
11·4 per cent oxygen	12.49	22·3	60·9	16·0

In the above table are given the results of one test. In this case 0·4 gm. of the drug was given orally. The pulmonary ventilation was much greater when breathing the low oxygen mixture after the administration of the drug.

The above effect was demonstrated in the minority of the small number of subjects investigated.

Cobalt Manuring and Pining in Stock

It is well established from experiments carried out in New Zealand[1] and elsewhere that certain forms of pining in stock can be prevented or cured by the addition of cobalt to the soil. The cobalt content of the herbage is thereby increased to a value above that at which pining due to cobalt deficiency occurs. We[2] have demonstrated this in experiments in eastern Ross-shire.

Spectrographic examination of the herbage grown on soil which has undergone cobalt treatment has shown, in some instances, a marked increase in the molybdenum uptake, the content approaching that of teart herbages reported by Ferguson, Lewis and

Watson[3]. Data for two soils are appended. On soil A pining in sheep has definitely been both prevented and cured by the application of 2 lb. cobalt chloride per acre, and, although the molybdenum content of the herbage increases as a result of cobalt treatment, even 10 lb. per acre, a dressing considerably greater than any likely to be used in practice, does not increase the molybdenum content to a dangerous extent. Soil B, where a form of pining in cattle has been reported, but not definitely attributed to cobalt deficiency, carries a herbage which is initially quite high in molybdenum. Even 2 lb. cobalt chloride per acre causes a considerable increase in the molybdenum content of the herbage, and a content at which teart is liable to occur appears to be approached. It may be that the pining reported on this soil is a combined cobalt deficiency : molybdenum excess effect, and the addition of cobalt to the soil as a remedial treatment may have deleterious results. It appears from the work of Ferguson, Lewis and Watson that the uptake of molybdenum decreases with increasing soil acidity : the use of a cobalt-rich lime, as has been suggested in New Zealand, may therefore be dangerous.

In cases of cobalt-deficiency pining such as that occurring on soil A, the application of a cobalt-rich fertilizer is a simple and effective means of counteracting the disease, but it is evident from the foregoing that caution must be exercised in the general use of cobalt-rich fertilizers. More detailed investigation of the inter-relationships of cobalt, molybdenum and other trace constituents which appear to enter into the nutritional balance of the plant and the animal is necessary, and work on these lines is continuing.

COBALT AND MOLYBDENUM CONTENTS OF HERBAGE, FIFTEEN MONTHS AFTER COBALT TREATMENT, AS PARTS PER MILLION OF DRY MATTER.

$CoCl_2.6H_2O$ added lb./acre	Herbage from Soil A Co	Mo	Herbage from Soil B Co	Mo
0	0·08	1·7	0·07	6·3
2	0·22	2·2	0·20	9·2
10	0·63	2·4	0·89	10·0

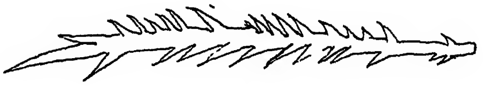
A Factor in the Dispersal of Burdock (*Arctium Lappa*, Linn.)

THE hooks on the involucral bracts of burdock, by clinging to passing animals, secure the removal to a greater or less distance of the fruits from the parent plant ; but they do not secure the scattering from one another of the fruits contained in the burr itself. A chance incident that occurred some years ago, but which I have only recently investigated, enables me to suggest the means by which this desideratum is probably achieved. One of the boys in a class with which I was studying hooked fruits happened, after pulling to pieces a burdock burr, to lean his cheek on his hand : within a few minutes he complained of intense irritation in the skin of his cheek, and soon there appeared on his face a rash like that caused by the hairs of some caterpillars. Some of the copious yellow dust that falls readily out of the ripe burr of this species had adhered to his hands, so I attributed the discomfort to this substance ; but only now have I examined it microscopically.



The microscope shows that the dust is composed of very fine and stiff bristles varying in length from approximately 1 mm. to 2 mm. and in breadth from 0·04 mm. to 0·06 mm. ; their distal ends are sharply pointed, and their sides armed with numerous short spikes, as illustrated. These bristles form a dense tuft (pappus) on the summit of each fruit, and their attachment to the ovary is so brittle when ripe that the slightest jar causes them to snap off and so lie free in the mouth of the burr. Their many needle-like points are certainly likely to irritate animal skin acutely.

I suggest that these pappus bristles are instrumental in bringing about the break up of the burr and the scattering of its fruits apart from one another. When a burr has become attached to the coat of an animal many of the bristles are certainly shaken out, and some, probably many, will reach the animal's skin, irritating it and causing the creature to scratch at the burr and in so doing knock it in pieces and fling the fruits fairly wide apart from one another.

Ascorbic Acid System in Barley

SZENT-GYÖRGYI suggested that ascorbic acid might play a part as hydrogen-transporter in some tissue respirations comparable with the role of cytochrome. This was supported by the discovery of an active ascorbic oxidase in a number of plant tissues. A difficulty which has hitherto retarded acceptance of Szent-Györgyi's suggestion has been the failure to discover any cellular reducing system, other than glutathione, capable of regenerating ascorbic acid from its oxidized form.

Though barley tissues do not yield any striking reaction for glutathione, they are well known to contain ascorbic acid and they also contain a reducing system which we found would readily reduce methylene blue. By manometric methods we were able to show the presence of an active ascorbic oxidase, freely soluble in diluted barley sap or phosphate buffer at pH 6. It was completely inhibited by $M/1,000$ cyanide and had other characteristics similar to the ascorbic oxidase previously extracted from other plants.

In searching for a hydrogen-donator which would maintain the activity of the system, we found that addition of $M/100 \rightarrow M/20$ lactic acid greatly increased oxygen consumption, although in barley sap without addition of ascorbic acid it had no effect. Titration with 2, 6 dichlorophenolindophenol showed that the presence of the lactic acid maintained the ascorbic acid in the reduced form. At the end of

the reaction, pyruvic acid was isolated as 2, 4 dinitrophenylhydrazone, confirming the removal of hydrogen from the lactic acid. Other hydroxyacids, namely, glycollic and tartaric, behaved similarly though less vigorously. Malic acid gave irregular results, and in this connexion it is noteworthy that we added no co-enzyme to the diluted saps. Hydroxyl groups were not oxidized in a number of other substances tried, including β-hydroxybutyric acid and catechol. Succinic and pyruvic acids were also found inactive. There is thus good reason to presume the existence in barley tissues of the system :

$$CH_3\,CHOH\,COOH + \text{Ascorbic Acid} \underset{H_2 \rightarrow}{\overset{\text{lactic dehydrogenase}}{}} \quad + \quad O_2 \underset{H_2 \rightarrow}{\overset{\text{ascorbic oxidase}}{}}$$

Lactic and pyruvic acids have been reported in barley tissues and we have no reason for believing this system unable to play a part in barley respiration. Mr. C. R. C. Heard, working in this laboratory, has found that addition of ascorbic acid accelerated the decomposition of hexosediphosphate by barley saps. A fuller discussion of the status of this system is being presented elsewhere ; but it may be remarked that it seems to us improbable that any one mechanism is solely responsible for the respiratory oxidations. It is, perhaps, significant that although catechol oxidase is absent from barley, we have been able to satisfy ourselves of the presence of small quantities of cytochrome.

Elastic Scattering of Fast Electrons by Nitrogen Nuclei

SCHERRER and his collaborators[1] have recently published results indicating that the scattering of electrons of energies up to 3·5 Mv. by nitrogen nuclei is anomalous, in that the observed scattering is many times greater than that to be expected on Mott's theory[2]. In particular, they apply a correction amounting to nearly 400 per cent for the geometry of the expansion chamber. This correction is necessitated by the rigid criteria adopted for the selection of tracks for measurement, and they suggest that the agreement between my results and theory, in the region 0·4–1·1 Mv., might be due to the omission of such considerations. In my measurements, however, examination of the tracks was made, not by stereoscopic reprojection, but by microscopic examination of the images on the camera plates in the manner so successfully introduced by Blackett for α-ray collisions. Tracks which after collision are only a few millimetres long are then easily measured as regards general direction. Even with the stereoscopic method such as I used in later work, large-angle collisions are quite easily detected, although they cannot be measured very accurately.

As I have often stressed, the adoption of rigorous criteria in track selection is of great importance in securing reliable results, and with ample data available, Scherrer's angular limitation criterion is highly desirable. In common practice, however, the experimenter is usually faced with the unpleasant alternative of strict selection criteria plus large statistical fluctuation, or less rigid criteria accompanied by less statistical fluctuation.

In my work, a total of 201 collisions was considered in an energy range 0·4–1·1 Mv., whereas Scherrer observed only about eighty collisions in the same energy range. For scattering between 20° and 60° his results are, *in this energy range*, not in appreciable disagreement with theory when statistical fluctuations are considered. For angles greater than 60°, reference to my own results shows that the scattering rises somewhat above the theoretical values, although statistical fluctuations would not allow a comparison to within ± 50 per cent. From Scherrer's more limited data, however, he deduces an excess above the theoretical value by a factor of 10. In view of the fact that he finds an excess of about five times the theoretical value for energies so low as 0·15 Mv., whereas Neher[2], using a Faraday cylinder arrangement, found an excess of only 30 per cent at this energy for the light element aluminium, it seems possible that Scherrer's result may be a considerable over-estimation. Combined with Stepanowa's[3] results, however, the evidence is now strong that nitrogen exhibits marked excess scattering of electrons at energies greater than 1 Mv.

Origin of the Automatic Microtome

IN his very sympathetic obituary notice on W. H. Caldwell in NATURE of Nov. 8, p. 557, Dr. G. P. Bidder asks all biologists to remember that they owe to Caldwell the ribbon method of cutting paraffin sections. In this connexion I would like to direct attention to a short account of the invention of the microtome for cutting continuous ribbons of paraffin sections written by the late Sir Richard Threlfall, in *Biological Reviews*, 5, 357 (1930). Caldwell and Threlfall were contemporaries and friends at Caius ; both were then scholars and later on fellows of the College. In a characteristically personal manner, Threlfall recounts in his article how when he was still an undergraduate he discussed with Caldwell their joint invention, and he tells the part that he himself played in making the new type of microtome which was to become an essential tool of zoologists. Threlfall's article includes a photograph of a copy of the original instrument; this copy is now in the Science Museum, London. The original instrument is in the Zoology Department, Cambridge.

Distribution of Energy among the Cathode Rays of a Glow Discharge

EXPERIMENTS have been carried out to determine the energy distribution among electrons originating in the cathode dark space of the glow discharge through gases. Two methods have been employed : a method of retarding potential applied to electrons which escape through a hole in the anode into a low-pressure region behind it; and a method employing electrostatic focusing and deflexion of the same issuing beam. The following general conclusions have been drawn from the experimental study :

(*a*) At low pressures and high voltages where the discharge is strongly abnormal, the issuing electrons

are substantially homogeneous in energy. This energy corresponds approximately to the potential difference across the discharge. This is the region where the discharge forms a useful source of electrons of homogeneous velocity for use in high-speed cathode-ray tubes and electron diffraction cameras.

(b) At higher pressures and lower voltages, the electron beam possesses a wide range of energies. The general form of this energy distribution is independent of current and voltage. The maximum of the distribution curve occurs always at the maximum energy, and this in turn corresponds closely with the potential across the cathode region of the discharge. In general, at constant pressure the greater the current the greater is the proportion of electrons which possess the full energy. As the pressure is increased, the relative number of electrons in the lower energy regions increases while the fraction of the current carried by electrons decreases. It would appear that in all cases the greater number of electrons originates at the surface of the cathode itself. Except at the highest pressures, there is no support for the conclusion of J. J. Thomson that ionization is uniform throughout the cathode dark space, an assumption which has been accepted generally as necessary to explain the observed potential distribution.

A detailed account of these experiments will be published elsewhere at a later date.

Early Logarithmic Works

READERS of J. Henderson's bibliography of logarithmic tables ("Tracts for Computers", No. 13, Cambridge, 1926) will be aware of the interest attached to Ezechiel de Decker's "Tweede Deel vande Nieuwe Tel-konst" (Gouda, 1627), in which was first published the important de Decker-Vlacq table of 10-decimal logarithms of numbers from 1 to 100,000. After the existence of this work had been doubted by many authorities, a complete copy was found at Utrecht by van Haaften in 1920.

In September of this year my attention was directed by Mr. H. G. Ward, of the Harold Cohen Library of the University of Liverpool, to the existence of a copy of Vlacq's "Arithmetique Logaritmetique" (Gouda, 1628) among a collection of books bequeathed to the University by T. G. Rylands in 1900, and now housed in the Harold Cohen Library. On examining the volume, I found, bound in at the end, pages 1–36 (a–d^4, e^2) of the "Tweede Deel", forming a treatise on the use of logarithms in arithmetic. Title-page and foreword (both reproduced in facsimile in Henderson's tract) are wanting, so that neither the name de Decker nor the date of publication occurs. The logarithmic table, which is known to have been published in both de Decker 1627 and Vlacq 1628, is wanting as a part of de Decker's work, since the Liverpool copy of the table has the French (not the Dutch) sub-title, and belongs to Vlacq's work, as a part of which it is collated.

There is nothing obviously incomplete about the Liverpool copy of the introductory treatise; rather the reverse, in view of the final half-section e^2. It may well prove to be complete, when it becomes possible to obtain detailed information about the Utrecht copy. In the meantime, it seems desirable to put on record the existence of a copy in Liverpool.

Also bound in the same volume is a copy of the rare extra section of 12 pages of Briggs's "Arithmetica Logarithmica" (London, 1624), containing 14-decimal logarithms of numbers from 100,001 to 101,000, and 11-decimal square roots of numbers from 1 to 200, with first differences in each case. I mention this now because the section has also been described by De Morgan and by Glaisher (see Henderson's tract, p. 41), and in respect of the table of square roots their descriptions differ from one another and from the above.

Nov. 18.

John Mayow, 1641–79

ACCORDING to numerous histories of science and similar works, John Mayow was born in London of Cornish descent. The writers of these works give the date of his birth variously as 1640, 1643, 1644 or 1645, with a preference for 1645. This preference is presumably due to a statement made by Anthony à Wood that Mayow was "descended from a gentile family of his name living at *Bree* in *Cornwall*, was born in the parish of S. *Dunstan in the West* in *Fleet-street, London*, admitted Scholar of *Wadham* Coll. 27. *Sept.* 1661 aged 16 years"[1].

In some recent researches, which are too long to describe here and which will shortly be detailed elsewhere, I have been able to show that Wood's statement is wrong. As it now appears that the present month of December is as near as can be ascertained to the tercentenary of Mayow's birth, we may here briefly summarize this new evidence that he was born in Cornwall in 1641.

C. S. Gilbert describes Mayow as "a descendant from the ancient and genteel family of his name, living at Bray, in the parish of Morval"[2]. The manor of Bray was acquired by the Mayows in 1564 when Phillip Mayow of East Looe bought it from Christopher Copplestone[3]. Wood's "Bree" is, therefore, the manor of Bray in the parish of Morval near Looe in Cornwall. A search in the parish registers of Morval, by the courtesy and with the assistance of the Rev. E. A. Saunders, vicar of Morval, showed that John Mayow, the second son and third child of Phillip Mayow and his wife, Frances Stukeley, was baptized in Morval Church on December 21, 1641. As confirmatory evidence we may quote here, with the kind permission of the Warden of Wadham College, Oxford, the following extract from the records of the College: "John Mayow (Mayouwe), matriculated 2 July 1658, received as commoner, but admitted scholar 23 Sept. 1659, said to be of Bree, Cornwall and aged 17". Thus the John Mayow of Wadham College is also the John Mayow of Bray in Cornwall, who, being aged seventeen in September of 1659 (he would have been eighteen in December), or possibly said to be of that age in July of 1658 (he would have been seventeen in December of that year), was baptized in Morval Church on December 21, 1641.

GLASS FURNACE PROBLEMS

THERE has been little advance in glass furnace design since the invention of the Siemens regenerative furnace in the sixties. Such improvements as have taken place have been largely in the resistance of the various refractories to the temperature of which this type of furnace is capable, and even yet a producer-gas fired furnace can be run at a substantially higher temperature than the refractories themselves will withstand for long periods. The Society of Glass Technology, in co-operation with the Department of Glass Technology at the University of Sheffield, has given continuous thought to the problem of furnace design during the twenty-five years of its existence, and it was therefore appropriate that the twenty-fifth anniversary meeting which was held at Sheffield on November 19 should take the form of a symposium on glass furnace problems.

The morning session was devoted to two papers dealing with the fundamental aspects of heat transmission, of which one, by Prof. D. T. A. Townend and his associates in the Department of Fuel at the University of Leeds, referred to radiation from flames and furnace linings, and the other, by Mr. J. B. Wagstaff, of Messrs. Hadfields, Ltd., had particular reference to the use of heat-resisting steels in recuperators. The second session, in the afternoon, dealt with the problem (of more immediate importance to the manufacturer) of the possibility of determining figures which would represent the performance of glass tank-furnaces, and provided a summary of the work which has been carried out by the Furnace Sub-Committee of the Department of Glass Technology during the last few years.

In discussing the question of metal recuperators, it was pointed out that the conditions for heat exchange in gases are fundamentally different from those for liquids, in that there is a high temperature difference between ingoing and outgoing gases, and the large volume of gases to be considered travel necessarily at a low velocity. For temperatures below 600° C., cast iron is reasonably satisfactory, and from that to 900° C. alloy steels meet the case. Even the best alloy steels are unsatisfactory at temperatures in excess of about 900° C., and the high nickel steels have the additional disadvantage that they are readily attacked by sulphur compounds. A metal recuperator, owing to the possibility of welding, can be made leak-proof, but the ordinary refractory recuperator, while standing up to the temperature and corrosion conditions, usually leaks so badly as to diminish its efficiency to a serious extent.

Mr. Wagstaff dealt in considerable detail with the fundamentals of the design of metal recuperators, and a point of considerable practical importance is the way in which the efficiency diminishes with a deposit of slag or dirt on the recuperator tubes. This was stated to be due to the increase in thermal resistance through the tube itself rather than to any change in the transfer of heat from the flame through the recuperator due to variations in the emissivity of the surface. In the course of the discussion it became clear that while some metal recuperators have failed in the course of as short a time as forty-eight hours, others have been found satisfactory for periods up to ten years; the main point that was emphasized being the necessity for selecting the metal appropriately to the particular conditions of the problem.

Prof. Townend provided a masterly summary of the fundamentals of heat transfer by radiation, and sketched in outline the theories that have been advanced to explain the radiation from water and carbon dioxide in the near infra-red. There is growing evidence of the existence of what he described as "over-activated molecules of relatively long life", which are, however, capable of giving up extra energy almost instantaneously on collision with the appropriate molecule or surface. Some of the facts which have led towards this conclusion are that silica-coated thermocouples record much lower temperatures than plain metallic thermocouples in the same gas stream, showing the effect of the surface on the rate of transfer. It has been shown also that most of the radiation from the Bunsen burner comes from the outer surface or the hot cone, indicating that all the energy is not instantaneously released on combustion. It is known that the addition of a small quantity of hydrogen to a carbon monoxide flame decreases the radiation disproportionately, but that the time of combustion increases. This was offered as a partial explanation of the known 'cutting' heat of a water-gas flame versus the 'soaking' heat of producer gas. In the flame spectrum of carbon monoxide there are bands superimposed on the continuous spectrum which are believed to be due to the over-activated molecules referred to above.

The effect of luminosity in the gas flame on the transfer of heat by radiation was then discussed by Prof. Townend. It has been shown that the radiation is greater than in the case of non-luminous flames but falls short of that emitted by a black body at the same temperature. Important factors in the rate of transfer in furnaces are the calorific value of the fuel as this affects the flame temperature, good mixing of the air and gas, and, related to this, the turbulence of flow. The point that is sometimes overlooked by the practical man is that the flame must always be considerably hotter than the walls of the closure.

Prof. Townend's colleague, Dr. A. L. Roberts, discussed the question of the radiation from solids, and pointed out that most refractory materials are initially selective radiators, and showed diagrams indicating how the purity of the refractory material affects the flame and its emissivity curve. Contamination of the surface of refractories in use tends to make them less selective, whereas the most hopeful lines of research would appear to be to make the walls radiate selectively so that the energy would be mostly radiated in the region where it could be most easily absorbed by the substance to be melted. The texture of the surface also has an important bearing on the effective emissivity. Rough surfaces have higher effective values although they, again, tend to render the radiation less selective. There are, therefore, two contradictory facts, and only experience can show which of them has the most important bearing on flame transfer efficiency.

The afternoon papers were, as stated earlier, more largely of direct interest to the glass manufacturer. Mr. W. A. Moorshead summarized the principles involved in the calculation of furnace performances

with particular reference to the effect of changes in regenerator efficiency on the thermal balance sheet. Dr. W. M. Hampton put forward a proposal for a performance figure for glass tank furnaces. While the accurate determination of a thermal balance sheet provides all the information necessary, it involves so much time and work that some simplified method of calculation is anxiously required. It has been the custom in the glass industry to consider the simple ratio glass made/coal used, but it was pointed out that the amount of glass produced in a furnace bears no necessary relation to the amount of glass such a furnace is capable of melting, as commercial considerations frequently come into operation. It is clear that the fuel consumption of a furnace increases with the throughput of glass, and after considering many alternative bases for comparison, it has now been agreed by the Furnace Committee that the fuel consumptions of different furnaces should be compared on the 'no load' basis, that is, the amount of coal needed to maintain the furnace at a given temperature when it is not actually producing any glass. Since the fuel consumption also varies with the temperature at which the furnace is run, Dr. Hampton proposed—and curves were provided to enable the transformation to be carried out simply—that the fuel consumption should be calculated as at a standard temperature of 1400° C.

It has also now been agreed by the Furnace Committee that the input to the furnace should be reckoned in heat units instead of in terms of various fuels, and the proposed performance figure suggested as the area of the furnace per unit input of heat which can be maintained at a temperature of 1400° C. when no glass is being produced. Using the information collected by the Department of Glass Technology over the last four years on glass tank furnaces in various parts of Great Britain, it was shown that there is a definite correlation between the size of the furnace and its performance figure, and also that the most important factor in improving the performance is adequate insulation. Differences in design are apparently of minor importance.

The general impression left by the meeting and discussion was that the glass industry is fully alive to the necessity for fundamental research, and that by the use of some agreed basis it should be possible to compare the performance of tank furnaces employed in making very widely different types of glass. Such comparisons should enable the effect of variations in design or materials on the performance of furnaces to be estimated, and so lead to substantial improvements in fuel economy. W. M. Hampton.

CIVILIZATIONS IN TRANSITION

Although cultural penetrations usually follow predictable lines in accordance with proximity, degree of difference between the civilizations involved, and their relative prestige values, notable exceptions indicate the wide variability of human reactions.

In the symposium on "Civilizations in Transition", held on September 25 as part of the celebration of the fiftieth anniversary of the University of Chicago, Prof. Robert H. Lowie, professor of anthropology in the University of California, and Prof. Michael I. Rostovtzeff, professor of ancient history in Yale University, discussed phases of cultural infiltration.

Prof. Rostovtzeff, speaking on "The Destinies of Hellenism in the Near East", described the trends toward hegemony and toward subordination which existed simultaneously in the case of the Greek settlers in Egypt. At first the Greeks, bearers of a high culture, were an *élite*, organizing a complex bureaucracy which virtually undermined the royal power and which milked the native population of its wealth. Later, Prof. Rostovtzeff said, the tendencies towards cultural acclimatization began to take effect, and by the time of the rise of Roman power, the Greek creative force in Egypt had been exhausted.

After the death of Alexander the Great, a wave of Greek emigrants swept into Egypt.

Since the status of the Greeks was that of a privileged class, the higher strata of the native population naturally tried to acquire for themselves this status. The prerequisite for it was Greek education and participation in Greek life. Thus a certain part of the native population became gradually 'Hellenized' and some of them received from the king the status of Hellenes.

Prof. Lowie discussed numerous examples of primitive groups in which cultural transfer depended on such obvious factors as the conqueror-conquered relationship and geographical proximity, but also listed situations in which these factors were outweighed by customs and other cultural phenomena which prevented transfer of traits of civilization when other circumstances were apparently favourable. Speaking on "The Transition of Civilizations in Primitive Societies", he also pointed to societies in which culture spread from the conquered to the conqueror and across apparently insuperable geographical barriers.

Although contact between two cultures usually results in an exchange of cultural traits, it does not always have this result. Dr. Lowie cited as an example four tribes in the Nilgiri Hills of southern India all of which live within easy walking distance of one another. The Toda are buffalo-breeders; the Badaga raise millet; the Kota serve as smiths and musicians; the food-gathering Kurumba practise magic. Transference of traits among the tribes is inhibited by the intense caste sentiment that prevails. When a few Kota attempted to wear turbans, after the fashion of the Badaga, they were at once beaten up by their outraged neighbours. Geographically there is an ideal set-up for a levelling of cultural differences, but any such process is frustrated by the prevailing ideology.

Class consciousness hinders the free spread of ideas by checking one of its most natural promoters, intermarriage; and it is equally potent when material advantages are reserved to a dominant people.

In Ankole, an East African country, the subject Bairu cannot turn into independent stock-breeders so long as their Bahima overlords claim the right to own all productive cows. Another factor preventing exchange of traits is the emotional revulsion to a novelty which, however useful, flouts accepted

standards, as when Buddhistic scruples prevent the Buddhist from raising silkworms.

Although the raising of edible plants usually spreads rapidly from one culture to another, it is not difficult to find exceptions. Why did rice fail to penetrate Oceania? Why do the contemporary Tahitians, with the example of the Chinese colonist before them, disdain to raise it ? Why did potato cultivation remain confined to Andean cultures in pre-Columbian times even though wild species occurred to the north ? Why did the tomato, a native of South America, reach the Ijca of northern Colombia only in recent times ?

Though not all such instances are explainable, Dr. Lowie considers that a partial explanation is that borrowing of cultural traits is not likely to occur when the potential recipient possesses an adequate counterpart.

In discussing the influence of borrowed traits upon culture, Dr. Lowie pointed out that borrowed traits, because of their extreme novelty, seldom are acceptable to the religious aspects of a culture. He cited as examples the reluctance of American Indian tribes to accept horses and guns into their religious ritual and worship, long after both horses and firearms had been widely used by the tribe. The horse remained of little religious importance. Even though it was an object constantly prayed for, we rarely, if ever, hear of a supernatural horse on a par with the bear, eagle, beaver, or other animal spirits. One Crow band had a horse dance, but the celebrants believed that they derived their power from an eagle.

The principle that novelties are religiously inferior holds true for weapons as well. In 1805 the Crow, obliged to obtain firearms and ammunition from the village tribes of the upper Missouri, were still poor shots with the gun. The deficiency was soon overcome, and, what is more, the wresting of a gun in a hand-to-hand fight came to be recognized as an honorific exploit equivalent to the older bow-snatching. Yet in the preparations for the sacred sun dance it was explicitly ordained to shoot a bull without the use of a gun.

Dr. Lowie also referred to the Crow practice of beginning a war expedition on foot, out of respect for the ancient method of fighting, even though the warriors later mounted horses.

Prof. Rostovtzeff stated that while 'Hellenization' was effected among the well-to-do natives, it did not touch the masses of the population of the two monarchies, the peasants of the country and the artisans of the cities, towns, and villages.

In time, the Greeks became privileged servants of the king and soon a powerful bureaucracy grew up dominated by the Greek administrators. From the point of view of the masses, the Greeks were their oppressors. They extracted from them ever heavier taxes, they supervised their compulsory labour, they acted as agents of the Government in exercising an ever stricter control over their economic life. The native working classes complained to their protector, the king, but they soon found out that the kings were helpless to relieve their sufferings. The powerfully organized bureaucracy was stronger than the royal will. No wonder then from time to time the natives rose in revolt.

As the Greeks began to intermarry with Egyptians, Dr. Rostovtzeff declared, they became more and more influenced by Egyptian culture, and soon an 'Orientalized' type of Greek came into existence. The Greeks were gradually absorbed by their Oriental surroundings. Climate, food, environment had their natural effects. A new type was in formation. We know little of this type, but its existence is certain.

It is significant, for example, how rapidly the Greeks became 'Orientalized' in religion. From the very beginning they worshipped in Egypt the new 'Hellenized' god Sarapis, a blend of the Egyptian Osiris and certain Greek gods. They became more and more devoted to this god as time went on, and especially to his divine consort the mighty Isis, long familiar to the Greeks. There was also the growing devotion of the Egyptian Greeks to the various animal gods such as the great crocodile god, and to the pseudo-science of astrology.

Another symptom of 'Orientalization' was the gradual change in the spirit of the Greeks. The buoyant energy of the pioneers of the third century B.C., their creative force, gradually subsided. Creation was replaced by routine, the Greek tempo of work was followed by Oriental passivity.

By the time of the rise of Roman power, Dr. Rostovtzeff said, the Greek creative force in Egypt had been exhausted and Egypt and the entire Greek world became incorporated into the Roman Empire.

THE QATTARA DEPRESSION

By M. G. BEADNELL

THE account in NATURE of November 1 of the career of the late Dr. John Ball, technical adviser to the Geological Survey Department of Egypt, brings vividly before me his enthusiasm on the subject of the Qattara Depression Scheme, with which his name was so closely associated in Egypt.

Roughly speaking, the depression is shaped like an elongated mutton-cutlet, and has a total superficial area of 19,500 sq. km., two thirds of which are more than 50 metres below sea-level, and the remainder reaching a minimum of −134 m. at a point south-east of the tiny enclosed Oasis of Qara. Its greatest length, from west to east, is 298 km., and greatest breadth, from north to south, 145 km. The depression extends from nearly 80 km. from Siwa on the west to within 205 km. of Cairo on the east, and its most northerly boundary is only 56 km. from the Mediterranean.

Nearly a third of the floor consists of a damp mixture of sand, clays and salts, known as "Sabakha", an Arabic term applied to deposits having a fertilizing value. (This area is so enormous that a proposal was put forward at the time by a Cairo newspaper that the depression should be exploited for its economic value, as a parallel to that of the Dead Sea, but this was never undertaken.)

The existence of this low-lying tract was discovered only in 1917, and quite fortuitously. The

commander of a military patrol going through that part of Northern Libya was requested by the Survey of Egypt to take aneroid readings, and the result was so surprising that at the earliest opportunity a scientific surveying party was sent there to confirm the data obtained. This led to a visit to the region by Hussein Sirry Bey (now Prime Minister), at that time director-general of the Survey Department, accompanied by Dr. Ball, director of the Desert Surveys branch.

There and then was conceived the huge project of bringing the water of the Mediterranean to the depression through a 60-km. aqueduct, part canal and part tunnel, and utilizing its fall from the exit —about 250 m. below the summit of the escarpment— for the generation of electric power on an enormous scale. They calculated that evaporation would effectively prevent the resulting lake from rising to the level of the site of the power-station.

This scheme appealed immensely to the people of Egypt—always worshippers of everything on a grand scale—for they immediately saw a navigable canal connecting the sea with a vast lake over which they might sail almost to Siwa, as well as a natural and inexhaustible electrical supply of 250–350,000 kw., providing cheap power and light for the towns and villages of the Delta.

After some experimental outlay on ascertaining the nature of the strata to be excavated, the idea was entirely abandoned, as its cost would have been prohibitive and exhausted the exchequer before any returns could reasonably be expected.

A point of considerable interest is that in the Miocene and later beds of the 300-metre escarpment of Qattara, a discovery was made of fossil bones of prehistoric animals, descendants of the Eocene ***Arsinoitherium Zittelli*** and contemporary ancestors of the elephant, excavated nearly forty years ago in the Fayum Province of Egypt. Owing to stress of work, this find could not be investigated, and is known only to the finder.

Qattara is the starting-point of many of the sand-dune belts of the Libyan Desert. Wind-erosion is persistently disintegrating the clays, sandstones and limestones out-cropping on the face of the escarpment, the grains being unceasingly swept away and blown southwards to add to the ever-increasing volume of these dunes, the most deadly obstacles to the domination of the desert yet encountered by man.

FORTHCOMING EVENTS

MONDAY, DECEMBER 15

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 3 p.m.—Mr. J. W. Crowfoot: "Syria".

TUESDAY, DECEMBER 16

ROYAL SOCIETY OF ARTS (DOMINIONS AND COLONIES SECTION) (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Dr. Maurice Ashby: "British Empire Drugs Production".

ROYAL INSTITUTION OF GREAT BRITAIN (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Prof. J. C. Drummond: "Recent Advances in the Science of Nutrition and their Significance in War-Time".

THURSDAY, DECEMBER 18

ROYAL INSTITUTION OF GREAT BRITAIN (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Sir John Russell, F.R.S.: "Collective Farming in Russia and the Ukraine".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5 p.m.—Dr. W. G. Radley and Mr. E. P. G. Wright: "Voice-Frequency Signalling and Dialling in Long-Distance Telephony".

MAN-POWER AND WAR PRODUCTION

THE dominant lesson of the War is that the quantity and scale of the equipment which the combatants can throw into the scales at the right place will go as far to determine the issue of the struggle as the military virtues of the rank and file or the skill of the commanders. The industrial effort of Great Britain and its Allies must be raised to a level from which the flow of equipment will swamp that of Germany. Not until it can be said of the Allied forces that, like the German fighting man, they are equipped with every offensive weapon and every device for their protection that forethought and ingenuity can provide, may our war production be regarded as adequate.

Ultimately war production resolves itself into the question of the disposition and control of man-power and woman-power, and in considering whether our industrial effort is adequate to our needs there are three main factors to be examined. The first concerns labour, the second management and the third staff work at the centre. The proposals outlined by the Prime Minister in the House of Commons on December 2, with the call for a further inroad upon the amenities of life, appear to lay the main stress upon labour, but the response in the subsequent debate to the Prime Minister's appeal for proposals for the development of the war effort indicates that Parliament is well aware of the importance of the second and third factors, as indeed the reports of the Select Committee on National Expenditure have already shown.

When Mr. Bevin called for a 40 per cent increase in production this winter, he justified by implication much of the criticism to which the Government has been exposed in this matter. That criticism has been essentially constructive, as is recognized in the whole procedure adopted by the Government in dealing with what Mr. Churchill termed the crisis of man-power and woman-power which will dominate the year 1942. The attention focused on the amount of man-power and woman-power by the White Paper which has now been issued, and discussions as to the means of directing our diminishing reserves to the points at which they can contribute most to the national effort, should not be allowed to deflect attention from the equally vital matter of the use to be made of the reserves thus deployed or of the forces already in action on the Home Front or in the Services. The full national effort will only be exerted when all possible reserves of man- and woman-power have not merely been brought into service but when their potentialities are being utilized to the best possible advantage.

It is on this question that there is the most serious reason for anxiety. A disquieting volume

of evidence, some of which was provided in the recent debate, some in reports of the Select Committee on National Expenditure, and some in the preliminary report of the Beveridge Committee on the use of skilled labour in the Services, indicates that management in the Forces and in industry has not been so efficient as it might be in eliminating waste. There is other evidence, notably in the handling of the concentration of industry, and of the distributive trades, the limitation of supplies and the registration of retail shops, of defective staff work at the centre leading to the dissipation or disappearance of labour which should have been released for war purposes by the closing of businesses or retail shops. The persistent reluctance of the Government to use boldly and imaginatively the wide powers, given to it by the Enabling Act, on the formation of Mr. Churchill's Government, is probably the most potent single factor in any uneasiness with which the Government's handling of this extremely complicated and difficult question of man-power and woman-power is still regarded.

If the Government has never taken full advantage of the psychological value of the Enabling Act, it is the more important that nothing should be done to impair whatever fresh opportunities the new National Service Act may afford. There should be no possibility of fresh charges of discrimination between class and class or of causing friction that may endanger single-minded devotion to winning the war. The exclusion of married women under thirty from conscription, whether or not they have home ties or duties, may easily engender a sense of unfair discrimination against the unmarried woman, particularly if already employed, or lead to untoward or undesirable social consequences unless the situation is carefully handled on some such lines as those now to be applied in the new system of reservation for men. Sufficient substance has already been forthcoming for criticisms of wasted man-power for the country to be entitled to an assurance that when the Government and industry receive these immense supplies of new labour they will be more efficiently used than those already available. The immense demands made on leadership and management by the system of individual rather than group reservation are scarcely realized. Sir John Wardlaw-Milne's comments regarding the Special and Central Registers voice an anxiety widely existent among scientific workers and one which will not be dispelled while there is any evidence of undue tenderness to management or workers who put selfish or sectional ends before the national interest.

The system of individual reservation will be welcomed by scientific workers, who have already from time to time expressed serious concern as to the use which is being made of Great Britain's scientific man-power. The closer scrutiny of the essential character of every man's work, however, makes demands on management as well as on the new man-power boards which will involve no small measure of public spirit and sound judgment, if their purpose is to be served and if no bottlenecks are to be created in any transfer of workers. There should be opportunities for much fuller co-operation by the professional associations of scientific men, and the new system is likely to call forth their utmost sense of public responsibility.

To remedy the lack of co-ordination and utilization of scientific and technical man-power, a conference of the Association of Scientific Workers in Birmingham has already suggested a programme for the full employment of technical staff, the pooling of technical information between the Government and industry and adequate training facilities for inexperienced personnel (see p. 759). Peace-time methods of organization were alleged to be preventing the fullest use being made of the reserves of existing laboratories, and it was also stated that production has been impeded by the absence of systematic pooling of scientific information. Certain of these criticisms and proposals will doubtless be further explored at the open Conference on Science and the War Effort convened by the Association in January, particularly at the session on January 11, when the material collected by the Association's Industrial Committee on the utilization of scientific personnel will be considered.

In the meantime, Mr. Bevin's decision to establish in the Ministry of Labour machinery a proper appointments department including the Central Register (see p. 747) will be carefully watched. "The time has come", he said, "when proper provision in the technical branches of industry, right up to managements, should be conducted by the State, and the right people within the department should be appointed to handle it as a specialist's job." That is an important step, and when implemented should do much to secure the more effective use of scientific and technical man-power and the appointment of managers capable of the staff work upon which so much depends if the new supply of labour is to be fully utilized. The present position of the employment of physicists is dealt with by the honorary secretary of the Institute of Physics on p. 756.

It has been widely appreciated that a more comprehensive survey of man-power cannot be made public without enlightening the enemy. Mr. Bevin's inability to place the Beveridge Report before the House is understandable. So, too, is the recognition that Britain lacks the man-power to maintain a great Navy, Army and Air Force and at the same time a sufficiently vast

industrial output. That main conclusion of Mr. J. D. Biggers's survey on President Roosevelt's behalf of British war production had already formed the basis here of an argument for a comprehensive strategy. What stands out above all else at the present time is the emphatic demand for careful and efficient administration. The need for perfecting the organization and use of man-power becomes greater, and the chief concern of most of the critics has been to strengthen the organization so that it may be equal to the burden placed upon it.

It cannot be fairly suggested that over the whole field output has fallen, as a result of slackness or indifference or absenteeism by the workers, much below what it would have been right to expect. The great body of workers, men and women, have worked well and consistently in conditions to which the War of 1914–18 could show no parallel, and Mr. Bevin's spirited defence of them is fully justified. Moreover, to some extent, what loss of output has been due to the workers, has frequently been the result of inefficient management as, for example, the absenteeism due to the attempt to work excessive hours, or sickness due to failure to provide adequate transport arrangements, canteens, efficient heating or ventilation and precautions against accidents. These are all day-to-day staff matters in industry, and the very fact that there have been such failures in Government factories, as well as in private industry, is bound to lead to some anxiety, in view of the increasing importance of such staff work with the growing influx of women in the war factories.

The utilization of married women, whether with or without children, and particularly on part-time work, involves even more complicated questions of administration and closer attention to welfare work. Apart from the questions of training, transport and hours, the provision of canteens and the like, there is the difficult question of shopping. Not all shopkeepers are as helpful as they might be to the industrial worker, and there is already a certain amount of discontent at the way in which a sheltered position is being used against the general interest. Government action in regard to shopping hours and facilities may become as imperative as in regard to the provision of crèches or day nurseries where local authorities or factories are slow to act. The chemical industry has already set an example in methods of co-operation which other industries might study with profit.

What is required, in fact, is not merely organizing ability and energy, but also sympathetic and imaginative insight into the needs and problems of potential and existing war-workers. It is this that gives special significance to a letter of Prof. Norman Bentwich in *The Times* regarding the use of neglected older men and women experienced in administration work, who are on the Central Register. Many such men and women would be content to do modest administrative work in the Services and would willingly be directed by their juniors in age. They might well supply that reservoir for the staffing of the welfare and administrative work of Government factories, which the Civil Service is untrained to provide and of which the Government, as the largest employer of labour, is in great need in the ordnance factories which have come or are coming into production. Prof. Bentwich suggests the formation of panels in the large towns and civil defence regions to interview those resident in the area and registered on the Central Register, with a view of recommending what use could be made of their services locally.

An admirable example of how the area boards themselves can contribute in such matters as the staggering of hours was described by Sir Edward Crowe in a lecture "Co-operation for Production" given before the Royal Society of Arts on November 28. The delegation of increased powers upon the regional boards of the production executive has been strongly urged as a means of revolutionizing output, coupled with effective staffing and the establishment of much closer relations with the industrial units. The work they have already done in removing bottlenecks, as described by Sir Edward Crowe, does indeed warrant the belief that there are wider spheres in which such boards could act promptly and with decision, and remove from the ministerial plane details of executive work which are properly handled by officials, as the Select Committee has already suggested.

The idea of a War Cabinet free from departmental responsibilities, the members of which could devote themselves to the major tasks of planning and of policy, like the establishment of a Ministry of Production to which Sir George Schuster inclines, is still resisted by the Prime Minister. None the less, Sir George's call for a new spirit as the greatest thing of all will meet with a wide response. It was apparent in the debate that on all sides of the House there are those who share his regret that the Government has not taken the step of enrolling every one for national service with payment on a subsistence basis during the War, and Sir George's suggestion of an expert committee to report on the effects of the present taxation system on industry has been warmly welcomed. In pressing for more unified direction of programmes at the top, for some organization for providing an independent check on the working of the Government machine with the view of learning from our errors, and for a thorough overhaul of departmental personnel and office methods, among other matters, Sir George was voicing beliefs widely held among scientific workers.

RELICS OF RICHARD JEFFERIES

The Nature Diaries and Note-Books of Richard Jefferies

With an Essay, "A Tangle of Autumn", now printed for the first time. Edited with an Introduction and Notes by Samuel J. Looker. Pp. 82. (Billericay: The Grey Walls Press, 1941.) 8s. 6*d*. net.

JEFFERIES has been dead for half a century, while three of his posthumous works were published in 1889, 1892, and 1909. Mr. Looker's scrap-book (it is scarcely more than that) of Jefferies' jottings will, therefore, come as a surprise to most people who, since Jefferies died at the age of thirty-eight after publishing twenty books in his lifetime, must have believed that only private letters remained to be read. Mr. Looker's remains, except for the short essay, "A Tangle of Autumn", are unhappily like the dead leaves brushed together by the gardener after the tree has shed them. They consist, apart from the essay, of a "Nature Diary" written between August and October, 1879, a notebook of stray gleanings between August, 1883, and July, 1884, and a couple of poems published in periodicals. The rest of the book is filled in by a longish introduction, a short bibliography, explanatory notes by the editor, and quotations from the published books where Jefferies had worked up an entry in the diary or notebook. It is not much of a harvest (the poems were certainly not worth reprinting), but the editor has at any rate performed a labour of love.

The mistake that nearly all commentators have made about Jefferies is indiscriminate praise, and Mr. Looker is no exception. It does his fame no good at all to speak of him as a great philosopher and profound metaphysician, which he emphatically was not. Many of the jottings in the notebook are obviously first drafts of "The Story of My Heart", a book which is now forgotten and, as the product of an almost pathological neurosis, not unjustly so. In that book Jefferies was stretching out towards "an existence infinitely higher than deity", which is rather like saying "I desire a life infinitely more deathless than immortality", and much of this fragile introspective stuff appears in the notebook in a briefer but not more intelligible form. The following is typical: "Aristotle: that God and design and all is a failure and immortality and soul: we must find something else: and reject the chart but sail the voyage and find a new thing, unforeseen". It is hard that poor Jefferies, who suffered so much from illness, disappointment, poverty and loneliness, should have his memory plastered with such babblings as these.

The essay is full of Jefferies' descriptive charm and eloquence (his strength was always in the objective, and it is sheer cruelty to his memory to resuscitate the subjective brooding of a frustrated life). But it is Jefferies at a good level average, not Jefferies at his best. The diary is very pleasant, and in its terse, brief, truncated observations not unlike Gilbert White's diaries, though not so good.

My own view is that Mr. Locker would have done better to have given us an anthology of Jefferies's published writings, with occasional passages from the unpublished work, each section of the florilegium illustrating some particular phase of the writer's genius. For example, Jefferies as a regional writer, as Clare, Bloomfield, Thomas Hardy, William Barnes and Gilbert White were. Jefferies was emphatically the poet-naturalist of a particular region, the Wiltshire-Berkshire borderland, though likewise of the South Downs and the once green belt of London. He was not a traveller like Hudson, and indeed he hated change:—"Let change be far from me; that irresistible change must come is bitter indeed. Give me the old road, the same flowers, the old succession of days and garland, ever weaving into it fresh wildflowers from far and near." He and Alfred Williams were the tutelary spirits of White Horse and Liddington Hills and it is good that a memorial stone has recently been raised here to their joint memory. In these days of standardization and diffused uniformity, to dwell on the regionalism of our choicest English writers would be a service not only to literature but also humanity.

Yet Jefferies' regionalism was incomplete, and there is a passage from "Field and Hedgerow" in Mr. Looker's pious collection which sharply illustrates in what sense it is so: "I wish the trees, the elms, would grow tall enough and thick enough to hide the steeples and towers which stand up so stiff and stark, and bare and cold, some of them blunted and squab, some of them sharp enough to impale, with no more shape than a walking stick, ferrule upwards, every one of them out of proportion and jarring to the eye. If by good fortune you can find a spot where you cannot see a steeple or a church-tower, where you can see only fields and woods, you will find it so much more beautiful, for Nature has made it of its kind perfect." What an extraordinary passage! Even Hudson, who was decidedly crotchety in his dislike of gardens and his indifference to the cultivated field, would never have committed himself to so outrageous a

myopia as this. It is not merely outrageous but silly, because the "fields and woods" are not pure Nature any more than the steeples and towers are man-made only. The latter are Nature working upon the works of man and the former man working upon the works of Nature with the result of a perfect synthesis between them, not to be matched anywhere else in the world. Yet Jefferies missed this unique beauty!

We shall do good rather than harm to the memory of a great Englishman if we recognize frankly that there is a fair amount of nonsense in Jefferies, that he was a more limited writer than either Hudson or Gilbert White and that his metaphysics will not bear looking into. They lack the stuff of thought. But as an observer of the familiarities of his own countryside no writer was greater than Jefferies, and to that power of seeing was often wedded an exquisite sensibility to the sheer beauty of the natural scene. His style can be monotonous, but at its finest it is that of a true poet. He could draw character too: Is there anything of its kind to touch his picture of a yeoman in "Amaryllis at the Fair"? "After London", too, is a very fine story, while his delight in colour and bird and beast and flower and fish and the great sun over all is true elementalism. So, if he lacked certain qualities as a writer, he possessed grace abounding in others.

H. J. MASSINGHAM.

PHYSICS OF THE SOIL

Soil Physics

By L. D. Baver. Pp. xi+370. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1940.) 24*s*. net.

SOIL physics, although a science having but few devotees, has grown up in two separate divisions, one dealing with soil as a habitat for plants and the other for large public buildings and roads, etc. Unfortunately these two divisions are still in almost water-tight compartments with respect to each other, there being neither any appreciable co-ordination between the two sets of workers nor, for so far as the agricultural workers are concerned, any ready access to the journals in which the civil engineering workers publish their results. The consequence is that text-books form the only easy means of finding out what the other workers are doing. The civil engineers are much better provided for than their agricultural confreres in this respect, as several good text-books have been published for them in recent years, while the last standard text-book on soil physics from the agricultural side was Keen's monograph published in 1931 and long since almost unobtainable. Now comes Baver's book to fill this important gap.

The author himself is well known for his researches in soil physics. But he has been a teacher as well as a research worker, and this book is the result of many courses of lectures he has given. Further, as he himself says in his preface, he has been fortunate in having ready access not only to the American but also to the extensive and very scattered European literature on soil physics. The result is a book containing references to the work of a great number of workers, and therein lies its chief limitation for the student but great utility for the research worker: for the incorporation of so much of the literature has been done at the expense of clarity in outline in some places where a clear outline could, in fact, have been given. Further, the author has not always quoted quite enough of some published work to make it self-explanatory, nor has he always indicated which points of technique in quoted work are fundamental to the interpretation of the results or to the use of the method and which are more or less arbitrary.

The book discusses all the subjects that usually come under the heading of soil physics from the agricultural point of view. It begins with a historical summary of the early work, and the reviewer himself was particularly interested in the many references made both here and in the body of the text to the work and results of the early pioneers. Then come two chapters on the mechanical composition of the soil, the definition, structure and properties of clay, and the various methods of mechanical analysis that have been devised and used. Mechanical analysis is discussed in great detail and on the whole very well, but it is marred by slurring over the concept of equivalent particle diameter. The author discusses all the main assumptions involved in obtaining Stokes's Law for the velocity of a freely falling sphere and discusses the complications occurring when one tries to apply it to soil particles, but the whole discussion is really trivial since he does not mention in this context that most clay particles are nowhere near spherical, and this introduces a far greater uncertainty into the interpretation of the results than all the other factors he has discussed. What he has not stressed is that the mean settling velocity of a non-spherical particle in water at a given

temperature has nothing whatever to do with Stokes's equation. The value of the equation is to transform this velocity into an equivalent particle diameter using a somewhat arbitrary value for the density of the soil particle.

The chapters on soil structure, soil air and soil temperature maintain a high standard, but that of soil water is less satisfactory. There is still a surprising confusion in the minds of most soil workers on the fundamental conceptions of soil water, which is reflected in this chapter by an unfortunate vagueness in some of the fundamental concepts and in particular in some of the consequences of these concepts. As an example, there is quite a good account of the concept of capillary potential or *pF* of the water in the soil, but the author does not seem to have realized explicitly the necessary connexion between the distribution of pore sizes in a sand or soil and its *pF* curve, with the consequence that a number of results on soil permeability are given as perhaps unexpected experimental results instead of obvious deductions from the underlying theory.

The last two chapters deal with the application of soil physics to soil cultivation and to erosion control. The former gives an excellent account of Nichol's work on the plough, and of the conditions one would expect in an ideal seed-bed, without, however, showing how far plants respond to these conditions. It also discusses briefly but adequately the effect of keeping the soil surface mulched. The last chapter discusses briefly such topics as the effect of slope and vegetable on soil and water run-off and on the rate of infiltration of water.

The text is well supplied with the relevant figures and tables needed to illustrate the main points discussed, and the book itself is, needless to say, very well produced. It forms a valuable addition to the very small library of books devoted to soil physics and it will amply repay most research workers and lecturers in soil science the time taken to study it. E. W. RUSSELL.

A PHYSICAL TREATMENT OF THE RAMAN EFFECT

Scattering of Light and the Raman Effect
By Prof. S. Bhagavantam. Pp. x+333+2 plates. (Waltair: Andhra University, 1940.) 15 rupees; 22*s*. net.

A BOOK on the Raman effect, written from a physical point of view, has been badly needed for some time. Since the discovery of the effect in 1928, there have been several attempts to review and collate the enormous literature which has grown up in the succeeding years. Although there are now several good bibliographies, and Hibben's excellent book on the chemical applications, Professor Bhagavantam is the first to give a general account of this phenomenon in English, with proper emphasis on the physical aspects. Almost half the book is quite properly devoted (as the title indicates) to the general subject of light scattering. In addition to providing a good up-to-date account of the basic phenomenon, this method of treatment helps to make clear the relation of the quantum theory to the classical theory of light scattering, and the extent to which classical ideas (for example, anisotropy and polarizibility) may usefully be employed in the interpretation of Raman spectra.

Any treatment of the Raman effect is naturally based on the theory of Raman spectra of diatomic and polyatomic molecules, and this is given with considerable skill, the essentially mathematical parts being relegated to appendixes. Applications of Raman spectra to problems of molecular structure, of crystal structure and to a variety of problems in physical, inorganic and organic chemistry are presented in five separate chapters. A particularly valuable chapter is included on experimental technique, since Professor Bhagavantam is an outstanding contributor here, and to obtain really satisfactory Raman spectra is not so easy as is generally supposed. In this connexion the description of the gradual discovery of the phenomenon is of considerable interest.

The only serious defect which the reviewer has noticed is the virtual omission of the interpretation of the magnitudes of Raman frequencies in terms of a molecular model with definite restoring forces between the atoms. The knowledge of inter- and intra-molecular forces which has been obtained from the Raman effect by this means is now very considerable. In this connexion the explanation of the breadth of the Raman bands of water given on p. 156 as "due to the existence of polarity and close packing" is not at all adequate. The exposition, while generally very clear, is occasionally marred by careless phrasing. For example, on p. 175 it is stated "that for a Raman line to occur with appreciable intensity either $\left(\frac{\partial \alpha}{\partial q}\right)_0$, or $\left(\frac{\partial \gamma}{\partial q}\right)_0$, or both should not vanish".

On the whole the book can be warmly recommended to anyone wanting an elementary treatment of this rapidly expanding branch of molecular physics.

G. B. B. M. SUTHERLAND.

GENETICS IN THE U.S.S.R.

By Paul G. 'Espinasse
Department of Zoology, University College, Hull

An opportunity to see old problems in new circumstances and discussed by new-comers is rare enough to be usually worth taking. Interest is added when the problem is the central one of biology and the speakers are Russians engaged in trying to build a society about which there may be as many opinions as observers, but which at any rate can be said to contain some novelties of a far-reaching character. Such an opportunity is provided by the report of a Conference on Genetics and Selection held in the U.S.S.R. in 1939. The proceedings[1] have been translated for the Society for Cultural Relations with the U.S.S.R. by Mrs. Beatrice King. The material thus made available was discussed at a meeting at the Caxton Hall on October 5, 1940. While the original Conference and the Caxton Hall meeting were noticed to some extent at the time, and rumours of genetic controversy occasionally reached Great Britain[2], it seems proper now to make some attempt to evaluate any contributions to genetic thought which may have been made in connexion with them.

First, the genesis of the Conference should be noticed. It was held under the auspices of a philosophical review, *Pod Znamenem Marxisma*, and its purpose was to determine whether any, and if any then what sort of, genetics should be taught in schools and the lower reaches of university courses, and to examine the philosophical credentials of the subject.

The reasons for the importance which the Russians gave to genetic theory are worth looking at. Ever since the Revolution the Russian Government has been engaged in trying to build up an economy strong enough to confer upon that country a degree of independence. In this endeavour time was considered to be a most important factor. It was believed likely that about twenty years was all that could be counted on before the onset of what was considered as the almost inevitable attack on the new regime by some Power or combination of Powers bent upon its destruction. As well as the building up of armaments and engineering works, it was felt necessary to increase the productivity of Soviet agriculture and horticulture so as to provide an increased food supply no longer based so largely upon the more vulnerable districts of the country. It was seen that genetics had an essential part to play in this programme. That is why, at a time when most of the world was burning coffee, destroying crops, and paying men not to produce, the Russian men of science were being asked urgently to increase yields. That is why the impact of genetics on a Russian was likely to be different from its impact on a citizen of another country.

It was because of the importance of the time factor that any offer of an increased speed in the production of desirable varieties of crop plants and of stock was so attractive to the people and Government of the U.S.S.R. The demand for speed led inevitably to the supply of offers, some honest and useful, some honest, ignorant and useless, and some, as in other countries, possibly to a considerable extent consciously fraudulent.

At the Conference the Russian geneticists who have made important contributions to genetic theory, among whom one of the well-known names is that of N. I. Vavilov, came into conflict with other workers, led by T. D. Lyssenko, who attacked certain of their conceptions. Some of these critics made it quite clear that they did not understand what it was that was being discussed. Others made real criticisms; often expressed in terms which make them most difficult to follow, but still real. The important criticisms were directed almost exclusively to three points, though they started from widely different fields and wandered about sometimes in a fatiguing manner.

The first real point of attack was the meaning, the reality and the interpretation of the Mendelian ratio of 3 : 1. Now, qualities resident in parents may appear in their descendants either never, sometimes, or always. If they never appear they are said not to be hereditary. If they appear always they are regarded as hereditary, but the mode of their inheritance would appear to defy analysis by familiar means. If, however, they appear sometimes, then the proportions in which they appear can be used as evidence about the mode of their inheritance. The conventional structure of genetic theory claims that the proportions in which heritable qualities appear are nearly always *sensible*. That is to say that they are regular in essence and that any apparent irregularity can be accounted for satisfactorily—can, in fact, be made sense of. This claim is coherent, and is based upon an immense body of observation and calculation. One of the simplest of these calculations leads to the expectation that a certain procedure in breeding will give descendants with certain qualities in the ratio of 3 : 1. Since this simple calculation is fundamental to the Mendelian concept its history is perhaps important.

Mendel noticed the proportions in which certain qualities in certain plants appeared in subsequent generations. He pointed out that in fact these proportions were those in which the qualities would be expected to appear if their appearance depended upon the distribution to the offspring of real physical entities present in the parents. To mediate the appearance of the qualities as observed, the entities would have to be present twice in the parents, to separate at the formation of the reproductive cells, and so to be present again twice, once from each parent, in the offspring. It was seen at the beginning of the century that chromosomes did behave and were distributed in a way analogous to this. Further work has shown that certain qualities in certain forms do depend upon the presence of certain parts of certain chromosomes. Mendel happened, it may be said by chance, to choose for investigation qualities which were mediated by factors present (in our terminology) on different chromosomes, or distributed as if they were, that is, practically at random with respect to each other by the crossing-over of chromatic material. If he had not done so he would presumably not have been able to make the generalizations which he did make.

If two parents are unlike in respect of one character in such a sense that in one both factors mediating it are similar, and in the other both are again similar to each other but different in state from those in the first parent, it can readily be seen that the mechanism described will give a first generation all alike and a second generation, derived by random mating in the first, in the proportions of one of each original type to two mixed. If one state of the factor permits the expression of the character if that factor is present only once, while in the other state the factor needs to be present twice, all the individuals will show the character except those which have the second state of the factor twice, once from each parent. This results in the second generation being in appearance three of one kind to one of the other. By an extension of the same argument, if two qualities are considered together the second generation will have four different appearances in the ratio 9 : 3 : 3 : 1.

Precisely these ratios are scarcely ever found in fact. Many things, such as differential death-rates, upset them. It was soon realized that the chromosomes were insufficient in number to account for the phenomena observed, and the factors were postulated as existing along the length of the chromosomes. They were called genes. The difficulty of expressing in terms of genes the heredity of such qualities as height, which can clearly vary continuously, soon made it necessary to consider the interaction of genes with each other, and such workers as Bridges and Timoféeff-Ressovsky were soon interpreting heredity in terms of the interaction of all, or at least many, of the genes with the environment. This enables genetic situations far less simple than those examined by Mendel to be analysed and expressed in Mendelian terms.

The critics at the Conference took the term "the 3 : 1 ratio" as standing for any of the ratios which would be given by such a mechanism as has been described, and in attacking it they were attacking this conception as a whole. They pointed out, what is well known, that these ratios are scarcely ever realized. They expressed this, in their very difficult terminology, by saying that the 3 : 1 ratio was a mathematical law, and not a biological law. Stated in ordinary terms this is simply the commonplace observation that many qualities which are hereditary have an inheritance mediated by many genes and not simply related to any one of them, and that many factors have to be considered as influencing the situation. If nothing is considered for the moment beyond the genes, it is clear that this means that the qualities will appear not in a simple 3 : 1 ratio but in a more or less complicated combination of such ratios, granting the whole Mendelian mechanism.

From this point the discussion really turns upon the question—a perfectly proper one—of whether the analysis of the inheritance of important qualities into terms which are likely to give so complicated a set of possibilities—almost as complicated as the animal one starts with—is really worth while. This question is not asked by Russians only. In Great Britain Hammond[3], among others, has recently suggested that the points which make a sheep good for killing are beyond useful analysis of this kind.

The fact is that animal- and plant-breeding are not the only customers that genetics has. Genetic theory has proved of immense value to the botanist and the zoologist engaged in constructing theories of evolutionary mechanics, where there is no hurry. Many papers on genetics are about its evolutionary aspects and the mathematics of inheritance in populations. Formal genetics, while it is used in much important work on many forms by many workers, has developed a side which is of little immediate use to the breeder. The reasons for this are fairly simple. The culture of Drosophila and the observation of populations are often based upon numbers which it would be inconvenient for the animal breeder to maintain if he were using cows. Some Russians believe that there "ought" to be a certain relationship between theory and practice, rather as some philosophers think there "ought" to be a certain relationship between, for example, what is said and the truth.

One cause of the distrust with which the Mendelians are sometimes regarded by some

breeders may perhaps have its roots in a misunderstanding of the claim by such workers as Muller that, in Drosophila, all heritable differences behave as Mendelian entities, or at least behave as they should do if they were dependent upon a number of these. Muller[4] mentions only one apparent exception, provisionally ascribed to the action of a virus. The breeder may sometimes feel the danger that this statement may be used to prejudge the nature of any instance of heredity in any form which may come up for discussion, and, worse, to belittle the successes of the breeder working with un-analysed material. It does not, for example, invalidate the truth of such well-authenticated observations as those of plastid inheritance in plants. The Mendelian behaviour of an inherited variation is a fact which has to be established for each variation. The formal geneticists feel strongly that, since about 1915, the onus is on the doubters to show that any case of inheritance is *not* Mendelian. Their opponents hold that until the mode of inheritance of any variation is known, it is formally inadmissible to presuppose one mode rather than another.

This questioning of the usefulness of the Mendelian analysis becomes involved with an attack on the logistic situation of formal genetics. Particulate genes, it is suggested, of a rather Lucretian atomicity, are invoked when convenient and, when inconvenient, are rendered almost unapproachable mathematically by an appeal to an ever more complicated system of interactions, only to reappear at the right moment. Perhaps partly because wheat is of great importance economically, it is in the discussion of the genetics of wheat that this second line was developed most clearly.

Wheat is normally a self-fertilizing plant. The widely used wheats to which names have been given have been produced by artificially crossing different strains. This is done by preventing self-fertilization and substituting pollen from a chosen source for that of the plant itself. The grains resulting are sown and the plants thus obtained are allowed to fertilize themselves in the ordinary way. If, now, the individual plants with the qualities desired in the new strain to be set up are alone allowed to survive, then as generation succeeds generation the variation in respect of these qualities grows less, because, in respect of the genes responsible for the mediation of these qualities the strain becomes more nearly homozygous—that is to say, the genes in question are present twice in an ever-increasing proportion of the population. The strain thus set up is called a pure line. It was pointed out long ago by Johannsen that the only variants to be found in a really pure line would be those due to environmental differences and so would not be inherited, apart from occasional mutants. Many of the strains of wheat set up by de Vilmorin in the middle of the last century are said to show no progressive changes since then[5].

Now, some of the Russian workers under Lyssenko claim to have produced strains of wheat by crossing within a previously recognized strain. If the strain in question is really a pure line this procedure of 'intra-varietal crossing' should be meaningless, and the wheats produced should be like their predecessors. The Russian workers claim that they are not. They claim that they differ, and that some of them are better than the wheats originally used.

They refuse to concern themselves with a full Mendelian analysis of the situation, holding it to be not worth while. The way in which the allegedly different qualities behave in heredity is therefore impossible at present to make out. Apart from accidental cross-pollination, the only thing that seems likely to change a really pure line, that is one that is really homozygous for the genes in question, is mutation. Wheats do mutate. If they did not it does not appear that they could evolve. It is conceivable that the Russians have obtained their alleged results by crossing plants which were not really homozygous for the genes concerned. But it must be borne in mind that through the breakage of the material of the chromosomes and other disturbing factors it is extremely difficult to get any individual pure, or homozygous, for *all genes*. It is, indeed, uncertain that such a thing has ever been done. It is here that a logical weakness in the structure of formal genetics is alleged. If all, or many, genes are relevant to any character, as they are assumed to be to account for other phenomena which are not easily accounted for otherwise, then, as more genes are reckoned in, the more improbable it is that any strain of wheat is homozygous for all the genes relevant to any quality, and the more meaning there is in 'intra-varietal crossing'. It should be remembered that the evidence for the persistence of qualities in de Vilmorin's wheats can in the nature of things only refer to qualities that can either be preserved dead for comparison year after year or else be precisely recorded. It is not evident that every single character of wheat, or even every useful one, falls into either of these categories. If the concept of the interaction of the genes is retained, as logically it seems that it must be, then any gene difference is relevant, and some would be possible between any two plants in a strain. In denying such a possibility the formal geneticist would be in a difficult position.

The third front of attack on the Mendelians at the Conference was much wider and much looser. There are certain technical procedures which can be carried out upon animals, and perhaps more upon

plants, which are useful inasmuch as they improve the plant or animal so treated. These procedures range from the commonplaces of agricultural and horticultural technique, such as seeing that the subjects are well nourished, to such bizarre performances as the grafting of a tomato on to a potato. Hammond, as well as discarding as useless the Mendelian analysis of the inheritance of some qualities in cattle, pigs and sheep, has emphasized the necessity of selecting stock for breeding in the best possible conditions of environment, including in particular those of diet. It may be doubted whether, in reality, these conditions contribute much more to the situation than that they enable the breeder to select those animals the genetic outfit of which permits them to take most advantage of good food. Selection in different conditions would produce different animals. Which is 'best' depends upon the available food and the humour of the market. If the environment of the selected animals is to be East Africa, a different procedure of selection will be proper from that which would be suitable if they are to be kept in Sussex.

If the effects of some of these technical procedures spread from the treated animals to their descendants either for a few generations or for ever, their value is evidently enhanced. The claim that they do is therefore tempting. It happens that the nature of the procedures and the nature of the material used in agricultural and horticultural practice make it far less easy to dispose of the claim that these effects do so spread than it is to dispose, for example, of the claim that the descendants of a mouse whose tail was cut off will have short tails. The two procedures which are of immediate importance in this connexion are vernalization and vegetative hybridization.

There does not appear to be anything particularly occult about vernalization. It has been found in Germany, and probably independently in the U.S.S.R., and confirmed in other countries, that if seed is moistened and warmed and then kept cold for some time and later sown, the seedlings grow faster than do those from seed not so treated. Some points about the process are beginning to be more or less understood. It has to do with the mobilization of food reserves in the seed, which mobilization is less checked by the cold than is the growth of the seed. When, then, the seed begins to grow after it has been sown, it has a more readily available supply of food material than if it had not received this treatment. The facts here seem fairly well established. They were greeted with considerable scepticism when they were first advanced.

It is claimed by Lyssenko and his associates that the effects of this treatment spread to generations subsequent to that treated. These workers, once more, refuse to engage in an analysis of the persistence they allege in terms of Mendelian inheritance. Such questions as whether the differences segregate they ignore. They are not interested. It may well be that they have not found anything in the least in conflict with orthodox genetics. While this state of deadlock persists, it is not easy to see how progress can be made. Each side in the argument considers that it has a set of terms in which the living universe makes sense. Each side believes that the other is childishly sensitive to what it mistakenly regards as an attack on an important and vital principle. The historian of science, with the centuries to draw on, will probably not find this situation unique.

The other procedure, that of so-called 'vegetative hybridization', once more raises the question of whether an effect does or does not spread to generations subsequent to that one which receives a particular treatment. Details of the procedures of grafting and the production of chimæras and 'vegetative hybrids', are given by W. Neilson Jones[6]. The chief facts are briefly these: in the ordinary way a scion grafted on to a stock grows under the influence of the stock and is affected by the qualities of the stock in various ways, probably partly, at any rate, through the sap which is shared. This is well known, and is recognized commercially in the selection of stocks suitable for different purposes. The relation between stock and scion may be of a more intimate nature. It occasionally happens that a bud with a mixture of cells derived partly from the scion and partly from the stock will grow from the region of the junction of the two. This bud gives rise to what is called a chimæra. The tissues may be related in different ways. Sometimes one tissue is on one side and the other on the other, and sometimes one is outside and the other inside. Finally, it has been claimed in the past that the relation may be of a still more intimate character, and that two nuclei, one derived from each source, may occasionally fuse as gametes fuse, and, with or without a subsequent reduction division, may give rise to a tissue the nuclei of which themselves contain a mixture of the contents of the nuclei of the two original plants, and are contained in a cytoplasmic environment strange to some of their genes. Such a plant, derived from the fusion of two vegetative nuclei, is called a 'vegetative hybrid' or 'burdo'. Whether such a plant has ever in fact existed is disputed.

The Russians under Lyssenko claim to have vegetative compounds of various kinds, the descendants of which display some of the mixed qualities. Yet again, they refuse to embark upon a Mendelian analysis of their material, holding it to be not worth while. At the Caxton Hall meeting of October 5,

Prof. J. B. S. Haldane suggested that some of the effects, if real, might be due to the transmission of something like a virus, as in the case of the recalcitrant Drosophila. It is a fact that some of the most striking examples claimed by the Russians are in the Solanaceæ, well known as the hosts of viruses sometimes with pseudo-hereditary effects.

While effects of this kind have been claimed in the past as occurring not infrequently, they may perhaps be considered to be rather rare on the whole. The Russians state that they have used large numbers in their experiments, and it may be that they have come upon an occurrence which has been overlooked in smaller numbers of subjects in work done elsewhere. No amount of appeal to other work can settle the Russian claim; only examination of the Russian material can do that. It is difficult at present to get a clear idea even of the simple facts of the chromosome situation of their plants.

It comes, then, to this. The followers of Lyssenko seem to the formal geneticist to be returning to the methods of the eighteenth century. This was suggested in NATURE in 1937[2]. But if the methods of breeders then were rule-of-thumb, they gave results which are, some of them, still to be seen. The followers of Lyssenko can retort that the formal geneticists are returning to the methods of the Middle Ages. It was believed then that stars moved in circles. If a star did not seem to be doing this very obviously it was considered proper to assume that the centre of the circle necessarily described in its path must itself be moving in a circle. This epicyclic method of explanation increases the complication of the situation it seeks to explain. This lack of economy is looked upon with disfavour. It affords a tempting refuge for the hard-pressed theoretician. Ptolemy is quoted[7] as having remarked, perhaps incautiously, that the phenomena could be saved by eccentrics and epicycles.

The phenomena do not need saving; they need investigating. It is suggested that now, in view of the recent tragic happenings in the U.S.S.R., many of the Russian varieties of plants and fruit-trees may be taken to Great Britain and the United States to be preserved from the invader. It is an irony of history that if this is done it will provide an opportunity for the analysis of the material when no one has time to do it.

SURFACE CHEMISTRY

By Prof. W. D. Harkins
University of Chicago

One of the most interesting of the Fiftieth Anniversary Symposia, held at the University of Chicago during September 22–27, was that on two-dimensional systems or surface chemistry. Introductory remarks on the origin and development of this subject at the University were made by Dr. Irving Langmuir, Prof. H. I. Schlesinger, and Prof. W. D. Harkins. [It is interesting to note that this symposium was organized in honour of Prof. Harkins and the twenty-fifth anniversary of the publication of his first paper in the field of surface chemistry.—*Editors*.] Experimental work on the theory of molecular orientations in surfaces was begun in 1912 on the arrival of Prof. Harkins at the University. The first course of lectures on orientation was presented in the winter quarter of 1913–14. The gist of the theory is contained in a statement from the notes of George L. Clark taken during a lecture which dealt with the more tightly packed films of long-chain organic acids: "COOH of acid down because both acid and H_2O associated in polar." This is the earliest recorded statement of the direction of orientation of surface molecules.

In the first problem considered, but not the first to be solved, it was found that the adsorption of polar-nonpolar molecules is much higher at the surface of water than at the interface oil-water, as was predicted by the initial electrical field theory of orientation.

Interest in this problem arose in connexion with work in Karlsruhe in 1909 on Haber's theory of muscular motion, which assumed, as one of several steps, that a change from acid to basic causes a very great lowering of surface tension both in (1) the muscles, and in (2) a benzene-water system, with a strong acid and a strong base as solutes. However, experimental work proved that (2), assumed from work done in Berlin, is incorrect, so it was planned to substitute an organic acid. This gave Prof. Harkins the idea that at the benzene-water interface the hydrocarbon ends of

the molecules would dissolve in the oil phase and the polar groups in the water, but there was no opportunity to begin a test of this idea until 1912. Later an extensive search through the literature revealed the fact that in 1912 Sir William Hardy expressed the idea that the asymmetrical stray field at the surface of a liquid or a solid causes an orientation of the molecules.

While Hardy gave no evidence in favour of this idea, Harkins found evidence for orientation in Hardy's values for the work of adhesion (W_A) between water and other liquids. Since this evidence was made somewhat uncertain by the inaccuracy in the drop weight method used by Hardy, a considerable amount of experimentation was carried out by Humphery, Brown and Davies, in order to give a high degree of accuracy to the method. This was the more necessary on account of the fact that the internal (surface) energy (E) is much more intimately related to the molecular orientation than is the free surface energy (F), and the determination of E involves the entropy, that is, the slope $(\partial\gamma/\partial T)_{p,\sigma}$, where σ equals molecular area.

Even at the present time one of the best lines of evidence for the orientation of molecules in interfaces is given by the values of W_A, and especially of E_A, at the liquid-liquid, and at the solid-liquid interface. For example, the energy E_C in erg.cm.$^{-2}$ required to pull n-octane apart is 100, while for n-octyl alcohol it is only 101, showing that the polar group has almost no effect, since the molecules orient so that only the non-polar hydrocarbon groups are pulled apart. To pull n-octane from water requires an energy of 107, but to pull n-octyl alcohol from water a much higher energy is needed (165), since the polar group must be separated from the water.

In recent work with Dr. G. E. Boyd the relative energies of immersion (E_I) of TiO_2 (anatase) are found to be: water, 1·00; butyric acid, 0·77; ethyl acetate, 0·69; butyl alcohol, 0·67; nitrobenzene, 0·55; carbon tetrachloride, 0·46; benzene, 0·28; iso-octane, 0·20, and these ratios are practically the same for the solids, which give the following values of the total *energy of adhesion* (E_A) in erg.cm.$^{-2}$: $BaSO_4$, 490; TiO_2, 520; SiO_2, 600; ZrO_2, 600; SnO_2, 680, and $ZrSiO_4$, 850, graphite 265. Graphite, however, exhibits abnormal values of the ratio, namely, 0·73 for CCl_4 and 0·85 for benzene. All the crystalline solids (except graphite) are found to be much more polar than water and the polar groups are turned towards the solid.

Values obtained by the adsorption of four vapours by H. K. Livingston show that all give the same area for any particular solid, provided the areas per molecule in the completed first monolayer are taken as: nitrogen, 15·4; water, 10·6; propyl alcohol, 20·0; and n-heptane, 55·0 A^2. The last value shows that in the completed monolayer *n-hydrocarbon molecules lie flat on the surface.*

In his paper on the properties of solid surfaces, Dr. Boyd gave examples of the *free energy of adhesion* between a solid and various liquids. With TiO_2 the values are: water, 380; propyl alcohol, 129; and n-heptane, 78. The corresponding values of $\gamma_S - \gamma_{SV_0}$ (energy of immersion in the saturated vapour) are 240, 82 and 38 erg.cm.$^{-2}$ for the clean surface of anatase. The values were calculated from the vapour adsorption isotherms obtained by Livingston and the proper Gibbs's adsorption equation.

Dr. Fritz London, of Duke University, considered the centres of van der Waals' attraction. A special type of long-range attraction is assumed to act between large molecules where the virtual electron oscillators are of appreciable extension.

If a molecule possesses considerable electrical anisotropy in its parts (as in the chemical bonds), it is no longer permissible to use the dispersion force as a central force, but rather specific formulæ must be employed. For example, the interaction energy between two anisotropic force centres (bond ellipsoids) is:

$$E_{\mathrm{I,II}} = -\frac{1}{R^6}[A - B - B' + C\,(\sin\delta\sin\delta'\cos\varphi - 2\cos\delta\cos\delta')^2 + 3\,(B - C)\cos^2\delta + 3\,(B' - C)\cos\delta' + B + B' + 4C],$$

where R is the distance between the centres I and II, $\alpha_{\parallel}\alpha_{\perp}$ and $\alpha'_{\parallel}$, $\alpha'_{\perp}$ the components of their polarizabilities, respectively, $\bar{\nu}_{\parallel}$, $\bar{\nu}_{\perp}$ and $\bar{\nu}_{\parallel}$, $\bar{\nu}_{\perp}$ the corresponding frequencies, δ, δ', the slopes of the two bond directions with respect to the line joining the centres, and φ the angle between the projections of the two bond axes into a plane perpendicular to the joining line.

In the special case where the interaction energy between large oscillators is desired for distances shorter than the spacial extension of the interacting virtual charge distributions of the molecules, it was found desirable to represent each oscillator by several distinct poles, 'monopoles', of different sign, suitably located in the molecule. As a consequence of the quantum mechanical treatment of the problem in these terms a new formula for the energy of interaction is reached:

$$E^{(2)} = \frac{\varepsilon^2\varepsilon'^2}{h\,(\nu + \nu')}\left[\frac{1}{R_{++}} + \frac{1}{R_{--}} - \frac{1}{R_{+-}} - \frac{1}{R_{-+}}\right]^2$$

where R_{++}, R_{--}, R_{+-}, R_{-+} symbolize the distance of separation of the respective monopoles; ε, ε' give the magnitude of the high-frequency dipoles.

The theory should be useful for systems containing conjugated double bonds, of which rubber is an example, and for large biological molecules.

Prof. J. G. Kirkwood, of Cornell University, discussed the theory of the transition expanded to the intermediate liquid phase. This transition is considered as an order-disorder transformation in axial orientation of the molecules which constitute the film. By postulating a free energy barrier of appropriate form, which hinders the relative axial rotation of neighbouring molecules, Kirkwood is able to demonstrate a phase change of the second order in a *model* film of cylindrical molecules of elliptical cross-section vertically oriented on the subphase. By means of the statistical mechanical theory of co-operative phenomena the magnitude of the discontinuities in the heat capacity, the coefficients of thermal expansion and compressibility attending the transition, have been calculated. These agree well with the experimental values of Harkins, Young and Boyd.

Surface entropy of pure liquids was dealt with in a paper by Mr. Henry Eyring of Princeton University.

A relation between free surface energy (A_S) and the Eötiös equation is:

$$A_S = E_S - TS_S = N^{1/3}\, V^{2/3} = 4{\cdot}4\,(T_C - T - 6)$$

The entropy, 4·4 Cal. mole^{-1} deg.$^{-1}$ arises from expansion of the surface region, the free energy of which can be estimated by the partition function of normal liquids (Walter and Eyring). The final equation is $\gamma = (\rho_L - \rho_V)\,(a - bT)$ where $a/b \sim T_C$.

Remarkable electron microscopophotographs of gas carbon, bacteria and the coatings of insects were presented by Prof. E. F. Burton, of the University of Toronto, the pioneer in this field in America.

Dr. George H. A. Clowes, research director of Eli Lilly and Co., described the interactions of biologically significant substances.

From extremely extensive data it is shown that many carcinogenic polycyclic hydrocarbons are highly soluble in sterol monolayers (10-methyl-1-2 benzanthracene in cholesterol), in which case the logarithm of the mol fraction of the hydrocarbon varies linearly with film pressure (π). A complex of one molecule of hydrocarbon to two of sterol forms with a free energy of 2·5 kilocalories or less. Increase of pressure on a two-dimensional solution may force the hydrocarbon into colloidal solution in the subphase. Such material penetrates the film at lower pressures. The relations to biology were discussed.

The intrinsic viscosities and the reciprocals of the frictional ratio of fifteen globular proteins were compared by Prof. Henry B. Bull and Mr. J. A. Cooper, of Northwestern University, and an empirical, linear relation found to exist between them. This empirical relation was used to estimate the average volume hydration, which was found to be 0·283 c.c. per c.c. of dry protein, with a standard deviation of the mean of 0·042 c.c.

A test applied to several theoretical equations in the literature relating viscosity and asymmetry of suspended particles is based upon the empirical linear relation between viscosities and reciprocals of the frictional ratios of the protein molecules. None of the theoretical viscosity equations are valid when applied to protein solutions.

Increase of surface tension (γ) by highly polar organic compounds was the subject of a paper by Prof. Ernst A. Hauser, of the Massachusetts Institute of Technology, and Mr. Adrian J. Grossman.

The increments of surface tension produced in benzene by a 0·5 mole fraction at 40° of dinitrobenzenes are: *ortho* 1·75 (6·05), *meta* 1·3 (3·81), *para* 1·2 (0·32), in dyne cm.$^{-1}$, where the values in parentheses are the dipole moments. Thus the increments in γ are related more intimately to the high bond moment (3·9) of the nitro group than to the molecular moment. Frequent changes in the slope $(\delta\gamma/\delta C)_{T,p}$ were found, and a deep depression of 1·2 dyne cm.$^{-2}$ was obtained with 1-nitronaphthalene.

Mr. Eugene Guth, of the University of Notre Dame, considered stress and elasticity in rubber. The theory presented on the basis of an ideal model of incompressible rubber considers an irregular network of flexible long-chain molecules, and predicts the characteristic S-shaped stress-strain curves found in experiments on an unaccelerated pure gum compound. In the analytical expression for the theoretical curves, the Langevin function of the theory of paramagnetism, or the Debye theory of dipole molecules, enters and describes the orientation of the long molecules due to the applied stress.

It is found:

(1) That the stress is due largely to the kinetic energy (entropy) of the molecules and not to the intermolecular forces, since the latter are found to contribute only about 20 per cent of the stress.

(2) As predicted by the theory the stress at constant length is proportional to the absolute temperature.

(3) The slope of the stress-temperature curves is negative up to 10 per cent extension and is positive above this, due to thermal expansion.

(4) Since the heat developed in adiabatic stretching is proportional to the temperature coefficient of the stress (Kelvin-Joule), heat is absorbed for 0 – 10 per cent extension, and is given off for greater extensions.

A new superliquid phase was described by Prof. W. D. Harkins, Copeland and G. E. Boyd.

At certain temperatures it is found that the condensed liquid (L_2) phase of a long-chain alcohol

on increase of pressure transforms by a *first order* change into a new LS phase, which has the compressibility of the solid phase, but exhibits a greatly lowered viscosity compared with that of the liquid from which it is formed by compression and the addition of heat. The internal energy increase and the increase of entropy when this phase expands are excessively large. In the transformation of the L_2 to the solid S phase there is no latent heat, so the change is second order.

Mr. Eyring considered the viscosity of monolayers from the theory of absolute reaction rates.

A decrease in viscosity with increase in pressure indicates that the activated state occupies a smaller area than the initial state, and vice versa. Similarly a decrease in viscosity with temperature indicates that the activated state has a greater energy than the initial state; and increase in viscosity with temperature that the activated has less energy than the normal state.

A thermodynamical theory of the spreading of liquids on surfaces was presented by Prof. Harkins.

(1) A duplex (D) or thick film may spread if its spreading involves a decrease of free energy. On water a D film is always unstable, since there is a decrease of free energy when it transforms into a monolayer (M) and a lens.

(2) Water and all oils spread on mercury, and all liquid oils on water to give monolayers, but if a duplex film cannot spread the pressure (π) of the monolayer may be small.

(3) $\pi_e = S_{b'/a} - S_{b'/a'}$ or the semi-initial minus the final spreading coefficient. Since $S_{b'/a}$ is always negative, π_e, the equilibrium pressure, is always greater than the semi-initial spreading coefficient, and almost always greater than $S_{b/a}$, the initial coefficient for the spreading of the dry oil (b) on clean water (a) as a duplex film.

(4) Water does not spread as a duplex film on any oil.

(5) It always takes *less* work to pull any oil from its first complete monolayer on water than to pull the oil apart.

(6) While lower hydrocarbons give duplex film spreading on water, higher hydrocarbons and some polar oils (as methylene iodide) do not, but form monolayers only.

Dr. Irving Langmuir, of the General Electric Co., discussed the permeability of monolayers.

Copper gauze supporting a layer of $CaCl_2 \cdot aH_2O$, mounted at a distance b above the surface of water in a film trough is used to measure the rate of evaporation. At equilibrium, the rate at which water escapes is determined by the resistance of the moisture-saturated air in the space between the liquid surface and the adsorbent. This resistance to diffusion, ω, is given by $\omega = Awt/M = b/D$, where A is the surface area evaporating, w the grams of water per unit volume of saturated air, t the time in seconds, and M the mass evaporated; D is the diffusion coefficient. A monomolecular film of an acid, alcohol, cholesterol or ergosterol placed on a clean water surface gives an increase in ω, but proteins do not. A logarithmic relation is found between ω and the film pressure. The permeability exhibits extreme sensitivity to impurities. Langmuir considers an impermeable film to be tightly packed at some *definite height in the film.*

NEWS AND VIEWS

In Defence of Liberty

LAST week, on the outbreak of war between the United States and the Totalitarian Powers, the King sent a message to President Roosevelt, which concluded with the words: "We share your inflexible determination and your confidence that, with God's help, the powers of darkness will be overcome and the four freedoms established throughout a world purged of tyranny." President Roosevelt, in his reply, paid a tribute to the courage of the British people during the past two years, and said: "The forces which have plunged the world in war, however strong, cannot prevail against the indomitable strength of free peoples fighting in a just cause."

This was also the text of President Roosevelt's stirring radio address to the American peoples on December 15, the one hundred and fiftieth anniversary of the adoption by Congress of the Bill of Rights The basic principles of the freedom of man embodied in the Bill have been accepted by all the republics of the Western hemisphere, and indeed by some four fifths of the peoples of the world. The present struggle is nothing less than an attempt on the part of the Totalitarian Powers to overthrow all the results that have flowed from the gradual growth of the liberty of the individual. It is an attempt to impose once more on mankind the tyranny and despotic rule of the Middle Ages, from which we have been set free by the courage and sacrifice of our ancestors. The present generation of Americans, President Roosevelt said, are as determined to preserve liberty as their ancestors were to win it, and he pledged Americans not to lay down the arms they have now taken up until liberty is once more secure in the world.

The Central Register

In reply to a question asked by Sir Herbert Williams, the Minister of Labour and National Service stated in the House of Commons on December 11 that as soon as the necessary arrangements can be made, the present Central and Supplementary Registers are to be merged in a new Appointments Department of the Ministry of Labour and National Service. This new department will deal with persons possessing specified administrative, managerial, professional, or technical qualifications and with others who, though not possessing specific qualifications, have a normal salary in excess of £420 per annum. It will operate through its staff at headquarters or through staff under the control of the Regional Controllers, according to the nature of the vacancies for candidates. It will maintain a separate register of persons within its scope who are known to be seeking an engagement and will endeavour to find suitable employment for such persons in some form of national service. The provincial organization of the department will be closely associated with the new district man-power boards.

Gas-producer Poisoning in Sweden

According to the October issue of the *Anglo-Swedish Review*, medicine and technology in Sweden are collaborating in the problem of poisoning from gas-producers, with the result of the establishment of the first clinic in the north at the Sabbatsberg Hospital in Stockholm. The work is being conducted on the following lines: (1) Examination in the laboratory of specimens of blood for carbon monoxide content. Up to the present 4,300 analyses have been made. (2) A clinic of ten beds has been set up and an out-patient department where over 700 cases have been examined. (3) Physiological examinations are being made to discover the most suitable form of treatment and the proportion of chronic cases. (4) Examination of the cerebrospinal fluid in patients who have died from asphyxia is being carried out. The experiments are being made on human volunteers and on porpoises and rats.

Use of Pitch as Fuel

It is well known that modern life in peace and especially in war depends on fuel in liquid form. While consumption of the lighter and more volatile fuels in internal combustion engines is more apparent to the layman, there is a large consumption of heavier fuel oils consumed for industrial furnaces and on board ships. In peace-time practically all the supply of such heavy oils used in Great Britain were imported and a relatively low price was efficiently maintained. Indeed, industry was furnished with a fuel often superior in quality to what was essential to the purpose in question. The reduction in available supplies of imported oil has compelled the use of heavier and lower grade petroleum oils and indigenous materials such as cresote and pitch-creosote blends.

An interesting development is the use of coal tar pitch itself, both solid—as pulverized pitch—and liquid—as molten pitch. Such materials find their application particularly where consumption is large and continuous—for example, in steam boilers and large furnaces. The fuel has certain attractive properties—low sulphur content, freedom from ash and water, uniformity in quality and calorific value. For use it must be heated to 200°C. and conveyed in pipes to the furnaces at this temperature. This has produced unusual engineering problems, the solution of which has required great skill, because the consequences of failure are serious, if ever the pitch solidifies in the mains. The plant used for this purpose was described at a meeting of the Institute of Fuel in London on October 30. This is a valuable technical achievement, because production of pitch has for years exceeded demand and there is in stock a very large quantity which can replace much petroleum oil formerly employed.

Standardization in the Electrical Industry

A thoughtful address was delivered on October 27 by Mr. H. G. Taylor, chairman of the Liverpool Centre of the Institution of Electrical Engineers, on "Co-ordination and Standardization". He regards co-ordination as the best means of arriving at standardization. He said it would be disastrous if the end of the War found engineers unprepared to face the problems of peace in a changed world. Immediately after the War of 1914–18, a major happening in the history of the electrical supply industry in Great Britain was the appointment by the Board of Trade of the Electricity Commissioners as a technical body under the chairmanship of Sir John Snell. As a result of their investigations and in conjunction with the Weir Committee, the Central Electricity Board was established in 1926, its function being to supply electricity in bulk to various distributors and concurrently to increase the availability of supply. This entailed co-ordinating the existing supply authorities, their personnel and plant, while the question of interconnexion of plant involved standardization of frequency, the necessity of which Sir John Snell foresaw, and powers to enforce a national standard of 50 cycles were consequently included in the Act of 1926. As a theory, standardization in electrical engineering is almost as old as the science itself, but its application in Great Britain has lagged too far behind technical progress to maintain a healthy condition in the industry, the development of the heavier engineering commodities having continued, for the most part, on individual lines.

The recognized centre now for dealing with standardization is the British Standards Institution, which now has more than a thousand committees, with about six thousand professional men who have given their time freely to this national work. It is an independent body in close touch with industrial requirements and modern technical knowledge, with the fullest Government support but free from Government control. It co-operates with the central standardization bodies in various parts of the British Commonwealth of Nations, and participates, directly or indirectly, in the work of international standardization.

After the War, we must produce for export not the apparatus which other countries rightly wished to manufacture themselves, but commodities in which we have the technical ability to make ourselves supreme. By complete co-ordination of industrial organizations and research establishments electrical engineers can assist very materially, and the adoption of international standards must be considered. Mr. Taylor suggested uniformity of design for utility electrical products in common use both in the industrial and domestic fields. Such a standard, to be effective, would need to have behind it the authority of the British Standards Institution, and its adoption might even need legislative action. Manufacturers would be encouraged to adopt these standard commodities as their first line of production, and in consequence they would ultimately replace the many specialized products now on the market.

Arterial Road Lighting

THE arterial road connecting Toronto and Niagara Falls, known as Queen Elizabeth Way, is lighted by incandescent lamps in parallel over its whole length of 70 miles. Already the lighting installation enjoys the distinction of being the longest in the world, and no doubt it will be continued on the proposed 20-mile extension of the highway to Fort Erie, making a total of 90 miles. In planning the installation provision was made for maximum silhouetting of obstacles. The Way consists of dual concrete tracks 20–23 ft. in width with an intervening strip of grass 28–30 ft. wide; the standard equipment comprises wooden poles, along the centre line of the grass, with welded cross-arms overhanging each traffic lane to the extent of 3 ft. The availability of cheap electric power from existing rural circuits operated by the Hydro-Electric Power Commission of Ontario seems to have been a determining factor in the adoption of incandescent lighting and parallel distribution. Sodium lamps are used to mark intersections. Distribution transformers of 15-kva. capacity feed the 115-v. lighting cables from the 2,300-v. rural distribution network. The lamps are of 6,000 lumens, 400 watts, spaced 200 ft. apart, and maintenance is by group replacement twice a year. Operating experience and costs from this installation should be of material assistance in planning the general lighting of arterial roads.

Discovery of Smithfield Industries in Kenya

THE September–October number of *Man* contains a letter which is of distinct importance to those who concern themselves with the problems of Stone Age Africa. It would seem certain that Archdeacon Owen has discovered in a rock-shelter in Kenya an early Smithfield industry, and that Prof. van Riet Lowe has agreed with his interpretation. Smithfield industries occur over large parts of South Africa, especially in the Free State, the material used for their manufacture being usually the local indurated shale which chips well. Scrapers, awls, beads, and occasionally a little pottery have been found. The range in time of the culture extends backwards from modern days to an unknown, but probably fairly remote, period, as the later Smithfield industries show differences when compared with the earlier ones. Thus the plano-convex knife is an early tool type and does not recur in the more recent finds, while pottery seems to be absent from the earlier ones. In South Africa, too, there are regional differences in the industries which add to their complexity. But the main great problem has always been as to whether the Smithfield culture as a whole was an autochthonous growth in South Africa itself, engendered perhaps by culture-contacts; or whether it was not rather introduced into the subcontinent by migrations from the north. Archdeacon Owen's new discovery of Early Smithfield material—considered in fact to be even somewhat older than the Early Smithfield of South Africa —in Kenya would suggest that the latter hypothesis is the correct one.

Folk-lore of Alcoholism

IN a paper on this subject (*Brit. J. Inebriety*, July–October), Dr. J. D. Rolleston remarks that with the exception of Hovorka and Kronfeld's great work on comparative folk medicine no writers have dwelt at length on folk-lore in relation to alcoholism. He has therefore collected the folk-lore of this condition, as he has recently done in the case of general medicine, dermatology and pulmonary tuberculosis. His paper deals with the nomenclature, popular phraseology, superstitions and leechcraft connected with alcoholism and alcohol, the term 'leechcraft' being that commonly employed in the language of folk-lore to indicate popular methods of prevention and treatment. In a previous paper on "Alcoholism in Classical Antiquity" (*Brit. J. Inebriety*, 24, 101; 1927) he directed attention to the numerous synonyms for inebriated or bibulous persons, both in Greek and Latin, as well as in English, which contained about seventy such terms, only a minority of which could be called slang, whereas there are more than 280 slang synonyms for the word 'drink', 160 for the verb 'to drink', and 150 for various forms of intoxication. Popular interest in the consumption of alcohol, especially in excess, was further demonstrated by the great variety of similes connected with the subject. After dealing with the superstitions and popular errors connected with alcohol and alcoholism, which are legion, Dr. Rolleston discusses the popular methods of prevention and cure for inebriety, which he classifies under the headings of animal remedies, including coprotherapy, plant remedies, of which a large proportion are mentioned by Pliny, mineral remedies, invocation of patron saints and water.

Tuberculosis and War

ACCORDING to an editorial in the August issue of the *Statistical Bulletin* of New York, tuberculosis is already on the increase in other countries than the United States, although the evidence is based only on provisional or fragmentary data. In England and Wales the death-rate among male civilians rose slightly in 1939 and in 1940 in both sexes. For males the death-rate from tuberculosis rose 13 per cent

between 1939 and 1940 from 77·1 per 100,000 to 87·4; for females the increase was 7 per cent from 50·9 to 54·7. In Scotland the deaths from tuberculosis in 1940 increased 14 per cent over 1939, and the death-rate in 1940 was the highest since 1932. In Canada the mortality from tuberculosis did not rise in 1940, but there was a significant increase for the first half of 1941. In Germany and the occupied countries statistics on tuberculosis are not available. As regards France, a sharp increase in the disease has been reported from Vichy. The longer the War lasts and the farther it extends the greater will be the increase in tuberculosis, as is shown by the War of 1914–18, particularly among the women and children in Germany, Belgium, and eastern and south-eastern Europe, and to a less degree among the neutral countries.

Prevention of Typhus Fever

AT a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine on November 28, Dr. Melville D. Mackenzie read a paper on the control of louse-borne typhus fever in Great Britain in the light of experience in Russia, Poland, Rumania and China. After discussing the epidemiological relationship of the disease to movements of population, under-nourishment and climatic conditions, he dealt with the rapidity of the spread of typhus fever, the frequency with which it is associated with other diseases and other factors which might complicate diagnosis, the method of infection, the importance of improved nutrition in the control of an epidemic, the value of reducing the number of lice in the population generally in addition to the tracing and delousing of contacts, the possible importance of dried fæces in the spread of the disease and the danger of the first cases being overlooked. Stress was laid on the necessity of utilizing young personnel in anti-typhus work. The greatest importance was attributed to the necessity for the thorough disinfestation of patients and contacts, the premises and their contents, as well as of the ambulance and the staff after duty.

The National Institute for Research in Dairying

THE report of the National Institute for Research in Dairying (University of Reading) for the year ended September 30, 1940, has just been published. Many members of the staff are now acting in an advisory capacity on various war-time committees appointed by the Government, especially the Ministry of Agriculture. The realization of the essential need for milk to balance the deficiencies of a war-time dietary and the multifarious problems that this involves is, of course, making demands on the work of the staff and thus a number of long-range research projects have been shelved in order that the staff may devote more time to advisory work and short-range investigations of war-time problems of the dairy industry. Details of the work of the various departments of the Institute, namely, dairy husbandry, chemistry, bacteriology, dairy bacteriology advisory, physiology and biochemistry, and of the experimental dairy are included in the report. Sixty-six research papers were published by various members of the staff during the year, and as usual a separate list of papers which can be supplied by the Librarian is appended. This latter list contains twenty-nine titles. The address of the Institute is Shinfield, near Reading, Berks.

Country-Side

THE first number of the war-time issue of *Country-Side*, the quarterly journal of the British Empire Naturalists' Association, has appeared to start the twelfth volume of this well-known journal. It is edited by Mr. Leslie Beckett, the honorary organizing secretary, and comprises a twenty-page octavo issue containing five original papers, a number of smaller notes and lists of regional field records on birds, insects and fungi. There is a list of twenty-one local branches of the British Empire Naturalists' Association (including a new one at Bath) which are remaining active during war-time. Mr. J. W. Bradley has a short article on the birds of Burma, Mr. E. L. Swann describes the formation of a Norfolk salt marsh and its subsequent flora, and Mr. M. B. B. Heath some recent observations of Mars. Among smaller notes there is an account of *sotto voce* song in the hen blackbird, the timing of the reeling song of the grasshopper-warbler to vary from 20 to 65 seconds with stops of 4–20 seconds between; Captain T. Dannreuther describes the immigration of clouded yellow butterflies to Great Britain in 1941. Mr. A. H. Wolley-Dod correlates the rarity of autumn bird song with the dry season, and there is a note on the abundance of privet hawk moth larvæ, even in London, this autumn. Field records include the wood-sandpiper, ruff, shelduck and gadwall at Cambridge sewage farm, the autumn passage of white wagtails in Lancashire, and October song of the blackbird in Wiltshire, where the speckled wood and comma butterflies were very numerous all the season.

Horticultural History

THREE papers in recent numbers of the *Journal of the Royal Horticultural Society* describe the history of gardens and gardeners of the past. The gardens at Wormley Bury, Broxbourne, Herts, have been the means of introducing many new plants to the horticulture of Britain. Sir Abraham and Lady Amelia Hume introduced many species between 1785 and 1825, including several notable Amaryllids, two species of Pæonia, *Rudbeckia pinnata* and *Humea elegans*, named after the introducers. Major Albert Pam writes the article (66, Pt. 9, Sept., 1941), and is himself the present owner of Wormley Bury. The other two papers (66, Pts. 9 and 10, Sept. and Oct., 1941) are by the assistant secretary of the Society, and deal with the activities of William Forsyth in founding the Royal Horticultural Society. Forsyth's memory is maintained in the genus Forsythia which Vahl named in his honour, but he also experimented upon the treatment of wounded trees by covering the cut portions to exclude harmful fungi. He made useful contributions in this connexion, but clouded them so with extravagant claims that the benefit came to be largely discountenanced.

Portland Cement Industry of the United States

STATISTICS relating to the Portland cement industry of the United States, compiled by the U.S. Bureau of Mines, show that the quantity of this substance produced in 1940 was 130,216,511 barrels (the unit of measure employed throughout the statistics is the barrel of 376 lb.). The output for 1940 is not only 7 per cent higher than the output for 1939 but also was the largest quantity manufactured since 1930. Nevertheless, the output for 1940 was less by 20 per cent than that for 1928, which still constitutes the peak year of production. Basing their figures on the quantities of cement dispatched from works into the various States of the Union, aggregating nearly 127,800,600 barrels, it is estimated that the annual *per capita* consumption of cement averaged 0·96 barrel (about 3 cwt.) in the whole of the United States in 1940, as compared with 0·94 barrel in 1939. These figures represent only the records of the consignments inside the country. During 1940, 80·9 per cent of the Portland cement dispatched from works in the United States was moved by railway, 15·6 per cent by motor lorry and 2·2 per cent by boat. Furthermore, 25·6 per cent of the cement was dispatched loose, in bulk, 42·4 per cent was packed in paper bags, 31·9 per cent in cloth bags, and 0·1 per cent in other containers, including steel drums and iron or wooden barrels.

Imports of hydraulic cements into the U.S. in 1940 totalled 91,000 tons, compared with 321,000 tons in 1939. In both years the chief supplying country was Belgium and the second was Denmark. In spite of its large annual cement production, the export trade of the United States is small, totalling in 1940 a little more than 1 per cent of the production. The exports for 1940, however, which totalled nearly 284,000 tons, were higher than in any other recent year. Of the 1940 exports, 206,000 tons were dispatched to various countries on the North American Continent, the Central American Republics, the West Indies and Canada. The largest quantity was consigned to the Panama Canal Zone, namely, 82,000 tons. According to *Engineering* of September 26, South American countries imported in 1940, 73,400 tons of cement from the United States, Europe merely 76 tons, Asia 1,320 tons, Africa 2,390 tons and Oceania 70 tons; 248,500 tons of cement were shipped to Alaska, Hawaii, Puerto Rico and other outlying territories of the United States.

Animal Production and Veterinary Science Abstracts

To meet the requirements of those engaged in the animal industries, a new section of *Biological Abstracts*, to be known as "Section F, Abstracts of Animal Production and Veterinary Science", will begin in January next. It will contain all the abstracts published in *Biological Abstracts* that have to do with the breeding, nutrition and metabolism, husbandry, reproductive and other physiology, anatomy, pathology and parasitology, and arthropod pests of livestock, poultry and semi-domesticated animals and birds, including pet stock. The new section will consist of ten abstract issues a year. The annual subscription rate will be 5 dollars, and subscribers will receive the index to the complete edition of *Biological Abstracts*. *Biological Abstracts* now covers some 1,450 periodicals, so the new section will, from the beginning, afford a very complete survey of the biological literature pertaining to the animal industries. Inquiries should be addressed to *Biological Abstracts*, University of Pennsylvania, Philadelphia.

Announcements

PROF. EMILE PICARD, For. Mem. R.S., permanent secretary of the Paris Academy of Sciences and a distinguished mathematician, died on December 12, aged eighty-five.

The Symons Gold Medal for 1942 of the Royal Meteorological Society has been awarded to the late Dr. J. S. Owens, whose death occurred on December 6. This Medal is awarded biennially for distinguished work in connexion with meteorological science. The presentation will be made at the annual general meeting of the Society on January 21 next.

DR. R. B. McConnell, assistant field geologist, has been appointed geologist of the Lands and Mines Department, Tanganyika.

DR. ORLANDO PARK, Northwestern University, will in future edit the "General Animal Ecology" Section in *Biological Abstracts*, thus succeeding Dr. W. C. Allee. The "Speciation" Section will be edited by Dr. Alfred Emerson, of the University of Chicago.

THE title of professor emeritus of logic and scientific method in the University of London has been conferred on Dr. A. Wolf, on his retirement from the professorship of logic and scientific method at University College and the London School of Economics.

PROF. HERMANN STEUDEL, emeritus professor and director of the Institute of Chemical Physiology at Berlin, has been awarded the Goethe Medal for Art and Science on the occasion of his seventieth birthday.

THE Financial Secretary to the Treasury stated on December 11 in reply to a question in the House of Commons that the number of students at universities and university colleges in Great Britain during the past autumn was approximately 25,000, of whom 5,900 were grouped as taking arts subjects and 19,100 scientific, technical and medical subjects.

MR. R. J. FLINTOFF, of Goathland, Yorks, founder of the Northern Ecological Society (see NATURE, December 13, p. 722) bequeathed his notebooks on plants to the British Museum; £1,000 to the Linnean Society of London for a medal; £1,000 to the Chemical Society for a medal; and £1,000 to the University of Manchester for a prize; he also made provision for the publication of his researches.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

Names of Electrical Units

WHILE the use of the metre-kilogram-second-coulomb system of units is rapidly becoming more widespread, that of the E.M.U. system is almost non-existent, except in elementary courses and old-fashioned text-books. In purely electrostatic problems, on the other hand, the general use of the E.S.U. system is likely to continue. The lack of distinctive names for the units in this system is a drawback in several respects, of which I will only mention the difficulty of checking dimensions. To remedy this defect a practice has arisen of using names such as 'statcoulombs', 'statvolts' and other equally cacophonous terms. This nomenclature has already been criticized in a recent review of a text-book (*Proc. Phys. Soc.*, **53**, 624; 1941), but no alternative has been proposed. I therefore wish to propose a terminology which should be acceptable to all English-speaking people.

I suggest that the charge which repels a similar charge at a distance of one centimetre with a force of one dyne be called a *franklin*, in honour of Benjamin Franklin, the pioneer of static electricity.

There is no need for any other new names. The accompanying table gives the units of the most important electrostatic quantities in centimetre-gram-second-franklin (C.G.S.F.) units and in metre-kilogram-second-coulomb (M.K.S.C.) units. It seems unlikely that one should want to use the C.G.S.F. system for magnetic measurements, but it can be so used; the unit of H would be franklin/sec. cm. and that of B would be erg cm. sec./franklin.

At the same time, to avoid ambiguity, I suggest that, whatever units be used, the ratio D/E should always be called the *permittivity*, a nomenclature already widely used in the United States, and that *dielectric constant* should denote the ratio of permittivity of medium to that of empty space and should thus be a number independent of the units used. This suggestion is incorporated in the table.

One further point. An increasing number of physicists, though still a minority in Great Britain, prefer to use the rational system. I want to point out that this need not involve a change of units, but merely a change in the definition of D, so that at the surface of a charged conductor, $D = \sigma$ instead of $D = 4\pi\sigma$, and the electrostatic energy density becomes $\frac{1}{2}ED$ instead of $ED/8\pi$. Rationalization thus leaves E unaltered, but reduces D by a factor $1/4\pi$, and this statement is true whether E, D be both measured in C.G.S.F. units or both in M.K.S.C. units.

E. A. GUGGENHEIM.

Term	C.G.S.F. unit (E.S.U.)	M.K.S.C. unit
Charge	franklin	coulomb
Surface density of charge, σ	franklin/cm.²	coulomb/m.²
Displacement, D	franklin/cm.²	coulomb/m.²
Current	franklin/sec.	coulomb/sec. = amp.
Current density	franklin/sec.cm.²	amp./m.²
Energy	erg	joule
Energy density	erg/cm³.	joule/m³.
Potential	erg/franklin	joule/coulomb = volt
Field, E	dyne/franklin	volt/m.
Permittivity, D/E	franklin²/erg cm.	coulomb/volt m. = sec./ohm m.
Value of permittivity of empty space	$1\ \frac{\text{franklin}^2}{\text{erg cm.}}$	$\frac{1}{9 \times 10^9}\ \frac{\text{sec.}}{\text{ohm m.}}$

THE international procedure which in normal times can be adopted for agreement or otherwise to suggested changes in the nomenclature of fundamental units cannot function at the present time, but it is hoped that Dr. Guggenheim's suggestion, which can be brought to the notice of those it concerns through the columns of NATURE, will find the favour it seems to deserve, and will prevent the 'stat-coulomb' becoming an established term, which has neither the merit of euphony nor symmetry in the systematic naming of the electrical units.

Refractive Indexes of Gases at High Radio Frequencies

SINCE atmospheric refraction plays an important part in the bending of ultra-short radio waves round the surface of the earth, an adequate study of the propagation of these waves requires a knowledge of the refractive indexes of gases at very high frequencies. It was thought desirable to test the assumption, made in all previous theoretical work, that the values of these indexes were the same as their values at lower frequencies. When this work was begun, no figures were available for the refractive index of any gas at a frequency higher than about 4 Mc./sec. Since then, however, a result for water vapour at 42 Mc./sec. has been published by Tregigda[1].

A standing wave method has been used in this work, the standing waves being produced in a gas-tight concentric tube Lecher circuit, by bringing it into resonance with a highly stable crystal-controlled oscillator to which it was loosely coupled. The apparatus was so constructed that the changes in the length of these standing waves as the pressure or composition of the gas inside was varied could be determined with some precision, the refractive index of a gas for a wave of given frequency being equal to the ratio of the length of the wave in a vacuum to the length in the gas. The concentric tube form of Lecher system is very suitable here, as the gas under investigation can be placed in the space between

the inner and outer tubes, and further, the outer tube itself forms a most effective shield from external disturbances. The temperature of the concentric system was maintained constant by a steam jacket round the apparatus, while the temperatures of the oscillating crystal and the water vapour supply were stabilized by means of radiation thermostats, based on that developed in this Laboratory by Laby and Hopper[2].

Results have been obtained for the refractive indexes of dry air and water vapour as follows: for dry air, at 58 Mc./sec., 100°C., 76 cm. mercury;

$$\mu = 1\cdot00024_0 \pm 0\cdot000006\,;$$

and for water vapour, at 58 Mc./sec., 100°C., 76 cm. mercury,

$$\mu = 1\cdot0030_1 \pm 0\cdot00007.$$

It had been hoped to carry out work at other frequencies, temperatures and pressures, and with other gases, but this has been prevented by the War.

The important part played by the water vapour in the atmosphere in the propagation of ultra-short waves can be seen from these results. The figure for water vapour is found to agree with the value of 1·0060 for the dielectric constant of water vapour at 42 Mc./sec., 99·8°C. and 76 cm. mercury, obtained by Tregigda[1] using a heterodyne method.

The work, which was carried out under the direction of Prof. T. H. Laby, was supported by the Australian Radio Research Board.

Application of the Gibbs Adsorption Equation to Solutions of Paraffin-Chain Salts

Within recent years considerable doubt has been cast upon the validity of the Gibbs adsorption isotherm as applied to aqueous solutions of the paraffin-chain salts (soaps and soap-like molecules)[1,2]. The chief objection has been the numerous well-established examples of dilute solutions showing a minimum in the surface tension – concentration curve, usually at a surface tension of 30–35 dynes, presenting the paradox of a surface tension very much lower than that of water, and yet a zero or negative surface excess of solute as calculated from the Gibbs equation when applied in the customary manner.

Because of this apparent paradox, McBain and Mills[1], in a recent review, have concluded that the Gibbs equation is only a limiting law, and that terms allowing for the effects of orientation, of submerged double layer, and of free electrical charge (if any), should be included. This argument cannot be supported, however, since the systems under discussion are electrically neutral, and the other terms, assuming as they do a particular molecular interpretation of the surface layer, cannot be used as correcting factors, since they would be already included in the thermodynamically rigorous Gibbs equation.

Long and Nutting[3] have recently put forward an explanation based upon the assumption that there is a surface *layer* of solute (giving positive adsorption at the interface) above a diffuse double layer of considerable depth, the concentrations in this double layer then determining whether the "Gibbsian *surface excess*" of solute is positive, zero or negative. (The hypothetical geometrical surface is chosen so that the surface excess of water is zero.) Unfortunately for this argument the total surface adsorption as measured by the microtome method, and which would include both surface and diffuse layers, is always positive[2]. Other techniques support this invariable positive adsorption[2].

The explanation suggested below, previously tentatively discussed by Powney and Addison[4], would seem to provide a simple explanation of the above anomalies.

It is generally accepted that with the solutions under consideration micelle formation sets in at concentrations close to (probably rather less than) that at the minimum surface tension[5]. Also it seems well established that the micelle, owing to its structure, is precluded from existing in the surface layer, the surface active species being the single ionized molecule[6]. Thus the micelles may influence bulk properties such as freezing-point and conductivity, but can have little effect on the surface tension except in so far as their presence influences the concentration of single molecules in the solution. Hence the activity term in the Gibbs equation should be that for the *molecularly dispersed* solute in bulk solution[7]. The much larger amount of solute present in micelle form acts as a 'buffer', keeping the concentration of the molecularly dispersed solute sensibly constant, as shown by application of the Law of Mass Action[6,8]. Accordingly, it is not surprising that, using the activity of the solution *as a whole*, as McBain and Mills, for example, have done[1], the Gibbs equation should break down.

That the Gibbs equation holds, even with the paraffin-chain salts, when micelles are absent, is shown by the results of McBain and Wood with lauryl sulphonic acid[2]. Thus at a concentration of 0·002 gm.mol./l. (concentration at the minimum 0·006 gm.mol./l.), their measured adsorptions were +2·7 and +3·0 (microtome and interferometer respectively), that calculated by the Gibbs theorem being + 2·4 (gm.mol./cm.^{2} × 10^{10}).

The above explanation is further strengthened by calculation of the adsorption of lauryl sulphonic acid at the minimum surface tension[9] which, assuming the adsorbed film to be monomolecular, gives a value of +5·7, in good agreement with that using the microtome[2] (+5·4) (units as above). Further details will be published shortly.

Vanadium Pentoxide as a Catalyst for Sodium Chlorate in Weed Destruction

It is well known that vanadium pentoxide, used as a catalyst, greatly increases the efficiency of sodium chlorate when employed as an oxidizing agent in the production of certain dyes. Investigations have been carried out to determine whether similar use could be made of vanadium in certain methods of weed destruction, more particularly in connexion with the practice of smearing the cut surfaces of bracken fronds with chlorate solution or introducing it into the tissues of bramble plants by immersing the ends of stems from which the tips have been cut.

The experiments were carried out in September of the present year. Brambles were treated by placing the cut ends of the trailing stems in small bottles each containing 50 c.c. of the various materials in aqueous solution.

Ten bottles of each of the following were employed:

(1) Vanadium pentoxide only; 0·02 per cent solution.

(2) Sodium chlorate; 10 per cent solution.

(3) Sodium chlorate; 10 per cent solution, plus 1 part vanadium pentoxide per 500 parts sodium chlorate.

Observations were made on rate of travel up the stem, as evidenced by the destruction of the parts, and on the intensity of the effects. The findings were as follows:

(1) Vanadium pentoxide only; no effect noted.

(2) Sodium chlorate only; the usual toxic effects, a fair degree of killing with dark brown scorching of the leaves, taking ten days to reach completion.

(3) Sodium chlorate plus vanadium; severe destructive effect noted after five days, the rate of travel having been greater and exceeding the final effect of the sodium chlorate solution without vanadium. Apart from this speeding up and greater intensity of killing, a remarkable bleaching effect appeared after twenty-one days. The stems for about a foot above the points of immersion became quite white, ranging to a light yellow above. The leaves took on a light yellow tint, and in the piece of cleared woodland where the trial was carried out, these vanadium-treated plants could be distinguished at a distance without reference to the labels.

Stems from all three treatments were kept under further observation. In treatment 2, they became blacker, but extremely tough and hard, and the leaves were retained. In treatment 3, the stems became soft and brittle and the leaves all broke off from the base of the petioles.

A further trial gave similar, though not so definite, results with an addition of 1 part vanadium pentoxide to 1,000 parts of sodium chlorate.

The above observations suggest the possibility of enhancing the value of sodium chlorate as a herbicide by the employment of a catalyst. Vanadium pentoxide in the proportion used would not be ruled out on the grounds of cost. It is, however, not readily soluble in water, and further investigation is required on this point.

Spectrochemical Analysis of Eggs

In the course of an investigation into the mineral content of foodstuffs, some analyses of hens' eggs were made. The white and yolk were treated separately. The ash was analysed by the ordinary arc spectrum method, and the liquids were also analysed directly by a spark technique similar to that described by Langstroth and Macrae[1]. Calcium, magnesium and sodium were present in relatively large quantities in all specimens. Potassium and lithium were also present in fair quantity. Traces of the following elements were also found in both yolk and white: copper, iron, manganese, strontium, silicon, phosphorus and aluminium. Barium was present in the yolk but could not be detected in the white. A very small trace of lead was indicated in one specimen of white, but its presence could not be detected in other specimens. The following elements were not present in detectable quantity in any specimen: boron ($< 0·2$), chromium ($< 1·0$), molybdenum ($< 1·0$), zinc (< 10), nickel ($< 1·0$), cobalt ($< 1·0$), cadmium ($< 0·2$) and antimony (< 20, < 200); the figures given in brackets indicate limits of detection in parts per million.

These results are in general agreement with those of Drea[2] except that he reported barium, molybdenum zinc and chromium as present in both yolk and white. He also reported rather stronger indications of aluminium and strontium. Drea used graphite electrodes, and Webb[3] has shown that spurious indications of a number of elements (including barium, molybdenum, zinc, chromium, aluminium and strontium) may be obtained with these electrodes. In order to avoid this effect, the present work was done with a silver spark technique, and this probably accounts for the fact that a smaller number of elements is reported as present. My analyses indicated that the copper and manganese content was of the order 0·001 of the magnesium content and did not exceed a few parts per million. Chemical analyses[4] indicate magnesium content of order 100 parts per million and copper content of order 0·3 parts per million. From my analyses the order of magnitude of the abundance of the other metals may be roughly estimated (in parts per million) as follows: iron ($> 1·0$), strontium (0·2), aluminium (0·2) and barium (0·2).

A number of fertilized eggs were examined at different stages of development in order to try to trace changes in the passage of mineral elements from the yolk to embryo. The changes found were, however, only of the same order as the differences between different specimens at the same stage of incubation. The only conclusion to be drawn was the purely negative one that there is no rapid and obvious preferential removal of one mineral constituent from the yolk during early stages of incubation.

This work was carried out in the Physical Laboratory, Trinity College, Dublin, under the supervision of Prof. R. W. Ditchburn, with the aid of a grant from the Medical Research Council of Eire. I wish to thank Prof. T. W. T. Dillon of University College, Dublin, for his advice, and the Albert College, Glasnevin, for a supply of eggs.

'Klino-kinesis' of Paramecium

THE suggestion made by Gunn and Walshe[1], that the avoiding reaction of Paramecium fits into the scheme of klino-kinesis, receives some support from the behaviour of the animal in a uniform high temperature, as I described it in 1939[2]. If the temperature of a culture is gradually raised, nothing happens at first except an increase in the speed of the animals. Then at a temperature of about 30° C. avoiding reactions begin, and as the temperature is further raised they become more frequent, with the result that forward motion practically ceases and the animals dance backwards and forwards like particles in Brownian movement. If the temperature is kept steady soon after avoiding reactions have begun, they gradually become less frequent and finally cease altogether. Once the rate of occurrence of the reactions has become very high, however, there is no acclimatization and death soon follows.

But while the term 'klino-kinesis' may be useful as a description of the behaviour of ciliates in unusual experimental conditions, there does not seem to be any justification for its use, instead of the simpler term avoiding reaction, for the ordinary behaviour. For when a paramecium retreats from a hot region or from contact with a solid object, there is no question of sensory adaptation. What happens is that a stimulus is received, a reaction follows, and in many cases this directs the animal away from the stimulating region. There need be no teleological assumption that a reaction occurs *in order to* avoid things: the implication is the quite correct one that by the reaction the animal does, in fact, avoid certain situations.

Production of Proliferation-promoting Factors by the Ultra-violet Irradiation of Algæ

PREVIOUS papers from these laboratories have shown that the subjection of yeast, other micro-organisms, and several animal tissues to various forms of injury, such as ultra-violet irradiation, X-rays, mechanical injury, chemical irritation and oxygen lack, results in the release into the intercellular fluids of substances which stimulate cellular proliferation. Because of the mode of formation these substances have been spoken of as "intercellular wound hormones"[1].

In order to determine the generality of the phenomenon it has been of interest to extend the experiments to as wide a variety of cells as possible. Accordingly, preliminary experiments were carried out with mixed cultures of algæ in which the algæ were subjected to ultra-violet irradiation and the cell-free filtrates obtained from the irradiated algæ were tested for their power to increase the proliferation of fresh alga cultures. The preliminary indications having been favourable, more quantitative experiments were carried out and are reported in this note.

30–40 c.c. of a heavy suspension of *Hormidium floccidum*[2] in Detmer's 1/3 medium were irradiated with a Sperti Mercolite ultra-violet lamp (42*TC*) for from two to three hours at distances of 15–25 cm. The suspension was stirred mechanically throughout the irradiation period, as was a similar, but non-irradiated, control suspension. At the end of the irradiation period, both suspensions were filtered, first through filter paper and then through sterile Berkefeld "N" filters. 1 c.c. of the filtrate from the irradiated algæ was added to 5 c.c. of a very dilute fresh suspension of the algæ in Detmer's 1/3 medium, and 1 c.c. of the control filtrate was added to another 5 c.c. of the alga suspension. Four or five tubes were used in each run for both filtrates. Sterile technique was employed throughout. The tubes were kept for 2–3 months at a temperature of approximately 25°–30° C. in the light. At the end of the experimental period the number of algæ in the experimental and control runs were counted by means of a hemacytometer.

Eighteen determinations were made in four separate experiments. In every case the algal suspension treated with the filtrate from the irradiated algæ contained more cells than the corresponding suspension to which the filtrate from the non-irradiated suspension was added, the increase in the various experiments running from about 45 to 115 per cent. These results, in conjunction with the more extensive work in our laboratories on other organisms, indicate to us that algæ, when injured with ultra-violet radiations, release into the intercellular fluids substances which stimulate proliferation of the algæ.

These experiments are being extended to other algæ, including *Stichococcus bacillaris* and *Chlorella pyrenoidosa*. The results will be reported in detail later. The possible effect of the irradiated extracts on chlorophyll formation will also be considered.

Simple Modifications of the Camera Lucida for Making Larger Drawings

WHEN drawing objects under a microscope with a camera lucida the size of the drawing is normally dependent solely on the magnification of the microscope. Usually this magnification can be adjusted to give a drawing of the required size; but when drawing objects which are only a few microns long, such as chromosomes or the spores of fungi, the image produced by even the highest powers of the microscope is too small to give a drawing of a reasonable size. The devices described below are for the purpose of making large drawings with a camera lucida in such circumstances.

In using a camera lucida the image of the object seen down the microscope is made to coincide with the image of the drawing (and hand and pencil) produced by the prism and mirror of the camera lucida. Now if the image of the hand and pencil is, by optical means, made small relative to that of the object, a large drawing will result. What appears to be a very small hand with a minute pencil traces the drawing in the usual way, and appears to draw it the same size; but as the hand and pencil are in fact their usual size the drawing is an enlarged one.

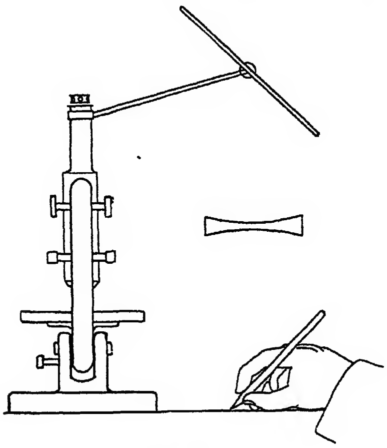

Fig. 1

This result may be achieved in one of three ways: (1) by placing a *concave* lens between the camera lucida mirror and the drawing (Fig. 1); (2) by replacing the plane mirror of the camera lucida by one which is *convex*; (3) by using three plane mirrors instead of the usual one, arranging them as shown in Fig. 2.

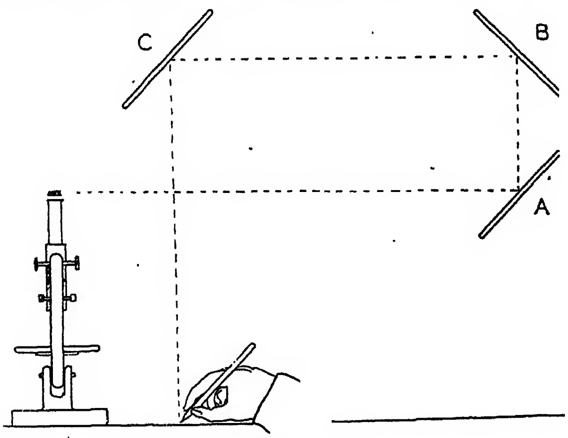

Fig. 2

The simplest of the three ways is the first, using a concave lens. This should be placed about half-way between the mirror and the drawing. If the lens is too high the image of the pencil may come within the least distance of distinct vision so that the eye will not be able to focus it sharply. If the lens is too near the paper the drawing will not be much enlarged. When looking down the microscope the image of the concave lens should come in the centre of the field. The lens should be fairly large so that the work can be confined to near its centre, as there is some distortion near the edges.

The second method, using a convex mirror in place of the plane mirror of the camera lucida, is very similar to the first. A convex driving mirror of a car is suitable for the purpose. The centre of the mirror should be at the height of the prism of the camera lucida and its general direction should be at 45° to the vertical. It may be necessary to fit the convex mirror rather farther from the microscope than the mirror it replaces, to prevent the image of the pencil from coming within the least distance of distinct vision.

In the third method three plane mirrors, *A*, *B*, and *C* are substituted for the usual one as indicated in Fig. 2; retort stands or other means of support are not illustrated. *A* may be almost any distance from the microscope; the farther away the greater the drawing. It is at the same height as the camera lucida prism and is tilted upwards at 45°. *B* is vertically above *A* and is tilted downwards at 45°. *C* is near the microscope, vertically above the drawing and at the same height as *B*; it is tilted downwards at 45°, at right angles to *B*. *C* must be high enough not to obscure the view of *B* from the prism. This arrangement is a little more troublesome to set up than either of the other two; but enables a drawing of any required enlargement to be made, and, provided good quality mirrors are used and they are at 45°, there is no distortion.

The image of the pencil is brought nearer to the eye by the first and usually by the second methods, and is taken farther away by the third method than it is with an ordinary unmodified camera lucida, and some may experience difficulty in controlling the focusing of their eyes so that the pencil is clearly seen through the camera lucida even when the lighting is properly balanced. This is because when looking down a microscope which is in focus the object appears to be sharply focused whether the eye is focused for near or for distant vision; but the pencil seen through the camera lucida is clear only when the eye is focused for the one particular distance. If the eye is focused for almost any other distance the object will be clearly seen, but the pencil will not. Those who find difficulty in focusing their eye on the pencil will find it helpful momentarily to shade the substage mirror of the microscope with the hand.

I wish to thank Miss F. L. Stephens for directing my attention to the problem and for helping me try the methods.

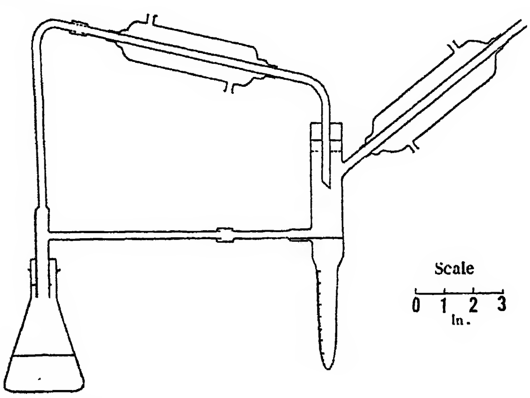
Rapid Determination of Water in Animals and Plants

IN a recent communication, Lowndes[1] has pointed out the advantages attained by applying the Dean and Stark method[2] for the determination of water to plant and animal tissues.

A modification of this well-known method has been used for the determination of water content of tumour tissue in these laboratories. The main disadvantage experienced in the use of the normal type of the Dean and Stark apparatus with solvents lighter than water lies in the fact that droplets of water adhere

to the condenser column. This adhesion of water is recognized in the method of water determination covered by British Standards Specification, 756—1939, in which the recommendation is made that it should be removed to the receiving column by a soft camel hair brush. We have eliminated this disadvantage, however, by modifying the apparatus as shown.



The condensed water is washed into the receiver by succeeding portions of liquid, whilst the return flow takes place through a lower connecting tube. The second condenser is introduced to prevent any loss of solvent. Connexions are made by synthetic rubber ('Neoprene') tubing, which is resistant to organic solvents, across butt-end glass joints. We are indebted to Mr. L. G. Wilkinson for the construction of this apparatus.

In our determinations benzene (b.p. 80°) was used rather than xylene (b.p. 135°), as it was considered that use of the former would give results more comparable with those obtained by dehydration at 105°. A determination on a 5 gm. sample takes approximately one hour.

The accuracy of the method is limited by error in reading the volume of water (for example, an error of 0·05 c.c. on a 1 c.c. reading will produce a percentage error of five), and its use is therefore restricted to bulk samples from which 5–10 c.c. of water can be obtained. Experience showed that the use of a measuring tube narrower than that illustrated was unsatisfactory, as the globules of water imprisoned benzene in the lower part of the tube.

For small samples (up to 1 gm.) the method of dehydration at a 100° has been employed.

The tissue, weighed into a combustion boat, was introduced into the inner tube of a small horizontally placed Liebig condenser. Heating is effected by passing steam through the outer jacket. A current of air dried by bubbling through sulphuric acid is passed over the sample. The moisture taken up by the air is absorbed in two tared calcium chloride tubes. Since the weight of water in the tissue is much greater than the dry tissue weight, a very accurate determination of water can be effected on small specimens.

The modified Dean and Stark method has been particularly useful as a means of obtaining average values for the water content of mouse tumours (Twort carcinomata).

Surplus moisture is first removed by laying the tissue on filter paper. In one batch of mice the moisture content of six tumours, estimated by the second method described, gave values of 80·0, 81·5, 72·4, 76·9, 77·6, 84·8; the Dean and Stark method applied to the remaining twenty-three tumours, taken four or five at a time, gave the figures 79·1, 78·9, 79·0, 78·8, 78·9, 78·8.

[2] Dean and Stark, *J. Ind. Eng. Chem.*, 12, 486 (1920).

A rapid method for the estimation of water in animals and plants consisting of distillation with an immiscible liquid has been suggested[1]. The liquid used was xylol, and some charring of sugar occurred. If toluene (b.p. 110·7° C.) is substituted for xylol, the amount of decomposition and charring is much reduced and is scarcely appreciable even with sugar-containing substances such as jam, honey, fruit extracts, and confectionery products. The boiling-point of toluene is sufficiently high to ensure rapid and complete vaporization of all water present, and the method gives results comparable with those obtained by drying *in vacuo* or by oven drying after the addition of alcohol, and higher than those obtained by 'straight' oven drying, at 105–110° C.

Employment of Physicists

In view of the statements made in recent articles in Nature regarding the employment of scientific workers in connexion with the national effort, the following statement of the situation as it concerns members of the Institute of Physics may be of interest.

With negligibly few exceptions all our members are at present engaged in a professional capacity, practically all of them on work either directly or indirectly connected with the war effort. Owing to the pressure for greater output from all works and factories, a certain number of our less senior members with substantial research experience are now engaged on more or less routine work (testing, servicing, and so on) which does not exercise their abilities to the full. It must be remembered, however, that the work they are doing is essential to the maintenance of quality and output, and that both would suffer if the men were taken for higher duties before suitable juniors had been trained to replace them. It may be pointed out, in this connexion, that the present intensive drive for the production of radio experts will inevitably mean that fewer fuller trained physicists will be turned out by the universities.

Only the Cabinet and its advisers can be in a position to know the relative importance at the moment of research, industrial production and operational control (either with or outside the armed forces). So far as physics is concerned, the available man-power is already fully engaged, but it would certainly be possible to increase the research potential, if that is desired, at the expense of other forms of war service.

MODE OF ACTION OF CHEMOTHERAPEUTIC AGENTS

THE Biochemical Society held a discussion meeting on the mode of action of chemotherapeutic agents on November 29 at the Courtauld Institute of Biochemistry, Middlesex Hospital, Prof. E. C. Dodds being in the chair.

Dr. G. M. Findlay, in opening the discussion, said that chemotherapeutic action can be classified as direct or indirect. Except in the case of parasites present in the intestinal canal, it is essential that the chemotherapeutic drug should be absorbed into the body, that it should penetrate to the site where the parasites are acting, and that it should not be excreted or converted too rapidly into an inert form. Time must be allowed for chemotherapeutic action, and in some cases for the conversion of the compound from an inactive into an active form.

When once the drug and the parasite have been brought face to face, three stages can be distinguished, adsorption, interference with metabolism, and death or such injury to the parasite that it is destroyed by the phagocytes of the host. An absorbed chemotherapeutic drug may prevent an essential food factor from being adsorbed or it may cause a breakdown in metabolism by combining with a specific substrate or by competing with an essential cell metabolite for an enzyme or coenzyme. One break in the chain of metabolic reactions may rapidly give rise to others. Specific immune serum and sulphapyridine do not compete for the same receptor group in the pneumococcus and may therefore enhance one another.

Parasites may be killed in the body without the aid of phagocytes, but usually when a parasite has been damaged it is destroyed by the normal defence mechanism of the host.

Indirect action produces such changes in the environment that parasites can no longer grow. Physical changes may prevent growth, the temperature or the *p*H reaction may be altered, the formation of immune bodies may be stimulated or the character of the cells may be altered, as in the treatment of gonococcal vulvovaginitis in children with œstrin preparations. The highly specific action of certain drugs and the no less specific reactions of certain closely allied parasites can be explained by postulating that, after adsorption of the compound at the parasite/solution interface, the nature of the interference with the metabolism of the parasite depends on what groupings in the molecule of the compound come within the influence of other acceptor groups in the parasite: there is thus a multipoint action.

Prof. A. Fleming, continuing the discussion, said that in 1929 he applied the name penicillin to an anti-bacterial substance of unknown constitution elaborated by *Penicillium notatum* when grown in ordinary bacteriological media or in a modified Czapek-Dox medium. The action is mainly bacteriostatic and shows a marked degree of specificity. Pyogenic cocci, Clostridia and some other bacteria are sensitive, while the coli-typhoid, hæmophilic chromogenic bacilli and others are insensitive. Pathogenic Gram-negative cocci (Gonococcus, Meningococcus and *M. catarrhalis*) are sensitive, while saprophytic varieties, for example *M. flavus*, are insensitive, thus differing from the sulphonamides.

The action of penicillin is not interfered with by substances that inhibit sulphonamides, bacteria, bacterial extracts, pus fluids, tissue autolysates, peptones and *p*-aminobenzoic acid. Penicillin is non-toxic to leucocytes and animals, but in low dilutions it affects the morphology of bacteria and interferes with division. As penicillin and also gramicidin are apparently of a different constitution from the sulphonamides, the isolation and synthesis of the pure active principles will open up a new chemotherapeutic field.

Prof. Warrington Yorke described the action of the aromatic diamidines which were evolved by Dr. Ewins, after it had been shown that synthalin (decane diguanidine) acts on trypanosomes not by reducing the sugar but by direct toxic action. Some aromatic diamidines exhibit a remarkable trypanocidal activity. The most active are 4 : 4′-diamidino-stilbene, 4 : 4′-diamidino-diphenoxy-propane and 4 : 4′-diamidino-diphenoxy-pentane. Cases of kala-azar have now been successfully treated by diamidine-stilbene—Indians, children in the Mediterranean area and patients with the Sudanese variety, which is resistant to antimony. Babesia infections in dogs have been cured by the stilbene and propane derivatives, the stilbene being highly active against *Trypanosoma congolense*. The compounds have a highly specific action. Drug resistance appears to be due to a change in the surface layer of the parasite. Trypanosomes resistant to a number of compounds have now been prepared, including a diamidine preparation. It has also been possible to prepare a diamidine-resistant Babesia and a plasmoquine-resistant strain of *Plasmodium knowlesi* in the monkey.

Discussing trypanocidal substances, Dr. F. Hawking said that from the phenomenon of drug resistance four kinds of receptors on the trypanosome are recognized. Trypanocidal action comprises fixation of the drug, secondary chemical reactions inside the cell and death. Only about the first process is much known: it occurs quickly in a few minutes and is reversible. With arsenical compounds, fixation apparently depends on the tervalent arsenic atom linked to a benzene ring. Certain side chains ($-NH_2$, $-OH$) prevent fixation on animal cells but not on normal trypanosomes: the receptors of resistant trypanosomes are modified. Over a wide range, the amount of drug fixed is proportional to the concentration in the surrounding fluid: in the case of acriflavine the partition ratio (concentration inside the trypanosome/concentration outside) is 8,000 for normal trypanosomes, 60 for resistant trypanosomes. Fluorescent compounds, acriflavine and diamidino stilbene, are concentrated in the blepharoplast and cytoplasmic granules of the trypanosome.

The importance of having a theory of chemotherapeutic action was emphasized by Sir Henry Dale, who congratulated the Society on arranging a discussion meeting in war-time. It was one of Paul Ehrlich's great contributions to the subject to have produced theories which, though they will probably not survive unmodified, have given tremendous stimulus to research; thus, his explanation of the action of certain dyes on infection by trypanosomes as due to injury of the reproductive power of the trypanosomes, without affecting their other vital functions.

At the time, this suggestion seemed artificial and unconvincing, but when Dobell and Laidlaw found a method for growing *Entamœba histolytica* in permanent culture *in vitro*, it could be demonstrated that the action of emetine was just of this type. The 'factor of persistence' is also of importance in chemotherapeutic activity. This seems to be the reason why a quinquevalent arsenical on one hand, or an arseno-compound on the other, is a better chemotherapeutic agent than the arsenoxide produced by reduction from one or by oxidation from the other, although the arsenoxide is recognized as the directly parasiticidal agent. In the same way, sulphaguanidine seems to owe its effectiveness in bacterial dysentery to its poor solubility, enabling it to remain in solid form in the intestinal contents and to keep up a steady, low concentration in contact with the infected mucous membrane. Aromatic diamidines, the brilliant promise of which has been made clear by the results reported by Prof. Warrington Yorke, may similarly owe part of their superiority to their limited solubility. Sir Henry suggested, as problems the solution of which might greatly accelerate advance in parts of the field of chemotherapy, the discovery of a method of keeping trypanosomes alive and reproductive indefinitely in artificial culture, and the discovery of a method of treating a strain of trypanosomes which has acquired a drug resistance, so as to restore the normal susceptibility.

Dr. D. D. Woods spoke of the interference of antibacterial agents and essential metabolites. This interference may be due to the formation of a compound between the antibacterial agent and the essential metabolite, as between mercury salts and —SH compounds, or by inhibition of an enzyme reaction involved in the synthesis or utilization of an essential metabolite. An example of this is the competitive inhibition by sulphanilamide of an enzyme reaction involved in the further utilization of *p*-aminobenzoic acid, this inhibition occurring by virtue of the chemical relationship of sulphanilamide and *p*-aminobenzoic acid. The latter has been isolated from natural sources and is a growth factor for *Clostridium acetobutylicum* and higher organisms. Following out this hypothesis, the following substances all chemically related to a known essential metabolite, the latter shown in brackets, have been found to have some antibacterial activity; pyridine-3-sulphonic acid and amide (nicotinic acid and amide); aminosulphonic acids (analogous amino-carboxylic acid); sulphonic acid analogue of pantothenic acid (pantothenic acid); indole-3-acrylic acid (tryptophan); barbituric acid (uracil).

Dr. H. McIlwain said that an organism which is deprived of the use of enzymes or metabolites by various types of interference is nutritionally more exacting than in its normal state. *Bacterium coli* and *Streptococcus hæmolyticus*, inhibited by acriflavine components, require for further growth two types of material not normally required. Type 1 is best replaced by nucleotides, type 2 by a concentrate of amino acids but partly by phenylalanine. In the presence of type 2 compounds, but not without, artificial hydrogen carriers are further active against inhibition of *Bact. coli*. Type 1 compounds form complex salts with acriflavine components. The inhibitors probably inactivate enzyme systems of which type 1 compounds are essential parts, of which type 2 compounds are substrates or products and of which some can be replaced by the hydrogen carriers.

The relationship between chemical constitution and bactericidal action in certain amino-acridines was described by Dr. W. H. Linnell. Among the isomeric diaminoacridines, a 1-amino group causes complete loss of bactericidal activity and reduces toxicity; a 2-amino group increases activity and this is further enhanced by another amino group in the 2-, 3-, 4-, (in the other ring) or 5-positions, accompanied by increased toxicity in the case of a second 2-substituent. When two 3-amino groups (= 3 : 7) are present, activity is moderate but the 3 : 8 diamino acridine (= 2 : 7) is as active as proflavine but less toxic. A 4-amino substitutent confers small activity, while position 5 is highly active, but probably leads to increased toxicity. Albert has shown that similar differences in activity exist among the five isomeric-amino acridines, their activity paralleling their strength as bases and their partition coefficients between oil and water. The corresponding acridones are inactive, as are certain amino derivatives of 5 : 10-dihydroacridine and of iminodihydroacridine, suggesting that the intact acridine molecule is necessary.

L. G. Goodwin said that the uncertain action of antimony in protozoal diseases, of which the resistance of Sudanese kala-azar to antimony is an example, is an added difficulty in investigating its mode of action. The active form of antimony may be the stibinoxide grouping, but while this is probable in trypanosome and schistosome infections, it is unlikely in leishmaniasis, where quinquevalent compounds are the most effective and massive dose therapy is successful.

Excretion of antimony after doses of the quinquevalent compounds or of stibophen is much more rapid than with tartar emetic. There is indirect evidence that the rapidly excreted fraction of the drug passes through the body unchanged.

Both direct toxicity action on parasites and stimulation of the hosts' defence mechanisms are produced by antimonials. Increased phagocytosis may be of primary importance in leishmaniasis, though histological work on the spleens of infected hamsters injected with a quinquevalent antimony compound suggest some degree of direct action.

Dr. E. Chain described the chemical and physical properties of penicillin in relation to its bacteriostatic action. It is a strong acid with two, or a multiple of two, acid groups. A purified barium salt gives a carbon content of 55 per cent and a hydrogen content of 6·3 per cent: only carbon, hydrogen and oxygen are present in the molecule. Methoxyl groups cannot be detected but two hydroxyl groups are present. The dried barium salt of penicillin keeps indefinitely and in watery solution is most stable between *p*H 5 and 7. With heavy metals, except $Fe^{\cdots}$, it forms water-soluble salts. The antibacterial action is lost by oxidation with hydrogen peroxide and potassium permanganate. Dr. E. P. Abraham said that the instability of penicillin necessitates three methods of purification dependent on distribution between solvents, adsorption and reduction. The crude barium salt obtained from an amyl acetate extract of the medium has an activity of 15–25 units per mgm. Distribution between water and ether at *p*H 2 and *p*H 6, adsorption of impurities by charcoal and chromatographic analysis on alumina yield a light yellow barium salt with an activity of about 150 units per mgm. On reduction of this material in neutral solution with aluminium-mercury couple the remaining pigment is adsorbed by alumina. The

white barium salt obtained from the supernatant has an activity of 240 units per mgm. It completely inhibits Staphylococcus in a dilution of 1 in 5,000,000, partially in a dilution of 1 in 16,000,000.

The behaviour of sulphanilamide, p-aminobenzoic acid and chemically related compounds, aniline and sodium benzenesulphonate, at the surface of *Bact. coli* has been studied by Dr. F. R. Bradbury and D. O. Jordan by electrokinetic methods. The shapes of the curves relating variation of mobility with time of contact for sulphanilamide and p-aminobenzoic acid are quite different from those of the curves for aniline and sodium benzenesulphonate. The curves for sulphanilamide and p-aminobenzoic acid are similar, suggesting that the two compounds behave in a like manner at the bacterial surface.

Prof. A. St. G. Huggett said that dyes such as chlorazol sky blue *F P S* (Chicago blue) and chlorazol fast pink *B K S* are excellent anticoagulants. Structurally, they resemble afridol violet, from which Bayer 205 is derived; they have a trypanocidal action while Bayer 205 has an anticoagulant action. The dyes act at two points in the clotting mechanism as antikinase and antithrombin. Their anti-enzyme action with blood clotting may have an analogy to their mechanism as trypanocidal agents.

CO-ORDINATION OF SCIENTIFIC AND TECHNICAL WORK

AT a conference organized by the Association of Scientific Workers and held at Birmingham on December 6, the need for greater co-ordination and collaboration in all fields of applied science was urged. The essential part which the scientific worker has to play in the modern community was emphasized by Mr. D. P. Riley, who opened a discussion on "The Responsibilities of the Scientist to the Community". Not only most of the greatest industries but even agriculture are dependent upon his work if they are to develop rapidly enough to satisfy the needs of the whole community, and in time of war it is even more important that this should be recognized, particularly in view of the five years' start which our enemies have over us in the application of science to war problems. As an interesting example of the need for the proper understanding of the scientific facts underlying certain decisions by those entrusted with executive power, Mr. Riley took the case of the encouragement of the consumption of wholemeal bread on account of its vitamin B content. The fact that this bread also contains an appreciable amount of phytic acid, the calcium salt of which is insoluble, and the consequent danger of avoiding vitamin B deficiency only at the expense of incurring calcium deficiency, has apparently not yet been given attention in public policy. Not only are many scientific workers still not occupied to their full capacity, but they are even in some cases urged to give their attention to the development of post-war plans, as well illustrated by an advertisement in a well-known daily paper describing a sewing-machine made largely of plastics and saying that now is the time to plan its post-war production.

The Association of Scientific Workers, which is working to secure the fullest application of science in the service of the community and a responsible status for men of science, is trying to meet the need for organization without which the individual man of science can do little in his attempt to ensure that his work is used for the war effort. In particular, the Association wishes for any evidence of definite misapplication or inefficiency in the use of scientific man-power, since it has been requested by the Ministry of Supply to prepare a report on this subject.

The immediate problems of producing and maintaining equipment for our armed forces was dealt with by Mr. Swann in his address on "The Role of the Scientist in the National Effort". He produced figures to demonstrate the superiority of Germany and the occupied countries over ourselves and the U.S.S.R., including also the help given by the United States, leaving no ground for optimism. He mentioned the dissipation of effort in competition between private firms, the operation of the 'cost-plus' contract, inadequate pooling of information and the determined grip of firms on their trade secrets as some of the many factors combining to hold up production, and criticized the feeling of complacency fostered by Russia's successes and America's promises of support. He urged the formation of production committees, where these do not already exist, on which technical staff should play an active part, and the need to provide the Ministry of Supply with all relevant facts as to means to eradicate inefficiencies.

Mr. J. A. Henley pointed out how, as the industrial scientist has passed from the position of being an independent consultant or even his own manager to that of one wage-earner among many in a large firm, it has become necessary for him to co-operate with his fellows in a professional organization which could look after his interests and his status. This need has become peculiarly great since the outbreak of war; hence it is not surprising that the Association of Scientific Workers has grown very much faster since its registration as a trade union than formerly.

After discussion, the following resolutions were passed:

"The Birmingham Conference of Scientific and Technical Workers reciprocates the expressed desire of the scientists of the U.S.S.R. for the fullest possible co-operation in the fight against Fascism, and pledges its maximum efforts to this end.

"This Conference, realising that maximum efficiency in the war effort will be achieved only as a result of fullest possible co-operation between technical staffs, work-people, and those in control of production, supports all activities leading to this end, in particular the setting up of production committees.

"This Conference calls for complete pooling of technical information between manufacturing companies with similar problems.

"This Conference stresses that the present anomalies in conditions of working and remuneration must lead to grievances that seriously hamper the war effort."

SOCIETY OF AGRICULTURAL BACTERIOLOGISTS

THE Annual Conference of the Society of Agricultural Bacteriologists, held at the Midland Agricultural College during September 12–13, covered a wide range of subjects. The papers may be classified, somewhat arbitrarily, into those concerned with dairying and those with other fields.

Instances of the economic importance of the sulphate-reducing bacteria included the formation of the black colour in the mud of certain districts, the evolution of hydrogen sulphide in sewage, and the discoloration of paper pulp. The role of these bacteria in the underground microbiological corrosion of metals was considered in some detail. Another paper described how the principle of the activated sludge process may be applied to an aerated culture of nitrogen-fixing bacteria so as to build up continuously a stock of bacterial protein from carbohydrate and atmospheric nitrogen.

Media containing thallium salts have been found to yield excellent results in the diagnosis of streptococcal mastitis and in the isolation of lactic streptococci from milk and fæcal streptococci from water samples.

Papers of considerable interest to water bacteriologists dealt with investigations on the bacterial flora of lakes and streams. In lakes during the winter months, when the waters are in circulation, the counts of bacteria tend to be much the same at different depths, while during the summer, when the waters are stratified in two layers, counts in the upper layer are of a higher order than those in the lower layer, where they tend towards a low constant value. Coliform bacteria in relatively pure lakes and streams, though smaller in numbers than those in waters subject to pollution, show unexpectedly a higher proportion of the fæcal type.

Items of general interest included recommendations for economy in the war-time use of peptone for bacteriological media, and the role of statistics in the planning of experiments and in computing the error of the plate count.

In the field of dairy bacteriology, there were several papers on the methylene blue and the resazurin tests for bacterial quality of milk. A high correlation has been observed between the plate count and the methylene blue test and between the reduction of methylene blue and the reduction of resazurin to the vivid pink stage. Two causes of anomalous results in these tests are: (*a*) the growth of cryophilic bacteria during storage of milk samples in the refrigerator; and (*b*) the decrease, during storage, in the reducing power of milk containing large numbers of leucocytes. For pasteurized milk a reduction time of six hours or less in the test at 15·5° C. has been found to indicate either contamination by coliform bacteria or poor keeping quality.

The phosphatase test, applied to milk pasteurized in bottles, has revealed the fact that in one of three commercial plants examined a high proportion of samples had probably been underheated. The acid-producing bacteria which predominated in the freshly pasteurized milk were rapidly supplanted by alkali-forming types and played little or no part in spoilage during storage. Heat-resistant cocci which survived pasteurization appeared to consist largely of *Micrococcus luteus* and were not derived from the cow's udder.

Several papers were concerned with the bacteriology of starters and cheese. Infection of starters with bacteriophage is found to be an important cause of general slowness in cheese-making in Great Britain, even though mixed starter cultures are customary, but the incidence of the trouble may be reduced by observing certain precautions and by adopting a 'vitality' test as a measure of control.

Studies in cheese ripening have disclosed the fact that lacto bacilli may assist flavour through the liberation of an intracellular lipase on autolysis of the cells, while some light has been thrown on the sources of the carbon dioxide evolved from cheese during storage in cargo. In Cheddar cheese the gas results from bacterial action, but in Stilton it is mainly correlated with the growth of the mould.

Problems in disinfection received attention from several workers. For hypochlorites to be effective in the treatment of dairy utensils, the latter must be scrupulously clean, free from corrosion and open seams, and must be agitated or scrubbed during treatment. A technique was outlined for routine disinfection in the cowshed to combat, *inter alia*, the spread of mastitis streptococci.

An item of interest to the dairy industry was the demonstration of a portable apparatus, depending in principle on measurement of *p*H value, for rapidly testing the quality of the incoming milk at a creamery.

THE FORTIFICATION OF FOODS

THE diet of man now contains a variety of foods very different from those consumed by his prehistoric ancestors. Cooking, which may wash out or destroy mineral constituents and vitamins, has long been practised, while more modern processes such as the decortication of cereals, and the extraction and refining of oils and fats, may lead, according to the results of animal experiments and clinical evidence of human disease, to dietary deficiencies. Recent advances in methods of analysis of foods and in our knowledge of man's need for some of the vitamins and essential minerals have enabled us to estimate the dietary significance of these more modern methods of preparing foods. Now that a number of synthetic vitamins or vitamin concentrates are available it is possible in some cases to fortify foodstuffs so as to increase man's intake of these essential dietary factors to the level which modern investigations have shown to be desirable.

The great interest attached to this problem of fortification was reflected by the very large attendance at a joint meeting of the Society of Public Analysts

and Other Analytical Chemists, and the Food Group of the Society of Chemical Industry held at Burlington House on December 3 to discuss "The Fortification of Human Foods by the Addition of Specific Nutrients".

The first paper on "The Principles of Food Fortification" was read by A. L. Bacharach, who defined fortification, which he held to be synonymous with enrichment, as the addition of specific nutrients. He laid down a number of principles which should govern the whole policy of fortification. The amount of enrichment should be adjusted to the need of the consumer for the specific nutrient; this might have to be altered at different times or in different areas according to the amount already available in the diet. The nutrient should be added to some widely consumed foodstuff, such as bread or margarine, in order to ensure even distribution to the whole community, and, as the need must be greatest for those of limited means, fortification should not result in an increase in the cost of the foodstuff, which might defeat the principle of general distribution. Precautions should be taken to ensure that the consumer actually received the added nutrient, which should be stable and not be physiologically incompatible with any other component of the fortified food. Due allowance should be made for any loss likely to occur during the normal preparation of the foodstuff for the table. Fortification should not impair taste or flavour and so should not be detectable by the consumer, though the analyst should be able to determine the amount of the nutrient present. Mr. Bacharach's last principle, that of disclosure, is one which has not yet received official recognition in Great Britain, though it was endorsed by all subsequent speakers. When a food is fortified with a particular nutrient the amount of this nutrient present should be stated in simple and concise chemical or biological units and not, for example, in terms of 'summer butter'.

Illustrating his principles by references to examples of fortification already in operation in Great Britain or in the United States, Mr. Bacharach pointed out that the addition of iodine to table salt was probably the first fortification which was carried out not simply to replace something lost during purification but to overcome what is, in some areas, a known dietary deficiency in iodine by distributing this element in a simple and economical manner. Thus the aim of fortification should be to remedy some known dietary deficiency, not merely to imitate some allied foodstuff; white bread fortified with calcium is a better source of available calcium than wholemeal, though it may be inferior to wholemeal in other respects; vitaminized margarine should, if the need arises, contain more of the vitamins A and D than summer butter.

Mr. Bacharach vigorously attacked the naturalist school which professes an almost mystical belief in the superiority of dietary factors present in, or isolated from, natural sources. Members of this school would, apparently, condemn the fortification of flour with synthetic aneurin, but would applaud the same fortification if made with vitamin B_1 laboriously isolated from yeast. Ascorbic acid cannot wholly replace orange juice, but it can prevent scurvy if administered in the proper amounts.

Mr. Bacharach concluded by referring to the need for extending fortification to cover other nutrients and mentioned the advances which have been made in the United States. Iron should be added to white bread, and attempts should be made to lower the cost of production of riboflavin.

The second paper, on "The Technological Aspects of Fortification" by Drs. D. W. Kent-Jones and A. J. Amos, was read by Dr. Amos, who distinguished between fortification and enrichment, preferring to reserve the former term for cases in which losses of nutrient due to purification are made good, as, for example, when B_1 is added to white flour, or when a food is strengthened with some particular nutrient to make it equivalent to some allied food, as when vitamins A and D are added to margarine. Enrichment, on the other hand, should be reserved for additions of a nutrient to a food which is not normally a good source of the nutrient.

The methods adopted to carry out fortification must ensure uniform distribution without loss of the added nutrient, which should have no effect on the palatability or keeping quality of the final product. The fortification of margarine with vitamins A and D was carried out by some manufacturers long before compulsory fortification was introduced in Great Britain. In the early days concentrates were used which sometimes imparted flavour, but with the introduction of calciferol and whale oil concentrates this difficulty was overcome.

The fortification of white bread with B_1 has been achieved in three different ways, all of which are now being used in Great Britain and in the United States. In the method adopted by the Ministry of Food, aneurin is added to the flour during the milling process. The physical properties of aneurin render impossible the direct addition of the small amount required (0·2 gm. aneurin to 280 lb. flour), so a concentrate similar to flour is prepared by spray drying a suspension of flour in water containing the requisite amount of aneurin. The addition of 1 oz. of this concentrate to each 280 lb. flour is then performed without difficulty by a special mixer. In the second method of enrichment the B_1 is introduced into bread via the yeast used to ferment the dough. This yeast, obtained by cultivation in a special medium, contains about sixty times as much B_1 as ordinary yeast. The third method is based on the addition of 20–25 per cent wheat germ to flour.

The proposed enrichment of flour with calcium is not yet in operation, partly because opinion is divided as to the merits of the scheme, but also because of technical difficulties. Creta Præparata has been chosen as the most suitable form of calcium carbonate, since it has the least effect on the hydrogen ion concentration of the dough.

The lack of stability of ascorbic acid in aqueous solution causes practical difficulties in fortification. The addition of this vitamin should be made as late as possible during the process, aeration should be avoided and care taken to exclude traces of copper and iron. If vitamin C is added to a fatty food, a water in oil suspension should be used. The difficulties encountered with vitamin C serve to emphasize the need for careful control at all stages of the fortification process. As an example of what can be done even with an unstable substance, Dr. Amos mentioned that jam for dispatch to British prisoners of war is fortified with vitamin C. The loss during manufacture is not greater than 15 per cent, while the loss on storage for twelve months in sealed containers does not exceed 20 per cent.

H. E. Cox later gave a paper on "The Machinery for the Enforcement of Standards for Fortified

Foods". Dr. Cox assumed that, in normal times, fortification will be optional and not compulsory. If optional fortification becomes general, the law will need fortification to deal with the chaotic conditions which would probably result from wild claims made for various fortified foods. At present the Ministry of Food has control of fortification, but, in times of peace this control should pass to the Ministry of Health, when fresh legislation will be necessary to empower the Minister to issue regulations covering fortification. Indeed, Dr. Cox argued that the present activities of the Ministry of Food are directly contrary to the will of Parliament as expressed in the Foods and Drugs Act 1938.

According to this Act the Ministry of Health may restrict or prohibit additions to food, but has no power to order that additions be made. When the emergency control of the Ministry of Food is ended, the new regulations should prescribe maximum and minimum limits for fortification as is now being done in the United States. These limits must be capable of detection by analysis, hence the urgent need for the standardization of methods of analysis. Eventually this analytical control should be done by the public analyst and not by nominees of the Ministry of Food. If the public analyst is to guard the public against fraudulent claims, all fortified foods must be clearly marked with the actual amount of added nutrient present in the food, and no vague claims that vitamins have been added should be allowed.

The final paper, on "Analysis of Fortified Foods", was given by H. E. Monk. As methods of analysis for minerals are well known, Mr. Monk confined his remarks to a well-balanced summary of the methods of analysis for vitamins and of the difficulties likely to be encountered by the public analyst employing these methods. Since fortification with vitamins is to be carried out for nutritional purposes, it might appear at first sight that biological assay should be used when possible. Chemical and physical methods have the advantages of speed, accuracy and cheapness and, except possibly for vitamin D, are likely to replace the lengthy biological assays. Microbiological assay such as is used for riboflavin should not, however, be excluded.

To carry out a physical or chemical estimation it is first necessary to extract the vitamin from the foodstuff, and great care is needed to ensure that this extraction is complete. Having obtained the vitamin extract, precautions must be taken against loss during the estimation. Finally, the method used should be specific for the vitamin, and in cases of doubt, alternative methods should be used wherever possible in order to guard against erroneous results due to the presence of interfering substances.

In the spirited discussion which followed, repeated reference was made to the necessity for disclosing the vitamin content of fortified foods. Thus it was stated that the vitamin D content of margarine has recently been doubled in order to make up for the lack of eggs. Only three members present admitted that they were aware of this change.

It was generally agreed that the meeting had been one of the most successful of its kind and that the knowledge of the tasks which lay ahead should inspire the chemist to investigate the accuracy of present methods and devise new methods for the rapid estimation of vitamins.

FORTHCOMING EVENTS

SATURDAY, DECEMBER 20

BRITISH PSYCHOLOGICAL SOCIETY (at Tavistock House, Tavistock Square, London, W.C.1), at 11 a.m.—Discussion on "Problems Affecting the Under-Fives in Total War".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER IN THE DEPARTMENT OF CIVIL AND MECHANICAL ENGINEERING—The Registrar, The University, Leeds 2 (December 29).

EDUCATIONAL PSYCHOLOGIST and a PSYCHIATRIST—The Secretary for Education, Education Offices, York (December 30).

TEACHER OF ENGINEERING DRAWING in the Department of Mathematics and Physics of the Polytechnic, Regent Street, London, W.1, now at Lancaster—Dr. J. Topping, Storey Institute Technical College, Lancaster.

NATURE

SATURDAY
Dec. 27, 1941

THE INTERNATIONAL LABOUR ORGANISATION

THE International Labour Organisation remains almost alone of the institutions framed to promote international co-operation, understanding and world order after the War of 1914–18. Although its staff has been drastically reduced and all but a small group of officials have been transferred to Montreal, the Organisation continues to function effectively. From its new working centre it is issuing the *International Labour Review*, its studies and reports, its Legislative Series and from time to time organizes a series of meetings and conferences. The recent Labour Conference in New York was the most outstanding of these meetings, and to many it was a surprising but impressive witness both of the contribution which the Organisation is rendering to the practical improvement of labour conditions throughout the world and of its importance in the tasks of reconstruction which already lie near to our hand.

It is not too much to say that the act of faith involved in summoning the Conference at the present period has given to the world a fresh inspiration of the worth of the principles embodied in the Organisation. Already the pledge of the delegations of Poland, Czechoslovakia, Jugoslavia and Greece, announcing the formation of a *bloc* of those nations to serve as a basis after the War for a confederation from the Baltic to the Ægean, in which the four freedoms will be assured, demonstrates how the Organisation serves, as no other institution, as a rallying point for the Governments of the nations overrun by destruction. The Organisation represents and upholds an international way of life which would build up wealth, progress and security through the pursuit of common aims and purposes, and the exploitation, not of men, but of the abundant material resources of the world.

The realization that the International Labour Organisation stands for ideals and a way of life diametrically opposed to those of the Axis powers gave vitality to the recent Conference and related it immediately to the war effort at present engrossing the attention and resources of the surviving democracies. That realization is reflected in the outstanding address of President Roosevelt to the delegates at Washington on November 7, and in such utterances as those of Mr. E. J. Humbro, president of the Norwegian Parliament, who declared : "If we do not win the war there will exist only one law in national and international labour relations—the law of master and slave."

The ringing challenge to Nazi-imposed serfdom with which the Conference resounds would alone have made it memorable in these days. Its attempt to interpret the ideals of social security and to translate into practice the four freedoms

of which President Roosevelt has spoken made it beyond question a world event the significance of which is likely to grow rather than diminish with the passage of time. The fresh impetus to the task of planning the organization of international co-operation, to ensure that the abundant productive capacities of the world are used to satisfy the needs of its peoples, may well prove its most enduring value.

What gives reality to this issue at the present time is not merely that social policy is a central preoccupation, both because of its immediate relevance to defence and because it is ultimately at the core of the issues which the War will decide. If freedom from want means economic understandings which will secure to every nation a healthy peace-time life for its inhabitants everywhere, or in the words of the Atlantic Charter, "fullest collaboration between all nations in the economic field, with the object of securing for all improved labour standards, economic advancement and social security", or again, "assurance that all men in all lands may live out their lives in freedom from fear and want", the realization of that support presupposes the whole-hearted co-operation of the American Government and people. Anglo-American co-operation is the first condition of success in the schemes of post-war reconstruction that the International Labour Organisation may be able to prepare.

For this reason the proceedings of the Conference have rightly been viewed against the background of the Atlantic Charter with all the new hope of social security implicit therein. The report of the acting director, Mr. E. J. Phelan, on "The I.L.O. and Reconstruction", advocates the formulation of a social mandate which would represent an important step in preparation for the fulfilment of the great social aims to which Great Britain and the United States are committed in the Atlantic Charter. Mr. Phelan suggests that at a turning-point in the world's history when the general social objective of economic security is to be the mainspring of concerted political effort, the Organisation should be solemnly charged with its share of the task, that thereby men and women throughout the world should be given the guarantee that their Governments will vigorously pursue the effective realization of such a policy through its instrumentality. The formulation of such a social mandate would constitute a general declaration of international social policy and would give the International Labour Organisation a programme to implement, completing it with all the detail necessary.

The emergence of the social objective is emphasized by Mr. Phelan in a striking section of the second part of his report dealing with future policy. Leaders in countries not yet directly involved in the War are as committed to the idea that the objective of economic policy should be improvement in general conditions of life as are those of the British Commonwealth and her Allies. Twenty years of experience has testified to the grave inadequacy of labour legislation in the old, limited sense, and economic security itself is not to be interpreted narrowly but rather as the condition which enables men to build, on the secure basis of an assured standard of material well-being, a fuller, richer and a freer life. The Governments of the members of the Organisation, declares Mr. Phelan, seek economic security for all citizens, achieved in a manner which respects individual dignity and liberty; and since this can no longer be provided by the interplay of blind economic forces, self-preservation dictates that national and international policy must be directed deliberately to that end.

Mr. Phelan realizes to the full the gigantic task which the achievement of economic security represents, and the importance of the spirit in which that task is approached. In his survey of the social and economic background, however, he notes repeatedly tendencies or developments necessitated by war-time measures which should facilitate the mobilization of reserves for peace-time aims —the new conception of the duties of employment offices in the organization of a war economy is an example. Moreover, the whole character of the International Labour Organisation makes it natural for any reconstruction conference to turn to the Organisation in the consideration of social questions, and to use the Organisation as part of its machinery rather than attempt to constitute from its own membership a committee in which employers and workers could not easily be represented.

The stress Mr. Phelan lays on the tripartite constitution of the International Labour Organisation in this connexion is noteworthy. The character of its constitution may well be one factor that has been responsible for its survival when other international institutions have proved ineffective and fallen by the way. It is, however, of particular significance when the Organisation is domiciled in North America and much of its activity is concentrated in the Western hemisphere. The succession of strikes in the United States which has recently hampered production is a reminder that in labour relations that great democracy is a generation or more behind Great Britain. It may well be hoped that during its stay in North America, the International Labour Organisation may make important contributions to the establishment of smoother relations between the State and organized industry.

The New York Conference had before it a main report on methods of collaboration between public authorities and employers and workers' organizations, and the publicity which the Conference received should at least assist to make known to American public opinion the rich experience in such matters upon which the Organisation can draw. Moreover, the American people will not have overlooked the stress which Mr. Winant laid, in his valedictory report, upon co-operation between Governments and organizations of employers and workers. Unless such effective co-operation is achieved, said Mr. Winant, the democracies cannot survive.

Mr. Phelan, however, is not content to call for a social mandate in general terms. He sets out for discussion the main points and principles which such a mandate should cover. They include the elimination of unemployment; the establishment of machinery for placing, vocational training and re-training; the improvement of social insurance in all its fields and in particular its extension to all classes of workers; the institution of a wage policy aimed at securing a just share of the fruits of progress for the worker, and a minimum living wage for those too weak to secure it for themselves. Further points are measures to promote better nutrition and to provide adequate housing and facilities for recreation and culture; greater equality of occupational opportunity; improved conditions of work; an international public works policy for the development of the world's resources; the organization of migration for employment, and settlement under adequate guarantees for all concerned; and the collaboration of employers and workers in the initiation and application of economic and social measures.

Action clearly must be taken now on some of these points. Plans for the resumption or increase of the production of articles of general consumption now restricted or regarded as non-essential, plans for the establishment of new industries and the development of new materials and new techniques, such as the greatly increased industrial use of plastics, plans for housing schemes and for public works, both national and international, must be ready, together with the machinery for putting them into operation, if severe and dangerous dislocation of employment is to be avoided when the War ends. Certain forms of international action are likely to be taken to meet urgent needs without waiting for any general reconstruction conference —for example, measures to feed the peoples of Europe. An admirable broadsheet issued by Political and Economic Planning on planning post-war industry has already indicated the extent to which an attempt could be made now to treat the internal demand and supply schedules, even if it could not be fully decided.

This analysis itself gives cogency to Mr. Phelan's general argument. Unless some attempt is made to analyse demand and product, the unemployment situation alone may well once again get out of hand. P E P's attempt to list in very general form some of the questions which must be considered in drawing up reconstruction programmes, and to indicate the kind of principles on which the productive machine can be geared to the satisfaction of needs, is a valuable contribution to the constructive thinking and planning which alone can make possible any effective control of post-war production and distribution over a period of years. Without such control the basic industries will assuredly experience a violent boom followed by an equally violent slump. With control, replacement demands should provide industry with a steady load for some years after the War.

The P E P broadsheet concludes that the authorities responsible could give a lead to industry even at this stage of the War. Guiding principles could be formulated now and the preparation of post-war production programmes commenced. The Government could give the necessary stimulus and practical assistance to industrialists who are thinking of their own future, for it is most essential to decentralize the work behind the planning and the programmes among as many bodies, firms and individuals as possible. Programmes must be considered as a whole, since there are so many industrial inter-relationships to be taken into account. What is really important is that the guiding principles should be formulated as far in advance as possible, for it is the expectations of people which will condition the ease with which they accept particular policies. The expectations formed now will largely shape the future.

Reference is made in the broadsheet to an impressive number of public and private bodies, from Mr. Arthur Greenwood's Reconstruction Committee, Lord Reith's Consultative Panel on Physical Planning, Sir Frederick Leith-Ross's Bureau, Sir William Beveridge's Committee on the Social Insurance and Allied Services and the Inter-Departmental Committee on Demobilisation, to the regional reconstruction organization establishment in Birmingham, Manchester, Leeds, Newcastle-on-Tyne and elsewhere, the committees established by the Royal Institute of British Architects, the Institutions of Civil, Electrical and Mechanical Engineers, and the Reconstruction Department set up by one of the largest aircraft companies, which are making surveys of probable post-war markets and labour and material supply. All are facing one aspect or another of that first important task of domestic reconstruction after

the War—the conversion of British industry from the production of war supplies to the production of the basic needs of a civilized community with the minimum of dislocation, unemployment and social friction. Whether, however, we approach the problem from man-power aspects against the background of demobilization, from the consumer end, as in the broadsheet, or from that of the most effective structure to be given to British industry after the War, even the domestic problem cannot be handled in isolation from the international situation. International organization properly understood, as Mr. Phelan observes, is indispensable to the creation of the conditions in which national freedom can be effectively and safely exercised.

To deal with the social and economic problems which will be encountered at the end of the War, existing national powers will require to be used to the full for national measures. Concurrently, international measures must be taken by the appropriate international bodies if national action is to be effective, and not find itself baffled and defeated by circumstances out of its control. Indeed a real and determined attack on the social problem, the elimination of poverty and the social evils that arise from it, as well as of mass unemployment, and the securing of a higher standard of life for men and women throughout the world involve international action on a greater scale than that of the inter-war period, and greater financial resources to equip and extend international machinery must be forthcoming. Mr. Phelan's report contains abundant evidence to justify the act of faith which summoned the Conference in New York. The attention thus directed to the valuable experience already gained by the International Labour Organisation should lead, to the fuller recognition by all the Governments of the free nations of its effectiveness as an instrument of their declared post-war social policy, to its full utilization for that purpose and to placing at its disposal the necessary resources. Nothing is more certain than that the building of a new economic and social order to satisfy the hopes and expectations that have already been aroused, and to compensate for all the sacrifices now being made in the cause of freedom, will demand not only all the greater powers and resources placed in our hands by science, all the new experience of social and economic controls and of the government of world industries being acquired in our war effort, but also all that rich experience of co-operation between workers and managements and Governments the world over which twenty-two years of service have made available in the International Labour Organisation.

AN INDICTMENT OF CIVILIZATION

Man: The Mechanical Misfit

By G. H. Estabrooks. Pp. xi+251. (New York: The Macmillan Company, 1941.) 10*s*. 6*d*. net.

THE thesis maintained in this book by the professor of psychology in Colgate University, is that civilization is to perish, not by war, but by the action of certain evils which are inherent in our Western way of life. "Let us suppose," he writes, "that this war takes the very worst turn possible. All the countries, including America, are in turn invaded, and their cities reduced to ruins. Hardly possible, but let us suppose it occurs. Even so, it would seem to the writer that the reverse would be purely temporary. We still have ample human brains to reconstruct our culture from memory or from books." In this verdict the reviewer is in agreement with the author.

According to the author, man made a fatal mistake when "some 10,000 years ago," he began to clothe himself in that "glossy stuff called civilization"; it was then he threw overboard Nature's basal law, which Darwin named 'natural selection'. Cromagnon man, who lived in uncivilized times, was the product of "open competition", "an almost perfect man-beast". His successor brought the germs of that most fatal of all human diseases —civilization. Nature had given him a large brain "to aid in the bitter struggle for survival in a ruthless world". Instead, civilized man "side-stepped" Nature and used his big brain to succour the weak. So it has come about, according to Prof. Estabrooks, that our cities are filled more and more with men and women who suffer from hereditary disabilities of brain and body. It is only a matter of time, and civilization must come to an end for lack of people who are fit to carry it on.

This bald statement of the author's main thesis does a grave injustice to the racy and epigrammatic style in which he has presented it. In dealing with serious problems—and the annihilation of mankind by the civilization he has so laboriously created certainly belongs to this order—it is well to strip away the wrappings and get at the contents of the parcel. The chief content is the assertion that, in the human world as in the animal world, natural selection, survival of the fittest, the law of the fang and claw, to use the author's phrase, is the fundamental axiom of Nature. Perhaps the emphasis

which Darwin gave to the law of natural selection has led so many popular writers to overlook the fact that among social animals the qualities of the "heart" are just as potent in the struggle for survival as are claws and fangs. If only Darwin had expanded the brief paragraph I am to quote from his "Descent of Man" into a long chapter, for which he had ample material, the error into which so many writers on human evolution fall would have been avoided. The paragraph is this:

"For these communities which included the greatest number of the most sympathetic members, would flourish best, and rear the greatest number of offspring." (Chap. iv, p. 163.)

We have now good reason to believe that from the very beginning of what may be termed the period of human evolution, men were grouped in local communities, such as Darwin has postulated in the paragraph just cited. The ever-increasing duration of the period of the infancy of the human young rendered the prevalence of the laws of mercy and of co-operation within the groups more and more advantageous. The law of 'claw and fang' also prevailed, but its main objective was the defence of the local community. Pity for the weak was just as much the subject of natural selection as were man's sterner pugnacious qualities. I therefore hold that Prof. Estabrooks is in error when he assumes that our solicitude for the unfit is an attitude of mind introduced among us by civilization.

To this criticism Prof. Estabrooks may reply: "No matter when mankind began this maudlin sentimental care for the unfit, see how the practice works in a modern state." In the United States there are ten million feeble-minded citizens, one million of them confined in institutions. A "college group", 1,000 strong, provides the succeeding generation with only 800 individuals, while one thousand morons contribute 6,000. No State could stand up to such a substitution in its population. Thirty-two of the States have sanctioned by law the sterilization of the hereditarily unfit; the law is a dead letter in all thirty-two States save one. Is this refusal to face a problem in eugenics a manifestation of the "insanity of the sane", as Prof. Estabrooks maintains, or is it the persistence of that instinctive love of mercy mankind brought with it from the jungle—a fear that if it tampers with one part of its birthright, it may lose the whole? I leave the query unanswered; but I believe that in a struggle between two nationalities, one of which nurses humanitarianism within its borders to the full, while the other throws it overboard, it is the humanitarian State which will be the ultimate survivor.

No doubt Prof. Estabrooks is in the right when he maintains that modern civilization has beset the path of its habitués with temptations which were unknown to our uncivilized ancestors. He instances the case of a pair of educated parents, finding they could not afford both a child and an 'auto', decide on the latter. This choice, according to the author, was made under the action of the "pleasure principle, the greatest force guiding human and animal behaviour", a principle which, in the reviewer's opinion, fails to explain several forms of human behaviour. The author, however, does not mention that our uncivilized ancestors—and some of our civilized—had also their temptations. They had to think whether there was food enough to fill a "new mouth" and, if not, solved their problem by the practice of infanticide. A tribe which indulged in this practice beyond replacement rate soon fell a victim to the law of natural selection.

The two most urgent problems which the civilized have to solve are, in Prof. Estabrooks' opinion, (1) the abolition of feeblemindedness and (2) the abolition of war. The solution of the first is "startlingly simple; sterilize all the mentally retarded for just one generation and feeble-mindedness will practically cease to exist"—a result altogether at variance with the verdict given by British geneticists. War he regards as "racial insanity"; it is "a wholesale butchering of our best stock". "Nature's great law, the survival of the fittest, is here not only ignored; it is reversed." Prof. Estabrooks does not give a moment's consideration to the position of a nation whose manhood refuses "the honour of facing the machine gun and tank"; such a nation does not survive; war illustrates the law he so strenuously advocates—the survival of the strongest.

In his preface the author informs us that "this book is intended to represent a point of view—nothing more". Certainly his point of view loses nothing from the vigour and clarity of its presentation. He shares with his colleague Prof. Hooton of Harvard, not only the gift of humour and a faculty for vivid verbal presentation, but also the tendency to gain emphasis by the use of exaggeration. When he informs us that "up to now, education in its broadest sense has been the most potent force leading to human degeneration", we feel he is seeking to produce an effect rather than to inculcate truth. It was by education that Galton hoped to introduce the practice of eugenics.

Notwithstanding my criticism, there can be no doubt that Prof. Estabrooks has written a book with a high and healthy purpose; he seeks to bring home to parents who spend on personal pleasure what should go to the building of a new generation, the guilt of racial embezzlement.

A. Keith.

SPECTROGRAPHIC TABLES

Tabelle der Hauptlinien der Linienspektren aller Elemente nach Wellenlänge geordnet

Von Prof. H. Kayser. Zweite Auflage, neu bearbeitet und herausgegeben von Rudolf Ritschl. Pp. viii+269. (Berlin: Julius Springer, 1939.) 28.50 gold marks.

Massachusetts Institute of Technology Wave-length Tables:

With Intensities in Arc, Spark or Discharge Tube of more than 100,000 Spectrum Lines most strongly emitted by the atomic elements under normal conditions of excitation between 10,000A and 2,000A, arranged in order of decreasing wave-lengths. Measured and compiled under the direction of Prof. George R. Harrison by Staff Members of the Spectroscopy Laboratory of the Massachusetts Institute of Technology assisted by the Works Progress Administration. (A Publication of The Technology Press, Massachusetts Institute of Technology). Pp. xxix+429. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 90*s.* net.

THE appearance of these books is a sign of a more permanent aspect of the times than that which unfortunately must now engage most of our attention. Not only are the tables now before us of great intrinsic importance; they are significant also as a symbol of the transition of atomic spectroscopy from the field of physical theory, where the greater part of its work has now been completed, to that of industry, biology, and other activities in which it can find practical application.

Spectroscopy—spectrum analysis, as it was then called—began as a department of chemistry, but owing to the vagaries which spectra exhibited, arising from little understood variations in the source of luminosity, chemists soon reverted to their more dependable methods, and the practice of spectrum analysis was left for a few decades to astronomers. Stars had to be analysed by their spectra or not at all, and despite many inevitable mistakes, the almost exclusively astronomical period of spectroscopy saw many important advances. It was not until 1913, however, when the Bohr theory indicated the true character of spectrum emission, that the apparent inconsistencies began to be understood, and for the next fifteen years the study of spectra dominated research into the structure of the atom. The knowledge thus gained made spectroscopy a trustworthy instrument for investigating not only chemical composition but also the physical conditions existing in laboratory and industrial processes, the transient existence of intermediate substances during chemical changes, and a variety of other problems to which its relevance had not been suspected. It is in this epoch that we are now well immersed, and its *sine qua non* is the existence of accurate and comprehensive tables of wave-lengths, intensities and identifications of spectrum lines. The volumes under review represent the latest and most complete attempts to provide such tables.

The Kayser-Ritschl volume is a revision of an earlier publication, the general plan of which it retains with some improvements. New lines have been included, and most of the errors of the previous volume have been corrected, though the V line at λ 3876·08 is still given as 3877·08, and the non-existent V line, 6219·55 (apparently an error for 6119·55, which, however, is given), still appears, while the V I and Ti II lines, at 4395·24 and 4395·04, respectively, are each given twice in different places. On the whole, however, the volume seems to have been considerably improved. One great defect of the earlier edition has been corrected by the definite division at about 2,000A. between measurements in air and those in vacuum. Formerly, no indication at all was given of the medium in which lines in this region were measured.

Harrison's book is the first result of an entirely new project, involving the mechanical measurement, by the now well-known instrument installed at the Massachusetts Institute of Technology, of most of the wave-lengths recorded. While Kayser-Ritschl contains about 27,000 lines between 90,000 and 32 A., Harrison gives nearly 110,000 lines within the range 10,000—2,000 A. The much greater 'density' of lines in Harrison is further accentuated by the fact that only lines of neutral and singly-ionized atoms are given, whereas Kayser-Ritschl is not confined within any excitation limits. Furthermore, Harrison very usefully includes 1381 band-heads, identified, however, not by the molecule of origin but by its 'principal' atom, so that the CN bands, for example, are assigned to C. This is an unfortunate "simplification" for which it is difficult to find the justification, unless it be the inadequate one that "the tables are designed principally for use in spectroscopic analysis of materials and for identifying impurities". The publication as a whole, however, is a remarkable *tour de force*, which it is difficult to admire too highly, and of which the value can scarcely be exaggerated. Some idea of the mechanical mastery achieved over a very difficult

problem is given by the statement that "the wave-lengths of more than a thousand lines can be recorded in one minute without difficulty", and it might be added that there is no evidence of any sacrifice of accuracy.

The Kayser-Ritschl data have been taken from what are considered the most trustworthy sources; there has been no averaging of all available figures. This is true also of those of Harrison's wave-lengths which are not original measurements, but, unlike Kayser-Ritschl, he gives the sources in such cases. Kayser-Ritschl's wave-lengths do not go beyond the second decimal, since the disagreement between observers seems to make greater precision illusory. Harrison usually gives a third decimal, but doubts its accuracy. Neither volume gives hyperfine structures. Kayser-Ritschl includes forbidden lines, with their identifications if known and celestial sources if not, but Harrison omits all such lines, even if they have been produced in the laboratory. *Raies ultimes* are denoted in Kayser-Ritschl by the letters LL after the chemical symbol in the main table. Harrison gives no such indication, but lists *raies ultimes* in two separate tables, in order of wave-length and classified under the several elements, respectively. The degree of ionisation when known is given in both volumes by the usual numeral, I, II, . . . placed after the chemical symbol. When it is not known, Kayser-Ritschl places B, F or G (denoting arc, spark, or vacuum tube) after the symbol, and the single intensity number refers to that source. Harrison, however, retains the older method of giving a separate intensity column for each source, though a warning is given that the scales of the columns are not comparable, so that a line given a larger intensity number in the arc than in the spark might yet be enhanced in the spark. Both volumes are well printed, but Kayser-Ritschl is the easier to read. The small Clarendon type used in Harrison needs careful scrutiny to avoid misreading, and, even so, one is liable to confuse Ti and Tl, for example.

Books of this character cannot be satisfactorily reviewed until they have been in constant use over a long period. Two years under abnormal conditions provides less experience than is desirable. The impressions on which this review is based have come mainly from the measurement of plates of a specially prepared *raies ultimes* mixture, containing all the spectroscopic elements except indium and the rare earths, and showing many hundreds of lines throughout the ordinary regions of the spectrum. This work has shown very definitely that the volumes are complementary to one another and cannot properly be considered as alternatives. For most problems, and for preliminary work in all, Kayser-Ritschl is the more useful, Harrison containing too many lines within a short range to do more than confuse the investigator. Suppose, for example, a prominent line appears at a position estimated as between 4020 and 4021A. It will probably be Sc I, which has a *raie ultime* at 4020·40. Harrison, however, gives 29 lines within this range of 1 A., two of which are given considerably higher intensities than Sc I, and others comparable intensities, although, in fact, they are all relatively unimportant lines of their respective elements. Kayser-Ritschl gives five lines, with Sc I as the strongest. Since most workers use small dispersion spectrograms, not permitting the highest accuracy in measurement, Harrison gives little help. For those, however, who have facilities for precise measurement and for whom accurate identification is essential, Harrison may become indispensable. It is claimed that the lines given comprise one-half of those known, and account for 99 per cent of the radiation emitted by atoms within the range of wave-length covered. It is therefore clear that the volume serves better as a means of excluding possible alternatives to an identification adopted than as a ready guide to the identification to adopt.

Incidentally, it may be remarked that an almost indispensable supplement to such tables as these is a table of multiplets of the elements such as is partially provided in Miss Charlotte E. Moore's "Multiplet Table of Astrophysical Interest". The problem of the Sc I line referred to above could probably be settled at once by looking for the other three lines of its multiplet, and taking the relative intensities into account.

The mention of intensities introduces the most glaring defect of both books—the extremely unsatisfactory treatment of the problem of intensity scales. The problem is admittedly very difficult. Obviously no significance can be attached to the relative intensities of lines of different elements when the elements producing them exist in unknown proportions in the source; nor can lines far apart be given directly comparable intensity numbers because of variation of plate sensitivity. Within a single spectrum and a short wave-length range, however, the numbers can be at least in the right order of magnitude, and this order is often the only available factor in deciding a particular identification. How badly the need is met can be illustrated by a single example, chosen before the recorded intensity numbers were looked up, so that it may be taken—as, in fact, it is—as typical of the general chaos. The example is the well-known *DF* sextet of VI, containing the *raie ultime* at 4379, which covers only a short range of wave-length. The following are the arc intensity numbers of the lines in the two volumes, compared with those recorded by Miss Moore in the publication

referred to above, which are based on King's furnace spectra :

	Kayser-Ritschl	Harrison	Moore
4379·24	10*R*	200*R*	150*r*
84·73	120*R*	125*R*	125*r*
89·99	100	80*R*	100
95·24	10	60*R*	80
4400·59	60	60	60
06·65	80	40	80
07·66	70	15*h*	70
08·21	70*R*	30	70
08·52	50*R*	30*h*	90
16·48	20	15*w*	20
21·59	20	30*h*	20
26·01	15	25*h*	20
29·80	15	30	15

This needs no comment, but a word may be added on the desirability—particularly in Harrison, where the lines occur at such small intervals—of making an attempt to give lines of different elements intensity numbers roughly proportionate to their relative prominence in their own spectra. The present numbers are utterly meaningless in this respect. For example, Harrison records two lines of Fe I, at 3243·109 and 3190·651, as having arc intensity 50. These lines are so weak that they do not appear on Buisson and Fabry's well-known map of the iron arc spectrum obtained from almost pure iron and intended as a record of the whole spectrum. On the other hand, the *raie ultime* of W, at 4008·753—in a region where plate characteristics should give it relative prominence—has intensity 45. It is much to be hoped that a satisfactory intensity scale will take precedence of the inclusion of wave-numbers in the future improved tables which Harrison promises.

In spite of all defects, however, these volumes represent an enormous advance over anything of the same character that has preceded them, and they are indeed indispensable in any laboratory in which spectroscopy is applied to practical problems. Spectroscopists everywhere will acknowledge a deep debt of gratitude to the compilers for the care and patience with which they have carried out a very great task. HERBERT DINGLE.

THE EXTRA PHARMACOPŒIA

The Extra Pharmacopœia

By Martindale. Twenty-second edition. In two vols. Vol. 1. Pp. xxxviii+1289. (London: The Pharmaceutical Press, 1941.) 27*s*. 6*d*.

THE first volume of the twenty-second edition of the Extra Pharmacopœia—Martindale—has appeared at about the time that it might have been expected if there had been no war. It looks like its immediate predecessors and, like them, will be almost indispensable to the physician and the pharmacist, who are expected to know all that is new in the way of medicines, whether they be respectable and approved or merely advertised. A great part of the material for this edition had fortunately been collected before the War had cut international communications and slowed up the output of scientific work. More than two thousand new medical and pharmaceutical papers are abstracted and the revision committee has had to put much more of the book into small print to make room for the new matter without making revolutionary changes in the format.

The arrangement of the information still leaves something to be desired, and it is fortunate that there is a good index. Drugs with closely allied actions are generally classified together, but choline, because of its relation to acetylcholine, is discussed in the article on acidum aceticum, which is absurd. Sympathomimetic amines are arbitrarily divided up so that some of them are included with adrenaline and others with ephedrine.

Data from the first three addenda to the British Pharmacopœia, the second supplement to the British Pharmaceutical Codex, the new French and Japanese Pharmacopœias and the new supplements to the United States and Dutch Pharmacopœias are included. Some of the information about proprietary names has been eliminated because the drugs are no longer available in Great Britain. This is unfortunate because it makes the book less complete as a work of reference, without any compensating advantages except a small saving of space. There is no guarantee that the drugs which are mentioned are available; many of them are not.

The amount of information in this book is prodigious, and it is difficult to select examples of the changes that have been made without making out a long list. Sulphanilamide and its derivatives occupy no less than 37 crowded pages. Many new hormones and vitamins have been dealt with and there is much information about such new interests as blood transfusion, heparin, penicillin, chlorophenolic and higher phenolic antiseptics. The section on vaccines, sera, toxins and antitoxins now covers 74 pages. An entirely new therapeutic index has been compiled in which diseases are arranged alphabetically, with a list of the treatments recommended and the pages of the book on which references to these treatments will be found. This index will be very useful to medical men.

The book as a whole gives an interesting picture of the unprecedented advances in therapeutics which have occurred in recent years.

The Revolution in Physics

By Ernst Zimmer. Translated, and with a Preface, by H. Stafford Hatfield. Pp. xv+240. (London: The Scientific Book Club, 1941.) 2*s*. 6*d*.

THERE are almost numberless little books written to help the layman to understand modern physics. At first sight this modest volume is yet another. But not quite. It deals, as they all do, with the rapid development of physics, indicating how it is that our concepts have become less and less mechanical. But here the similarity ends. The usual course is to make up for so much hard going by generous quantities of applied science, wireless, television, and other 'benefits'. In this book the author, however, decides otherwise. He makes a moving, almost passionate, appeal for pure knowledge, without thought of application, still less of reward. The whole outlook is remarkably unselfconscious, and, for that reason alone, most refreshing. Prof. Max Planck's short introduction is characteristic and charming.

Naturally enough, the writer is a little pedestrian in his dealings with the classical quantum theory, but very much the reverse in his discussion of positivism, determinism and Heisenberg's Uncertainty Principle.

There are a few typically Teutonic lapses; for example, Clerk Maxwell is described as "English"—more than sufficient to cause the first Cavendish professor to rotate in his grave. It is hard to judge of the translation without access to the original: on the whole it seems well done. Certainly it is faithfully done, since one gets glimpses both of the author's occasional touches of *Lehrkörperheit*, and yet of his natural facility as an essayist.

F. I. G. R.

The Observer's Book on Meteorology

By William Alexander and W. J. D. Allan. (The Observer's Books, No. 6.) Pp. 110. (London: George Allen and Unwin, Ltd., 1941.) 2*s*. 6*d*. net.

THIS book is written for pilots and observers in the R.A.F., who will find in it much useful information. It is marred by some inaccuracies, over-sweeping generalizations and dubious explanations of phenomena that meteorologists have not yet succeeded in explaining. One of the inaccuracies is probably a misprint—the reference on page 77 to a shallow depression as one above 1,100 millibars. Minor ones that might confuse a student of elementary meteorology include the statement (p. 36) that pressure gradient is usually expressed as the distance in miles between two isobars of two millibars difference in pressure, a quantity that is in fact proportional to the reciprocal of the gradient, and (p. 52) that in the British Isles it is customary to refer to northerly winds as polar winds and southerly winds as equatorial winds; apart from the absence of any necessary connexion between the direction of the wind and its past history there is the contradictory statement (p. 66) that polar air has a tendency to flow in a westerly direction and equatorial air in an easterly direction. In the paragraph on snow (p. 97) the explanation of the formation of snowflakes is unorthodox and unlikely, nor is it inevitable to have rain on the ground when snowflakes fall through a layer of air above 32° F. (Why not sleet?). One would like to know the grounds for attributing (p. 78) tropical cyclones and temperate tornadoes to the same cause. Weather forecasting with the aid of isallobaric charts is not as simple as the account on p. 110 implies, although the changes described sometimes take place.

Our Wonderful Universe

An Easy Introduction to the Study of the Heavens. By Dr. Clarence Augustus Chant. New edition, revised and enlarged. Pp. 281. (London, Bombay and Sydney: George G. Harrap and Co., Ltd.; Toronto: The Ryerson Press, 1940.) 5*s*.

THIS work is written specially for young people and the subject is approached from the observational side: mathematics are completely absent from the text. The copious illustrations will prove very helpful to the tyro as will also some of the simple experiments which have been suggested, for example, the camera and flash-lamp apparatus, described in Chapter 1, to illustrate the rotation of the earth. Part 1 gives a brief outline of the general structure of the universe and Part 2 deals with the solar system, concluding with a short account of the origin of the sun and planets. Reference is merely made to the nebular hypothesis and the tidal theory; in the limited space the author finds it impossible to state any of the objections to either of these theories. In Part 3 the reader will find an excellent account of the stellar systems, proper motions, variable stars, double stars, star clusters, nebulæ, etc. Detailed descriptions are impossible in dealing with such a vast programme in a single volume, but Prof. Chant has succeeded in condensing an enormous amount of useful information into the work, which will stimulate young readers to pursue the subject further in more advanced text-books. The value of the book is enhanced by the illustrations and photographs—210 altogether—which greatly increase the interest in the various sections.

M. D.

The Promise of Scientific Humanism Toward a Unification of Scientific, Religious, Social and Economic Thought

By Prof. Oliver L. Reiser. Pp. xviii+364. (New York: Oscar Piest, 1940.) 4 dollars.

THE author advocates the use of non-Aristotelian logic. This would mean abandoning the laws of identity, contradiction and excluded middle. He claims that such a revolution in thought would eliminate many ancient and modern fallacies, and introduce a new and better era in science, philosophy and social relations. In spite of some good points he fails to make out a case. His exposition is often rhetorical and cloudy; he uses indiscriminately all sorts of opinions, sober and speculative, good and bad; he shows no capacity for critical judgment. Altogether the new non-Aristotelian logic sounds very like the old sophistry that Aristotle's logic was designed to expose.

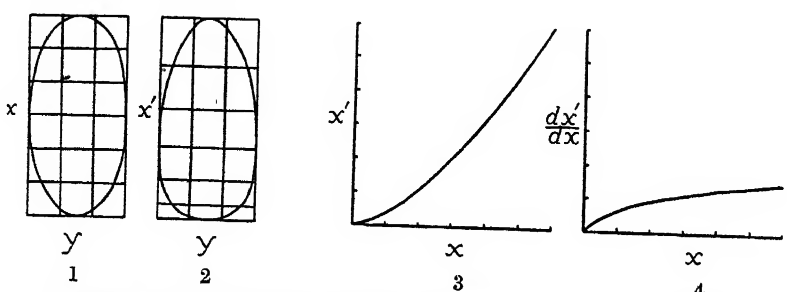
A. D. RITCHIE.

THE 'LAWS' OF BIOLOGICAL GROWTH

By P. B. MEDAWAR

DEPARTMENT OF ZOOLOGY AND COMPARATIVE ANATOMY, OXFORD

THE study of mere increase in size and weight has steadily lost the interest of British students of growth since D'Arcy Thompson[1] and later Huxley[2] directed their research to other fields. Many of the beliefs about organic growth that formerly seemed reasonable or even self-evident—in the existence, for example, of an integral biochemical process known as 'growth metabolism'—have now been refuted or superceded; and it is only quite recently that students of growth have stopped applying to the organism the fiscal concept of interest, or increments of size, accumulating at finite intervals. Minot[3] always used it. The inspection of curves of growth has nevertheless made known a number of general principles concerning the dependence of the size of organisms on their age which it is very worth while to collate and comment upon. These laws are of the growth of *individual* organisms. It was Davenport[4] who first pointed out the unsuspected extent to which curves of growth compiled from mass statistics may be corrupted by what are in reality curves of distribution. At puberty, for example, the growth of individual boys shows a marked spurt, the time of onset of which in the male population as a whole is normally distributed about a mean value at approximately $14\frac{1}{2}$ years. The 'adolescent growth component' of the mass curve of human growth, to which Robertson[5] fitted his well-known 'monomolecular autocatalytic' function, does not occur in the curve of individual growth. Davenport showed that it was essentially a modified Gaussian curve of error, indicating the distribution in time of the onset of adolescent growth spurts.



ILLUSTRATING THE TYPE OF CHANGE OF SHAPE BROUGHT ABOUT BY A SIMPLE GROWTH GRADIENT.

The transformation from an elliptical to an ovoid outline is illustrated by the grids superimposed on Figs. (1) and (2). The ordinates or x'-values in (2) are those which correspond to *integral* values of x in the normal grid (1). In (3) the 'mapping function' $x' = f(x)$ which defines the transformation is plotted in the usual way; its essential feature, as (4) shows, is that the slope of the curve $x' = f(x)$ never decreases as x increases.

The laws themselves require a varying amount of critical attention. Each describes a general trend of growth; they take into account neither short-term fluctuations or periodicities, as in animals with an annual cycle of growth, nor more pronounced singularities, such as those brought about by metamorphosis in animals which undergo it. Unlike some mathematical approximations, they lose accuracy and significance in proportion as the period of time over which they are intended to apply becomes shorter. Nor do these laws apply over the whole of the life-cycle. They should be taken to refer to the 'functional period' of development, namely the period which begins with the blocking-out of the main organ systems in the embryo.

1. *Size is a monotonic increasing function of age.*

Less formally, organisms do not decrease in size as they grow older. A more casual statement, such as that 'organisms increase in size as they increase in age', would be much less satisfactory, for it could be shown to entail an unproved belief, namely that in the course of their development organisms approach a limiting size. It is plausible to suppose that they do so, and most of the functions commonly used to describe the course of growth are functions with limiting values. But it is important not to exclude, at all events in a formal way, the possibility that organisms reach a *maximum* size at which they remain virtually stationary during the latter part of their life.

2. *What results from biological growth is itself, typically, capable of growing.*

Biological growth is fundamentally of the multiplicative type: that is the only 'law of growth' commonly recognized as such. It justifies the almost universal use of the relative differential $dw/Wdt = d/dt\ (\log_e W)$ as the one most likely to give a significant expression of change of size. The estimate it provides is of the *specific growth-rate*, and the special instance of growth by the compound

interest law corresponds to a uniform specific growth-rate.

3. *In a constant environment, growth proceeds with uniform specific velocity.*

The truth of this important principle, with its Newtonian flavour, has been demonstrated on a number of occasions, perhaps most clearly by Richards[6] for population growth in colonies of yeast. The 'constancy' which the law requires is not only of the external environment, but of the *milieu interne* as well. Outside work must be done on a growing system if its environment is to remain constant, and since the *milieu interne* of complex organisms is not accessible to the sort of experimental control which is required, it is only tissue-cultures and populations of non-cellular organisms which can be induced to grow 'logarithmically' for any significant length of time. The fourth law, then, relates the second to conditions which actually hold in the development of many-celled organisms.

4. *Under the actual conditions of development, the specific acceleration of growth is always negative.*

While the growth-rate may rise and then fall, as it does in any organism the growth of which is described by a sigmoid curve, the *specific* growth-rate always falls. There are few, if any, exceptions to this general rule. Roughly speaking, it means that 'what results from biological growth', although capable of growing, is not capable of growing as fast as its precursor. Minot regarded the degree to which it fails to do so as a measure of senescence. Senescence is therefore a process taking place continuously throughout life. This is Minot's great contribution to biological thought.

5. *The specific growth-rate declines more and more slowly as the organism increases in age.*

The specific acceleration of growth $d/dt\ (dw/Wdt)$, while always negative, rises progressively to zero during the course of life. In short, 'organisms age fastest when they are young'; or, to put it in a more familiar way, they develop more slowly as they grow older. The rate at which the specific growth-rate declines is an important parameter in any equation for growth, and its value can in certain circumstances be measured by purely experimental means[7].

These laws provide a fairly stable background for the quantitative analysis of growth. An obvious omission is of an expression for the differential growth of the parts of an organism, or of parts in relation to the whole. One possibility, which has been examined exhaustively by Huxley, is that the specific growth-rates of comparable parts of an organism bear a constant ratio to each other throughout the greater part of life. This relationship has been described as 'simple and significant'; and what it chiefly signifies is that senescence, measured by the rate at which the specific growth-rate declines, proceeds at an approximately uniform rate throughout the organism. This latter theorem, which is far from self-evident, and which might have been the most important *inference* from any established facts concerning constant ratios of specific growth-rate, was treated by Huxley as one of the *axioms* he used to provide a deductive basis for the doctrine of constant specific growth-rate ratios in general. A more general and far-reaching statement about growth-rate patterns is Huxley's theorem that, typically, the particular growth intensities of the parts of an organism are spatially arranged in an ascending or descending order of magnitude. Organisms which conform to this pattern may be said to 'exhibit a growth gradient'. The generality of the gradient pattern reflects our conviction that a large part of the physics of development is primarily a physics of diffusion. This is the chief physiological importance of the theory.

The gradient theory may also be used to define, within broad limits, the *type of change of shape* which occurs during the developmental growth of an organism or of one of its parts. For the transformations which can be designed to assimilate any two shapes adopted by a developing organism can, in principle, be defined by a substitution of variables in the equation which describes one shape or the other. The new variables are functions, sometimes called mapping functions, of the ones they replace. Transformations are defined by the properties of these functions. The gradient theory restricts the mapping functions which define the transformations of development to membership of a large but distinct class. Consider, for example, an axial gradient of growth which distorts the outline of an organism in one dimension only. If $F\ (x, y)=0$ describes the original outline, the new outline will be represented by the equation $F\ (x', y)=0$, where the key to the transformation is the mapping function $x'=f(x)$. The gradient theory, strictly interpreted, merely requires dx'/dx to be a monotonic function of x. In other words, the characteristic mapping function is one of which the first derivative is a monotonic function of one or the other of the original variables.

By a natural extension of this interpretation, the gradient theory can be generalized to admit transformations which are the *products of* transformations so defined. The product of one transformation with another is the result of applying one to the result of applying the other, and it should usually be taken in a definite order. In generalized form, the theory therefore states that complex changes of

shape can be significantly resolved into simple changes of shape of the type defined above. The word 'significantly' is meant to express our assurance that the whole procedure is not merely an analytical device, but that the product of transformations corresponds to the combined or successive action of distinguishable physiological processes.

This interpretation of the gradient theory, which will be given a fuller treatment elsewhere, relates it to the more comprehensive methods of analysing organic form which were designed by D'Arcy Thompson. The danger of over-simplification is of course very real: for example, the outline drawings of animals with which we are obliged to start our analysis of shape are themselves affine transformations of the three-dimensional objects they represent. But once they have been recognized as such, our purely informal simplifications and assumptions lose a great deal of their virulence. There is something more in the analysis of growth-rate patterns than a determination to see order where no order exists.

LIFE AT HIGH ALTITUDES

By PROF. A. J. CARLSON
UNIVERSITY OF CHICAGO

MEN of science at the symposium on "Life at High Altitudes and Aviation Medicine" held at the University of Chicago on September 23 as part of the University's fiftieth anniversary celebration heard dissertations ranging from a description of an "Altitude Human Race" to the physiology of the free fall and of parachute jumping.

Since fright, rather than basic physiological reactions like blood pressure or heart action, is one of the chief causes of fainting in a delayed-opening parachute jump, use of a small guide parachute which prevents twisting and spinning in mid-air—conducive of fright—will contribute much to the safety of parachute jumpers. In addition, the 'anti-spin' chute prevents tangling with the parachute lines which sometimes occurs, if the parachutist is twisting when he pulls the rip cord.

These points, given particular emphasis by the strategic military desirability of delayed-opening jumps, were made by Prof. Andrew C. Ivy, professor of physiology and pharmacology in the Northwestern University. Prof. Ivy reported research in collaboration with Prof. Anton J. Carlson, of the University of Chicago, in a paper on "The Physiology of a Free Fall through the Air".

It is worthy of note, pointed out Prof. Ivy, that the person who is in a position where a delayed fall is advantageous would be given confidence by the early opening of the accessory, 'anti-spin' parachute, and this, plus falling in a more natural, or semi-erect posture, would decrease the likelihood of inexperienced persons fainting from fright.

It is Prof. Ivy's belief that when it is necessary to bail out of an aeroplane, a delayed opening of the parachute has certain strategic advantages: the jumper is less likely to foul another jumper, an aeroplane out of control, or falling aeroplane parts; an open parachute is an excellent target for the enemy; if the parachute is opened at an altitude of thirty thousand feet or more the jumper may lose consciousness from lack of oxygen unless he carries a supply with him; if the aeroplane is moving rapidly and the parachute is opened soon after leaving the plane, the jumper is likely to be injured and the parachute and its attachments ripped. When a person jumps from an aeroplane, his rate of fall decreases or increases to an approximate rate of 120 miles per hour. At 300 miles per hour the shock load to the jumper and the parachute is five thousand pounds.

In experiments covering five jumps with a human subject, Mr. A. H. Starnes, following earlier experiments with dummies and apparatus, verified that:

(1) Except in flights as fast as would be experienced in a jump from a descending dive bomber, there is no appreciable unfavourable influence on heart-rate and blood pressure.

(2) A fleeting mental 'black-out' occurs shortly after the jerk of the riser straps caused by the chute opening. Otherwise in a calm and unfrightened jumper, mental reactions are clear, rapid and normal.

(3) The same difficulty in hearing was found as is experienced facing, or with the back to, a high wind. Vision was not impaired when goggles were worn ; the eyes watered without goggles.

(4) There was no feeling of nausea even in spinning, because of the brevity of the time. (The longest drop was 16,500 feet at 158 miles per hour, which took seventy-one seconds.)

(5) Contrary to the findings of Dr. H. G. Armstrong of the U.S. Army, there was no sensation of floating in space when the eyes were closed. Subjectively Mr. Starnes was aware of the drop because of the wind rush and other sensations. He "felt that he was falling, and falling rapidly".

The "Altitude Human Race", a biological entity differing radically in several respects from other branches of mankind, was postulated to describe the dwellers of the Andes mountains of South America by Dr. Carlos Monge, of the University of San Marcos, in Lima, Peru.

Listing a score of vital differences between the man of sea-level and the man of the Andes, living at 10,000–16,000 ft. above sea-level—Mt. Whitney, highest peak in the United States, is 14,495 ft. ; there are thirty-three South American peaks higher than seventeen thousand feet, the highest, on the Chile-Argentine border, Mt. Aconcagua, 22,834 ft.—Dr. Monge also described the disease 'chronic mountain sickness', which afflicts lowlanders when they start to live in the high altitudes.

In the Andes, Dr. Monge pointed out, twelve million persons are living all the time under conditions at an altitude where the oxygen pressure is 85. mm as contrasted with the sea-level pressure of 150 mm.

Describing the high-altitude human race, Dr. Monge said the heart of Andean natives actually beats more slowly following exertion. It seems that increased vagal action causes the bradycardia, which may be considered the law of the altitude heart. We find all the conditions of athletic heart. Chronic anoxia (lack of oxygen, such as that characterizing high altitudes) is a permanent stimulus to improve heart efficiency.

Dr. Monge suggested that this man has some of the biological characteristics needed for an aviator, and that perhaps a better knowledge of the physiology of the man born and living at fifteen thousand feet would help the learning of the required conditions of fitness for high-altitude flight. Since 1928, Peruvian aviators have flown over the Andes continuously at higher than fifteen thousand feet elevation.

Comparing the acclimatization of high-altitude dwellers to the instinctive force which causes the annual migrations of birds, Dr. Monge cited the factor of altitude as one which in the recent Bolivian-Paraguayan war "killed more people [high altitude soldiers made to fight in the lowlands] than the enemy's bullets". The day will come, he pointed out, when these vital matters will receive due consideration for the welfare of the altitude human race.

Men of the Andes may be considered as belonging to a special climato-physiological variety of the human race. In fact they are closely related to their geographical surroundings : altitude, radiation, humidity, ionization, and so on. The sociological behaviour of such men and the telluric (earth-related) environment appear as a whole, as a biological system which cannot be divided, as a climato-physiological unity. They have to adapt themselves on coming down to the coast ; they cannot always stand the meteorological conditions of lower lands ; they become predisposed to disease of the lungs, as has already been reported by Dr. Monge.

But the struggle for life obliges them to come down ; and then ensues a fact which is worth noting. Every year about one hundred thousand men come down to sea-level for agricultural work, but after about three months they go back to the altitude. They never stay at the coast no matter what it offers them.

These peculiar annual human migrations of high-plateau societies are a very well-known fact of biological significance. "Like the swallows, Andean men have the sense of returning home". Therefore, they have the same problems of acclimatization to face when going down to a land not always fitted for their physiological equipment. Usually acclimatization at the coast is easier than that on the highlands. But there are the facts, the study of which is of utmost importance for the knowledge of Andean populations.

How the body mechanisms which constantly tend to maintain the vital balance between acidity and alkalinity adjust to high altitude by stimulating increased breathing, but offsetting the chemical effects of this increase on the blood, was reported by Major David B. Dill, of the U.S. Army Air Corps. Major Dill spoke on "Acid-Base Balance in High Altitudes".

Reporting the Andean expedition to Chile in 1935, in which members of the expedition lived at 17,500 ft. and worked at 18,000 ft., Major Dill described the "beautiful integration of the mechanisms of the organism which combat disturbances of the balance arising from abrupt and prolonged exposure to oxygen deficiency".

In the long-run process of acclimatization, when the acid-base relation is thrown out of equilibrium because of limited availability of oxygen, he said, the increase in the number of red blood cells (oxygen carriers) makes it possible for arterial blood to take up as much oxygen as at sea-level.

In the short-run compensation for acute oxygen shortage, Major Dill listed four steps by which the balance is temporarily maintained: the reduced oxygen in the arterial blood stimulates increased breathing by the action of the carotid body, a small emergency mechanism lying beside the carotid artery (in the neck); this raises the oxygen content of the blood, but causes an increase in alkalinity; this excess is absorbed through the buffering capacity of body proteins, thus relieving the inhibition which alkalosis characteristically exerts on the respiratory centre in the brain, producing a balance between the activity of the respiratory centre and the carotid body.

The chain of events involved in acclimatization (as contrasted with short-run compensation) has been seen to involve a series of reactions:

(1) Lactic acid in the blood remains unchanged while at rest.

(2) After the first few hours of adjustment, the saturation of oxygen in the arteries attains a constant level.

(3) Lung ventilation is maintained at an increased rate.

(4) Arterial blood, after initial alkalinity, eventually assumes its usual reaction.

(5) Both free and combined carbon dioxide in the blood are reduced, but the ratio between them (which governs the respiratory centre) is eventually restored to its usual value.

Taking part in these reactions, Major Dill pointed out, are the lungs, the respiratory centre, the carotid body, the blood-forming tissues, and the kidneys. The over-all result is that man, without taking thought, is enabled to live and work in an atmosphere that contains only half as much oxygen as at sea-level.

Although in experiments in which atmospheric pressure was reduced to one-sixth its sea-level value, the exchange of gases in the lungs goes on as usual, it must be admitted that the possibility of a disturbed acid-base balance exists at any altitude above thirty thousand feet if the period of exposure is long enough. Decompression illness, or bends, may be experienced. If this affection becomes acute, one sees increased respiratory volume, and unless return to lower altitude is prompt there may be circulatory failure and collapse.

The symptoms here seen are like those of shock at ground-level. The stimulus to the respiratory centre presumably originates from a diminished blood supply to the brain and the accumulation of carbonic acid in the respiratory centre. With return to low altitudes, relief is usually prompt.

OBITUARIES

Dr. E. S. Beaven

THE passing on November 12 of Dr. Edwin Sloper Beaven at the age of eighty-four, after a brief illness, will be deeply regretted by a wide circle of friends in Great Britain, and by many in other countries to whom he was known either by personal contact or through his published works.

Dr. Beaven was born near Heytesbury in Wiltshire, and for the greater part of his life resided in the neighbouring town of Warminster, where he carried on the business of malting. Early in his career Beaven became associated with Messrs. Arthur Guinness, Son and Co., the celebrated brewers, an association which influenced the science of brewing, and more particularly all aspects of barley production in the British Isles, in a remarkable manner.

As a maltster the involved question of quality in malting barley attracted Beaven's inquiring mind, and one of his earliest investigations, carried out in collaboration with his friend Dr. J. M. H. Munro, dealt with conditions influencing this important attribute.

But Beaven came of yeoman stock, and it was not long before the convictions engendered by such an ancestral background led him to extend his investigations to the many questions affecting the production of barley. Thus, starting first in the garden of his residence, and later on a more extended scale on land acquired for the purpose, Beaven began a series of nursery and field experiments, now world-famous. These investigations, started on his own initiative, and continued for a period of more than half a century, entirely at his own expense, were a consuming interest throughout his long life. Largely because of the care in execution and then in the clarity of exposition of the results derived therefrom, the experiments at Warminster have for many years been a source of inspiration to visitors from all parts of the world.

One of the most valuable features of the material gathered together at Warminster with meticulous care and patience, was a world collection of species and varieties of barley. This material eventually formed the basis of an authoritative classification of the genus, published by Beaven in 1906, which remains a standard exposition of the subject.

Beaven's most active years coincided with the reappearance of Mendel's theory of heredity, and he applied the new conception enthusiastically in the production of improved varieties of barley. Early in the century he began a long series of hybridizations that culminated in the production of the now well-known and widely grown variety Plumage-Archer. This barley, which will always be honourably asso-

ciated with Beaven's name, exemplifies one of the few successful attempts to secure high grain productivity, allied with high malting value.

In the course of the development of Plumage-Archer, the necessity of a small-scale system of yield testing became insistent. To this Beaven applied himself with characteristic thoroughness, and eventually evolved the chequer board system, which with some modification is now widely employed by plant breeders, and later the drill-strip system for testing larger quantities of material on a field scale.

Beaven's interest in all aspects of barley production, both at home and abroad, was unbounded. No journey was too long, if at the end he could see something new or verify the basis of some conclusion he had arrived at. His audience was consequently always a large one, and because of his enthusiasm, always appreciative.

Despite the many calls of his business, Beaven took a keen interest in all activities directed to the improvement of agriculture, to which he himself had contributed so signally. He was present as a member at the first council meeting of the National Institute of Agricultural Botany in 1919. In 1929 he was elected chairman of the Council; he served again in the same capacity in 1939, and owing to the outbreak of war retained this position during 1940, and up to the date of his death. In 1932 he was chairman of the Farmers' Club.

Beaven's work in furthering the science of crop improvement was recognized by the University of Cambridge, from which he received the honorary degree of LL.D. in 1922. He was awarded the Horace Brown Gold Medal by the Institute of Brewing in November 1930.

Beaven's personality will remain a vivid memory to his friends and acquaintances. Apart from a boundless enthusiasm for his particular subject, his outstanding characteristics were a directness of approach to a problem, an independent outlook, and a fearlessness and tenacity in maintaining his point of view. He possessed a keen sense of humour, and although always severely critical, his generosity of feeling, particularly to youth, was unfailing.

Beaven owed much to the influence of a happy family life, and sincere sympathy is extended to his widow and to three daughters who survive him.

HERBERT HUNTER.

We regret to announce the following deaths:

Prof. Phillipo Bottazzi, formerly professor of physiology in the Universities of Genoa and Naples, aged seventy-four.

Prof. Carrie M. Derick, emeritus professor of morphological botany and genetics in McGill University, on November 10, aged seventy-nine.

Prof. H. S. Hower, head of the Department of Physics in the Carnegie Institute of Technology, on October 10, aged sixty-four.

Dr. J. A. Nelson, formerly research entomologist in the U.S. Department of Agriculture, on August 9, aged sixty-five.

Prof. W. A. Noyes, emeritus professor of chemistry in the University of Illinois, on October 24, aged eighty-three.

Dr. J. S. Owens, well known for his work on atmospheric pollution, on December 6.

Prof. Peter Sandiford, professor of educational psychology in the University of Toronto.

Prof. Hans Spemann, professor of zoology in the University of Freiburg-im-Breisgau, aged seventy-two.

NEWS AND VIEWS

Administration in International Affairs

THE Sydney Ball Lecture on "Administrative Problems of International Organization", delivered by Mr. F. P. Walters, which has now been published as Barnett House Paper No. 24 (Oxford University Press. 1*s*. net), is highly relevant to the tentative discussions on post-war international reconstruction which are now proceeding. On the grounds both of efficiency and economy, the advantages of a central organization at the service of all the special staffs required are obvious, and Mr. Waters postulates further that some such centre as Geneva and an annual meeting similar to the assembly of the League of Nations, as well as the secretariat, will be required before dealing with the special problems of administration concerned with the organization of an international centre and its relations with participating Governments. He stresses first the value of a separate department for League affairs, the need for which would have been more apparent in Great Britain but for the general efficiency of the Civil Service and the exceptional ability and energy of officials in the Foreign Office—a tribute from a League official which should be noted. He suggests further that the League budget should include an appropriation for ten or fifteen officials to be seconded each year from the Foreign Offices of different countries to spend six months or more in the secretariat, and he lays a great deal of emphasis on the advantage of cost of membership of committees, travelling expenses of delegations, general expenses of council meetings, the Assembly, and of conferences or special commissions being borne by the League budget as a whole and not by individual States. Similarly, he urges that assistance and advice given through the League or the International Labour Organisation should generally be regarded as a proper charge on the common budget.

The main point throughout Mr. Walters's review of the administrative side of international organization is that such work should be adequately financed. To starve it as has been done in the past may have

been a vital factor making the difference between failure and success. Mr. Walters suggests that an expenditure of from two to two and a half times the average expenditure of the last twenty years might have meant an increase in prestige and activity which would have meant success and not disaster. He considers that the sectional organization of the League secretariat has proved its value, as well as the planning of that secretariat on international rather than on national lines. Its morale has come creditably through a heavy test, and it has proved surprisingly easy to get people to undertake work for the League. The official attitude adopted by members of the secretariat has been fully justified. Apart from Mr. H. R. G. Greaves's study of the League committees, the administrative side of the League's work has received comparatively little attention, and the concentrated wisdom of this lecture should be sure of attention from all those who are giving close study to problems of international organization.

Mass Psychology and the 'New Order'

IN a paper in the *Journal of Social Psychology* (11, 59–77; 1940), Prof. Vyscheslevzeff, of the University of Geneva, maintains that modern sociology cannot function, nor contemporary upheavals be understood and 'new orders' firmly established without the application of collective psychology, notably that of Jung, and especially his "collective" ("common to all men") Unconscious. Dürkheim's view that the good lies in collective forms and division of labour is refuted by quoting Jung on the deformation of personality by specialization, which is held to be not really civilization but barbarism. The antinomy in classical German sociology of *Gemeinschaft* (community) and *Gesellschaft* (society) is particularly stressed. The former has the inner solidarity of, for example, the family or clan, and is characterized by a "collective unconscious", that is, the inherited propensities and archetypes of Jung; the latter is more like a constructed machine, that is, is artificial, and characterized by "collective conscious" (rationality). But they conflict (cf. Engels in the more limited economic sense), like the unconscious and conscious (including the 'personal' unconscious) in the mind of the individual. The problem is to harmonize this sociological conflict by a kind of fusion.

Prof. Vyscheslevzeff indicates that the conflict does not appear on the surface in Soviet communism because the *Gemeinschaft* has been eliminated or rather repressed (by the State), communism being solely rational, unreligious, non-traditional and non-mythical. But the paper under review was written before the outbreak of war and it might be suggested that the invasion of Russia has resulted in a re-emergence of *Gemeinschaft* and may possibly modify Soviet communism, spiritually at least, in the future. In Germany it seems to be implied that the two sociological group-categories exist side by side, in spite of leadership, for example, "racial superiority", "back to Wotan", etc., and "German organization". In looking for a nation which has succeeded in harmonizing the conflict, Prof. Vyscheslevzeff instances England, the Anglo-Saxon culture. "Only thus is it possible to understand the unusual adherence to tradition, to patriarch forms, to ancient symbols, to religion, to habit, together with a belief in progress, the striving for maximum rationalisation and ordering of all realms of life, everywhere bringing in the element of conscious purposefulness. . . . England presents an astonishing synthesis of 'community' and 'society': the collective unconscious with the collectively-apprehended and organised freedom." This view would seem to merit the attention of those who may desire to see a radically new order in Great Britain after the War.

Health of New Zealand

ACCORDING to Dr. M. H. Watt, director-general of health for New Zealand, the year 1940–41 was on the whole the most favourable for health that the Dominion has had. Infantile mortality of the European population fell to 30·21, of which 22·03 is accounted for by 722 deaths in the first month of life. Of these, 606 occurred in the first week and another 72 in the second week. In 330 deaths among the new-borns prematurity was the only cause of fatality. The death-rate from tuberculosis among the Europeans was only 0·388, which is a low record for New Zealand and probably for any country, but this disease came next to cardio-vascular disorders, cancer and violence among the causes of European mortality. Among the Maoris the mortality from tuberculosis was 4·132 out of a total mortality of 17·51. Although syphilis has always shown a low incidence among both Europeans and Maoris, it is increasing in both, especially among the latter. Hydatid disease is more prevalent in New Zealand than in any other country, 120 new cases with 16 deaths being expected every year. The low incidence of endemic disease during 1940 was shown by the fact that there was only one death from measles, and 11 deaths from Flexner dysentery among 161 cases. There was a fall in maternal mortality from 3·64 in 1939 to 2·93 in 1940 due mainly to decline in fatality of puerperal sepsis and septic abortion. The total European births shrank from 27,881 in 1927 to 23,935 in 1935, when the birth-rate reached the low level of 16·17. Among the Maoris, on the other hand, the number of births increased from 1,495 in 1927 to 4,265 in 1940, and the rate from 23·22 to 46·87, while the infantile mortality in 1940 was 87·22 and the general death-rate 17·51.

Smallpox in the United States

ACCORDING to the June issue of the *Statistical Bulletin*, the organ of the Metropolitan Life Insurance Company, of New York, there were fewer cases of smallpox in the United States in 1940 than in any previous year on record. The 2,839 cases reported represented a drop of more than 70 per cent from the previous year, and were little more than half the total reported in 1934, the previous record low year for smallpox. In an area containing one quarter of the population, namely, the New England States and

the Middle Atlantic States plus Delaware, Maryland and the District of Columbia of the South Atlantic Division, not a single case of smallpox occurred in 1940. In that year, as in every year, the majority of cases were reported in the north central area and in some of the western States. In most of these States large numbers of people disregard the danger of contracting smallpox, and minimize or ignore the efficacy of vaccination. On the other hand, in the neighbouring country of Canada, smallpox has been practically eliminated, as is shown by the fact that in 1940 there were only eleven cases and no deaths, while in eighty-seven cities there was not a single case.

Psychiatry in Sweden

IN a recent address (*Nordisk Med.*, 10, 1921; 1941) at the opening of the new Psychiatric Clinic at the Caroline Hospital, Stockholm, Dr. Viktor Wigert gave a retrospect of clinical psychiatry in Sweden during the last hundred years. In 1844 it was stated by the authorities in charge of the hospitals in Sweden that no expert knowledge was required for the treatment of insanity, which was therefore no concern of public health. This pronouncement had been occasioned by a demand made by a Royal Commission headed by Dr. Carl Ulrik Sondén that all institutions to be built for the care of the insane should provide for the treatment as well as for the confinement of the patients. Sondén, who was a pioneer in Swedish psychiatry, was the first to emphasize the importance of instruction in this branch of medicine, which was introduced in Sweden by Dr. Nils Gustaf Kjellberg, at the Uppsala Asylum in 1859. Kjellberg was an eminent man of science, who as early as 1863 expressed his conviction of a causal connexion between syphilis and general paralysis. In 1861 psychiatry was made a compulsory subject for the medical student in Sweden. In the 'nineties demands were made, particularly by Prof. Frey Svenson of Uppsala and Dr. Bror Gadelius of Stockholm, that special clinics for instruction in psychiatry should be created and that professors of psychiatry should be relieved of their duties as senior physicians to large asylums. Opposition to this demand, however, was not overcome until 1928, when it was decided to open a psychiatric clinic at the Lund University Hospital. The establishment of a similar clinic at the Uppsala University Hospital has since been decided upon, but this has not yet been completed. The psychiatric clinic recently established at the Caroline Institute of Stockholm finally realizes Sondén's desire for an institution for the cure of mental diseases.

War and Birds

ONE of the most noticeable effects of the war-time conditions upon British bird-life has been the rapid increase of magpies, judging from reports in many parts of the country. Much larger flocks than usual have been seen in many counties, like Cheshire, but there is no evidence of any harmful effect. The cessation of game preservation and 'vermin' shooting is the chief cause, and the jay, carrion-crow and sparrow-hawk have shown increases from a similar cause. The felling of woods on a large scale is, however, affecting the distribution of the long-eared owl, woodcock, heron, rook, hawfinch as well as some of the woodland mammals and rarer birds of prey. Efforts to locate hobbies breeding in Wiltshire in 1941 failed.

The Night Sky in January

THE moon is full on January 2d. 15h. 42m. U.T. and new on January 16d. 21h. 32m. Lunar conjunctions with the planets occur on the following dates: Mercury on January 18d. 5h., Mercury 4° S.; Venus on January 18d. 13h., Venus 2° N.; Mars on January 24d. 8h., Mars 5° N.; Saturn on January 25d. 17h., Saturn 3° N.; Jupiter on January 27d. 10h., Jupiter 5° N. On January 21d. 1h. Mercury is in conjunction with Venus, Mercury being 6·2° S. Mars, Jupiter and Saturn are well placed for observation during the night, and Saturn's ring system is well presented for observation. Venus can be seen in the evening hours in the west and does not set until 19h. in the middle of the month. The earth makes its closest approach to the sun on January 2. The Quadrantid meteor shower is active on the first few days of January: the radiant is at R.A. 5h. 24m., Dec. 51° N., but this shower is not usually very conspicuous. On January 26d. 22h. 17m. there will be an occultation of γ Tauri, mag. 3·9. During the month the interval from sunset to sunrise in the latitude of London shortens by 1h. 12m.

Announcements

THE following officers of the Iron and Steel Institute have recently been elected: *President*, Mr. James Henderson; *Vice-president*, Dr. Andrew McCance; *Hon. Treasurer*, The Hon. R. G. Lyttelton; *Members of Council*, Prof. J. H. Andrew and Mr. N. H. Rollason. Mr. Walter S. Tower, president of the American Iron and Steel Institute, has been nominated an honorary member of the Institute, and the presidents of the Sheffield Society of Engineers and Metallurgists and of the Sheffield Metallurgical Association have been appointed honorary members of the Council.

CATALOGUE 27, entitled "Science", has recently been published by Ifan Kyrle Fletcher, late of 26 Old Bond Street, London, W.1, and now of Merridale, Caerleon, Mon. It contains lists of old books on astrology, chemistry, mathematics, medicine and physics, as well as important works on civil and marine engineering from the library of Sir William Cubitt (1785–1861). Among the books of special interest and rarity are William Beaumont's "Experiments and Observations on the Gastric Juice and the Physiology of Digestion" (1833), Thomas Vicary's "The Englishman's Treasure with the True Anatomie of Man's Bodie" (1599), the "Histoire de l'Académie Royale des Sciences avec les Mémoires de Mathématique et de Physique", vols. 1700–1730, lacking the volume for 1728, but containing the rare supplementary volume for 1718, and Robert Boyle's "Paradoxa Hydrostatica" (1670).

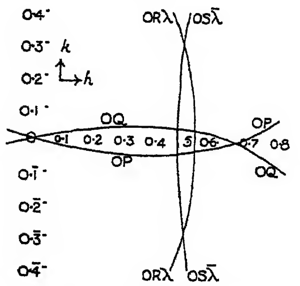
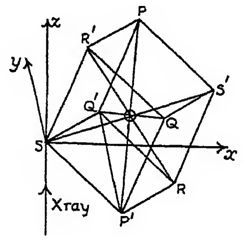
Diffuse Spots in X-Ray Photographs

IN a recent letter[1] Mrs. Lonsdale reports that the shapes of certain "diffuse spots" in the pattern due to mono-chromatic X-rays which have been scattered by sodium are in agreement with calculations made by Jahn, and points out that this is the more noteworthy because the calculations had to take into account the peculiar anisotropy of the elastic constants of sodium.

I have previously observed that simple diffraction formulæ provide an accurate position of the positions of the spots, and also of many of the peculiar forms which they assume[2]. These formulæ are independent of the elastic constants.

For example, one of the photographs attached to Mrs. Lonsdale's letter shows a four-square spot. The sodium cell is body centred. The four conditions that the centre of the cell shall be in phase (by means of integral differences of wave-length) with the corners can be stated in the form of equations, which describe the relations between the direction cosines of the diffracted ray. Four of these curves are found to intersect in four points close together (see the accompanying figure), and the positions of these points agree within experimental error with those of the corners of the four-square spot in the photograph. It follows that at each of these four points, the centre of the cell is in phase with two of the corners and very nearly in phase with the other two. The combination is strong, and the peculiar diffused spot may be supposed to be its consequence.





The figure on the right represents the body-centred cubic sodium cell. The points $SRS'R'$ are in the plane of the paper: PQ and $P'Q'$ are perpendicular to it, and so is the y axis to which they are parallel. The X-rays are parallel to the axis of z. The angle between SR' and the axis of z is $20·5°$. The figure on the left shows the (hk) curves. For example, OP is the locus of those values of (hk) which the diffracted ray must have if the path by way of O is of the same length as that by way of P: along $OR\lambda$, the path by O differs by one wave-length from that by way of R.

The simple diffraction formulæ have so far predicted accurately all the positions of the diffuse spots, except that in a few cases spots are absent that might have been present according to calculation. If I apply the theory which ascribes the spots to the interaction of the structural periodicities of the crystal and the periodicities of elastic waves, I am not equally successful. It may be that I misunderstand the theory, which I would describe in the following way:

To take a simple case, let a wave be travelling along one of the principal axes of a simple cubic cell (such as that of potassium chloride). The velocity of the X-rays is so great in comparison with that of the elastic wave that the latter may be taken to be at rest while it is under consideration. The full period along the axis is now the least common integral multiple of the two wave-lengths. A super-lattice comes into existence. Waves of various lengths running in all directions provide an infinite number of these super-lattices, all of them integral multiples of the cell lattices.

When monochromatic rays fall on a perfect crystal there are no reflections. Laue photographs are blank. But when these conditions are only realized approximately (the possibility of the number of scattering centres being small is excluded from the theory under consideration) there may be accidental reflections. The multiplicity of super-lattices provides increased opportunities, and the diffuse spots are supposed to be the consequence.

One method of calculating results in a simple if approximate way is to assume only the one crystal cell, and to allow planes to have at least one fractional index. In every zone one such plane can be found to be a reflecting plane in the circumstances of the experiment. If the axes of the zones lie in the cubic face of the crystal on which the incident rays are striking almost normally as in the case described in NATURE[3], the calculated result is a network which agrees closely with observation for points near the origin but is seriously wrong farther out. If other zone axes are chosen, and there seems to be no reason for limiting them in the above way, indications are given which do not agree with observation.

It would be a strong support to the elastic wave theory if the calculations could correct this interpretation and show an agreement with the case quoted in the communication in NATURE to which I have referred.

Influence of Temperature on Gel Formation

IT has been pointed out[1] that in the sol-gel change, gel formation should be more rapid the higher the temperature, in the absence of changes of solubility with temperature.

In the case of pectin-sugar gels, the method of preparation is generally such that the temperature of the mix is dropping while setting takes place, so that the dependence of setting rate on temperature is complicated. It is well-known, however, that jellies can be prepared by mixing a pectin-sugar solution not sufficiently acid for gel formation, with an acid solution; the mixture can then be maintained at a constant temperature during the setting period. Sucharipa[2] states that with mixtures of this type, setting is more rapid as the temperature is lowered: on the other hand, in a recipe booklet[3] for the use of these mixtures, it is stated that setting may be slower in cold weather.

It has been found in a series of experiments on jellies prepared from apple pectin, and containing 50 per cent sugar, that, over at least a limited temperature range, setting is much more rapid at the higher temperatures. The same effect was found, though to a less marked extent, with jellies containing 60 per cent sugar.

Two samples of apple pectin were used: *Pectin A*. Alcohol precipitated from commercial apple pectin. 80 per cent of total carboxyl groups esterified. Equivalent wt. = 1,110. *Pectin B*. Prepared by treating commercial apple pectin with sodium hydroxide in the cold, then acidifying and precipitating with alcohol. 67 per cent of total carboxyl groups esterified. Equivalent wt. = 630.

Jellies were acidified with citric acid or citric acid-potassium citrate mixtures: in all cases citrate was 0·8 per cent (as citric acid) in final mixture. *p*H measurements made on 50 per cent solution of jelly. The following are some typical results:

No.	Pectin (% as calcium pectate)	Per cent solids (refractometer)	*p*H	Time for first signs of setting			
				6° C.	13° C.	30° C.	50° C.
1	A, 0·35	52	2·80	15 days	Between 9 and 24 hours	100 min.	60 min.
2	,,	52	3·05	Not set 22 days	Not set 22 days	33 hr.	48 hr.
3	,,	62	3·38	3 days	55 min.	30 min.	20 min.
4	,,	62	3·70	Not set 12 days	5 days	3 days	4 days
5	B, 0·36	52	2·44	6 hr.	50 min.	70 min.	4 days
6	,,	52	2·80	Not set 10 days	Between 6 and 20 hr. (at 20°C.)	Between 6 and 20 hr.	Not set 10 days
7	,,	62	3·20	Several hours	7 min.	2 min.	7 min.

In all cases, mixtures which had failed to set at one temperature, set when the temperature was altered to that found to give most rapid setting. In all cases except series (6), the sugar-pectin solution was kept for several hours before mixing at the final temperature: the series (6) jellies were prepared by boiling, and then transferring portions of the mixture to tubes for storage at the temperatures given.

Of particular interest is the marked difference in the effect of temperature on mixtures made with the two pectin samples. This is in agreement with the more recent work on the effect of methoxyl content of pectin on jelly setting[4] and particularly with American work[5] on the relation between combining weight of the pectin and setting time (in a mixture which is cooling).

It is hoped to continue these experiments over a wider range of conditions: at present, it appears that the time for setting to commence is a minimum at a tmeperature dependent on the composition of the mixture, involving at least the composition of the pectin, the total solids present, and the *p*H.

I have to thank Messrs. H. P. Bulmer and Co., Ltd., for permission to publish this note.

Nomenclature of Fowl Genetics

The nomenclature of fowl genetics has become somewhat confused in recent years. So many characters have been investigated that the difficulty of designating symbols for the corresponding genes has increased considerably. There have been much overlapping and repetition, and the same symbol now frequently represents two, or even three genes. To experimental poultry breeders, and to students attempting to keep in touch with the latest developments, this position gives rise to much confusion.

The accompanying table gives a few symbols chosen at random, which have been used to represent more than one gene, and will serve to illustrate the difficulties:

Gene	Character	Quoted by[1]
F	Feathering	Munroe (1938)
F	Frizzled plumage	Jull (1940)
H	Hatchability	Hays (1924)
H	Henny feathering	Punnett (1937)
A	Broodiness (1)	Goodale *et al.* (1920)
A	Egg size (1)	Hays (1929)
A	Pigment	Numerous
C	Chromogen	Quin (1936)
C	Broodiness (2)	Goodale *et al.* (1920)
C	Egg Size (2)	Hays (1929)
P	Mesodermal Pigment	Bateson and Punnett (1911)
P	Pea comb	Numerous
P	Production persistency	Hays (1927).

I am drawing up a complete summary of known nomenclature; but it is evident from the accompany ing list that the system is in need of standardization. The use of symbols such as P^1, P^2, P^3, etc., is to be recommended, as it avoids the confusion which arises from the practice of some authors of using small letters appended to the symbol. Thus, the gene for light iris is given as *Br*, which is ambiguous, for it could equally well be interpreted as a combination of a dominant gene *B*, and a recessive *r*. This introduces unnecessary difficulties, especially if a long genotype is being dealt with; for example, *AABbFFBBCcLlRRPPccGGHHMmNNEeEEBrbrPp SSWwDD* would allow of numerous interpretations, instead of being at once a self-evident description of the bird's genotype.

The present system leaves much to be desired, and any hope of reaching an understanding of fowl genetics will only be possible when some definite standard of nomenclature is introduced.

Isolation of a New Alkaloid from Perennial Ryegrass

INDEPENDENT investigations in our respective laboratories have resulted in the isolation from perennial ryegrass (*Lolium perenne* L.) of a new constituent with unusual optical properties. Further study has shown that the material is an alkaloid of empirical formula (hydrochloride) $C_{36}H_{22}O_3N_4(OCH_3)_4.2HCl$. It yields precipitates with all the usual alkaloidal reagents and is soluble in alcohol and chloroform, slightly soluble in acetone, ether and water. Dilute solutions of the base in chloroform are golden yellow, with a green fluorescence which can be detected in ordinary daylight at concentrations of 1 in 5×10^6. The alkaloid is reduced by titanous chloride to a colourless material which can be quantitatively reoxidized by ferricyanide. The name perloline is proposed for this fluorescent alkaloid.

Some 40 gm. of perloline have been prepared in our two laboratories in the course of the past growing season, using the usual methods for chloroform- and alcohol-soluble alkaloids. The key to large-scale preparation lies in growing grass with sufficiently high alkaloid content, and this problem has not been completely solved.

The observed variation in concentration is high, ranging from a trace (about 3 μgm. per gram dry matter) to 1 mgm. per gram. The conditions governing high alkaloid content are obscure, but in general the highest concentrations have been noted at times corresponding with rapid growth.

A simple and rapid method of assay has been devised, depending on the colour of solutions of the base in chloroform. It requires only 2 gm. dry material.

In addition to perloline, several other alkaloids have been found in ryegrass, but data concerning them is at present indefinite.

A full account of the investigations on the preparation, characterization and pharmacology of perloline will appear in the *N.Z. Journal of Science and Technology*.

Determination of Death in the Larvæ of the Potato Root Eelworm

ONE of the major difficulties in the work of helminthologists has been to differentiate between living and dead nematodes. According to Lapage[1], most of those who have studied the metabolism of these worms have taken their failure to move either as a result of or without the action of a stimulus as an indication that they are not alive.

This difficulty has again arisen in the course of work by me on the biology and control of *Heterodera schachtii*, the eelworm which attacks potato roots and causes a serious diminution in crop in many districts.

First-stage larvæ are liberated by the action of potato root excretion on the cysts of the eelworm which are found in the soil of an infested field. These larvæ then penetrate the potato rootlets with the ultimate formation of new cysts which remain in the soil and thus increase the infestation. In the laboratory the larvæ can easily be obtained in quantity by immersing cysts in potato root excretion.

Normally under suitable conditions most of these larvæ are in active motion, but it frequently happens that they lie quite still for a relatively long period and then, for some undiscovered reason, recommence active movement. They may also show no sign of movement when observed in watch-glasses, but yet be able to penetrate potato rootlets. Thus it is exceedingly difficult to distinguish whether larvæ are in a state of dormancy or whether they are dead. According to Baunacke[2] who made a study of the beet strain of this eelworm, that part of the larval body near the oral end, which is almost completely hyaline in the living larva, becomes granular after death occurs. This tends to impart a uniform opacity to the dead larva. After treatment with certain solutions or after exposure to certain degrees of heat, larvæ of the potato strain of *H. schachtii* have been observed to be in a condition similar to that ascribed by Baunacke to a dead larva. Other larvæ have been seen to show a peculiar distension of the body wall near the higher end of the intestine, while this organ itself had become displaced.

Though it is known that living nematodes may in certain cases have the appearance of being dead, it has been ascertained that larvæ of the potato strain of *H. schachtii* in the above-described conditions could not be induced to form cysts on the roots of potato plants. Such larvæ were considered to be dead.

It was also determined that dead larvæ of both these types could be more clearly distinguished from living larvæ by staining with a solution of 0·025 gm. iodine in 100 c.c. 1 per cent potassium iodide solution. The most satisfactory procedure was to use five drops of this solution in 2 c.c. of a larval suspension. The suspensions employed contained some larvæ in active motion and some considered to be dead. The latter absorbed the iodine and were stained within a few minutes, being best observed after 10–20 minutes. Those larvæ which were moving and thus known to be alive originally became motionless after a few minutes but yet retained the appearance of living larvæ for several hours and did not absorb the stain. They were killed, however, when left in the solution overnight.

The iodine penetrates the dead larvæ through the mouth, and by careful observation a yellowish coloration may be seen starting at this end and gradually permeating the whole body.

Larvæ which exhibit a slight granularity in the upper region of the body, that is, larvæ which according to Baunacke's criterion are newly dead, do not take up the iodine immediately. They do stain, however, after being allowed to stand for 24–48 hours before applying the solution. Work along this line is being conducted in connexion with the thermal death point of the larvæ.

First-stage larvæ which had been kept in potato root excretion solutions for several weeks, and which by using up all their reserve food material had become practically colourless and clear except for a small granular portion near the mouth, absorbed iodine only slightly in this region while the rest of the body remained almost unstained. This is apparently due to the absence of intestinal contents in larvæ which had been in a free state for several weeks.

Hence larvæ of the potato strain of *H. schachtii* which appear granular in that part of the body which in the living larvæ is hyaline also show an internal absorption of iodine and may be considered as dead. The two main disadvantages of the staining process are that the iodine itself eventually has a toxic effect and that the staining does not take place immediately after death.

This work has been conducted during the tenure of a Carnegie Research Scholarship.

Sheets of Pure Epidermal Epithelium from Human Skin

THE margin between dermis and epidermis is one natural-splitting layer of human skin. By the gentle tryptic digestion of flat human skin slices for a length of time depending on their thickness, it is possible to disengage the epidermis in the form of an intact sheet uncontaminated by mesodermal elements. There is histological[1] and clinical[2] evidence that the *elastic fibres* of the so-called 'basement membrane' play an important part in anchoring the epidermis to the underlying tissue. Elastic fibres are known to be rapidly and specifically dissolved by trypsin.

The skin-slice should be the thinnest possible razor cut, the Ollier-Thiersch graft of plastic surgery. In theory, the Thiersch graft cuts through the base of the projections of the Malpighian layer into the dermis and therefore contains only so much of the dermis as lies between them. Studying expertly cut grafts I have found that even when the slice is so thin as to be transparent, it is lined on the inside by a sheet of dermis which is interrupted only by the holes into which the hair-follicles fit. Paper-thin shavings of rabbit, rat or dog skin may be used in place of human skin; but the excessive number of hair follicles makes the splitting reaction less clear cut.

The digestion fluid I use is a Seitz-filtered 0·5 per cent solution of B.D.H. trypsin powder in Tyrode's solution containing 1 : 100,000 phenol red and adjusted by means of it to pH 7·8–8·0. Digestion takes place at 37° C. Under these conditions, 1 ml. of the digestion fluid clots 5 ml. of calcified milk in 90–110 seconds. For *thin* slices, an hour's digestion is quite sufficient. The epidermis disengages of its own accord in the middle of the slice and can be lifted off or cut away with fine forceps and scissors.

Tissue-culture studies on the reagent described above show that at least some cells in isolated fragments of the chick-embryo's heart survive tryptic digestion even after a treatment lasting eighteen hours. There is this and other evidence that the epidermal sheet remains 'alive'. On the other hand, emulsions of isolated skin cells and epithelial islands, prepared by prolonging digestion until the Malpighian layer undergoes erosion and maceration, or, better, by simply scraping the epidermal sheet under Tyrode's solution, are probably irretrievably damaged, although they make excellent histological smear preparations. This is because the cells of the 'prickle-cell' layer are united to one another by fine cytoplasmic processes, and destroying one cell—for example, by pricking—initiates a reaction of nuclear coagulation which is propagated at least to immediately neighbouring cells[3].

This work has been reported at a technical stage in the hope that epithelial sheets will be useful to workers studying specific cellular metabolism, diffusion and so forth. Thiersch grafts cannot be cut exactly to the size of the recipient area, so that left-over pieces of skin are usually available in the theatre. They may be stored for a day or two at 4° C. after laying them raw side downwards on squares of gauze moistened with Ringer's solution.

The Relations between Science and Ethics

To the interesting discussion aroused by Dr. C. H. Waddington in NATURE[1] may be added comments reflecting United States opinion on the matter.

It was remarkable that three leading American biologists, representing the east, mid-continent, and west, should have come to about the same conclusion at the same time regarding a biological basis for ethics. Different approaches led to the same general position on the part of Prof. E. G. Conklin, emeritus professor of biology at Princeton University, Prof. C. Judson Herrick, emeritus professor of neurology at the University of Chicago, and Prof. Samuel J. Holmes, professor of zoology at the University of California. Conklin[2] says, "Biologically life is maintained by continual balance, co-operation, compromise, and the same principles apply to the life of society. The highest level of human development is attained when purpose and freedom, joined to social emotions, training and habits, shape behaviour not only for personal but also for social satisfactions. Conduct bringing the broader and more lasting satisfactions is the better." According to Herrick[3], "That social stability upon which the survival and comfort of the individual depend and that moral satisfaction upon which his equanimity, pose and stability of character depend arise from the maintenance of relations with his fellow men which are mutually advantageous." Holmes[4] says, "Morality becomes just one phase of the adjustment of the organism to its conditions of existence. As a good body is one which runs smoothly and efficiently in the maintenance of its vital functions, so a good man is one whose conduct not only maintains his own life on an efficient plane, but conduces to the enhancement of the life of his social group." Both Conklin and Herrick would agree with Holmes in saying, "Peoples may believe that their moral customs derive from a supernatural source, but one potent reason for their adoption is their conduciveness to survival."

These statements suggest that American biologists have come to the same position as Dr. Waddington in regard to the nature of science's contribution to ethics, that is, in revealing the character and direction of evolution with the elucidation of the consequences "in relation to that direction, of various courses of human action". Our British colleagues may recall

Conklin's volume, "The Direction of Human Evolution", which was published in 1921, and which offers much detailed evidence in support of Dr. Waddington's position.

At the 1940 Christmas meeting of the American Association for the Advancement of Science in Philadelphia, the Section on Historical and Philological Sciences held a symposium on "Science and Ethics". Participating in this symposium, over which I had the honour of presiding, were Profs. Herrick, Conklin, Holmes, Teggart, Mackay, Galdston, de Santillana, Sigerist, Sarton, Shryock, Gerard, Birkhoff, and Mayer. At the conclusion of the discussion, the section unanimously agreed to a descriptive statement which seems justifiably inducible from data now available. While taking into account criticisms of the intellectual validity of traditional ethical statements as raised by psychology, anthropology, dialectic materialism, or logical positivism, the statement of these American men of science indicates that they are willing to agree, at our present "level of analysis" as Dr. C. H. Darlington[5] might put it, that certain biological generalities have moral consequences. The recognition by conscious individuals of these consequences, results in "ethical principles as actual psychological compulsions derived from the experience of the nature of society."

The statement may be put in a formal manner: The probability of survival of a relationship between individual humans, or between groups of humans, increases with the extent to which the relationship is mutually satisfying and advantageous. This principle was first formulated in this manner at a memorable seminar in the Santa Cruz redwoods in July, 1939, when the Pharmacology Laboratory of the University of California entertained Profs. Conklin, Herrick, and Olof Larsell.[6] It was then appreciated that this formulation is merely a special case of the more general biological principle: The probability of survival of individual, groups, or species of living things increases with the degree with which they can and do adjust themselves harmoniously to each other and to their environment.

The ethical significance of this general principle appears in relation to the common biological urges for survival and satisfaction. Consciousness of the operation of this generality suggests the wisdom of such altruistic, considerate, and magnanimous conduct as is intuitively considered 'good' in all ethical systems. The social customs and conventions now with us have so far exhibited survival value in a Darwinian sense. We may apply evolutionary criteria to them and attempt the formulation of a *modus operandi*. Such a formulation constitutes the statement. The principle operates, whether we as humans are conscious of it or not. To promote the conscious appreciation of such natural principles is part of the business of science. There appears to be scientific justification for what philosophers have maintained for centuries, namely, that knowledge of ourselves and of our environment has in itself ethical significance and moral consequence.

Mathematical Theory of Population Movement

AMONG the obvious motives of mankind are the tendencies to seek company and to seek living-space. If we were to regard these tendencies as being in simple opposition to one another, we should expect the population to be able to remain uniformly spread over any uniform piece of land; and the familiar contrast between town and country would then appear, to the theoretical mind, as a mystery requiring explanation. We may, however, seek a hint as to why people concentrate into towns from Sir James Jeans's theory of why matter concentrates into stars[1]. For his theory is also concerned with two opposing tendencies: to draw together by mutual gravitation and to spread out by pressure.

Let ρ denote the density of the astronomical matter, supposed initially uniform, let $s = \delta\rho/\rho$ be its concentration at any time t and place, let p be its pressure and γ the constant of gravitation. Then Jeans showed that deviations from uniformity occur in accordance with the equation

$$\frac{d^2 s}{dt^2} = 4\pi\gamma\rho s + \nabla^2\left(s\frac{dp}{d\rho}\right). \qquad (1)$$

The essence of Jeans's theory is that the opposition between gravitation and pressure is not simple: the former is represented by a term in s, the latter by a term in $\nabla^2 s$. These considerations led me to inquire whether the existence of towns could be explained by

$$\frac{ds}{dt} = \gamma\rho s + \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right)\left(s\frac{dp}{d\rho}\right). \qquad (2)$$

in which ρ, supposed initially uniform, is the number of persons per square kilometre, $s = \delta\rho/\rho$ as before, x and y are horizontal co-ordinates on a flat portion of the earth, γ is a constant expressing gregarious attraction, and p is called pressure of population. The social equation (2) has been made of viscous type by replacement of the astronomical d^2s/dt^2 by ds/dt.

Whereas Jeans began the astronomical theory with γ known and p clearly understood, and thence deduced the spacing of the stars, we have to begin the social theory at the other end, and work backwards to find out more clearly what γ and p mean. Equation (2), in which $dp/d\rho$ is an unknown constant, explains why the population does not remain uniformly spread. For the amplitude of a standing wave of s either grows or diminishes, according as the wave-length is greater or less than a critical length. It can be deduced that $dp/\gamma d\rho$ is of the order of magnitude of the ratio of the number of persons in a country to the number of towns in it. Further, $dp/d\rho$ is seen to play the part of a diffusivity in equation (2). From the observed time of dispersal of concentrations having diameters much less than the distance between towns, it can be estimated that $dp/d\rho$ is of the order of 10^5 cm.^{2} sec^{-1}. Whence it follows that γ is of the order of 10 or 10^2 cm.^{2} sec.$^{-1}$ person^{-1} for normal people.

A fuller account is ready for publication as part of a book.

RESEARCH ITEMS

Production of Cancer by Ultra-violet Irradiation

THIS topic was discussed by H. P. Rusch and B. E. Kline at the Autumn Meeting of the U.S. National Academy of Sciences held during October 13–15. The idea that sunlight is an important causal agent in cancer of the skin is not new. The high incidence of skin cancer in sailors has long been known, and nearly fifty years ago 'seaman's skin' was described as a precancerous condition attributable to continued exposure to light. However, only in the last decade has experimental support been formed for the theory of direct causation of cancer by sunlight. The authors have determined the wave-lengths of the spectrum responsible for cancer production and measured the amount of energy required for the process. White mice were used in these studies. The wave-lengths responsible were found to lie between 2,900 A. and 3,341 A. The minimum time for the development of tumours was about two and a half months, and it was not necessary to irradiate the animals throughout the precancerous period. Once initiated, carcinogenesis proceeded without further exposure, and sometimes several months elapsed between the end of irradiation and the appearance of tumours. Very little radiant energy was needed to initiate those changes which culminate in tumour formation. The tumours produced were true malignant cancers of the same type found in humans.

Controlling the Micropopulation of the Soil

IN a paper read at the Autumn Meeting of the U.S. National Academy of Sciences held during October 13–15, C. Thom of the U.S. Bureau of Plant Industry reviewed experimental work towards control or direction of the microbial activities of the soil to produce desired ends. The destruction of waste plant and animal matter by soil micro-organisms is the function of the soil micropopulation most commonly understood. Variations from comparatively small totals to fabulous numbers of soil organisms were recorded. There arises the possibility of controlling this capacity of the normal groups represented in the population to multiply with great rapidity, in such a manner as to produce great decomposing power at selected times and for our purposes. For example, such activity may either rob a root parasite of available nutrients or actually destroy the parasite. Application of the principles developed in the control of take-all of wheat and cotton root rot were discussed.

Gardeners and the Moon

MANY practical gardeners insist that some plants grow best from seeds sown at a particular phase of the moon. K. Mather and J. Newell have obtained some experimental evidence on this question (*J. Roy. Hort. Soc.*, **66**, Pt. 10, Oct., 1941). There is apparently no consistent lunar effect upon germination; but it is unfortunate that the authors do not appear to trust their results in one experiment where a marked effect of the April full moon was demonstrated. The work requires to be repeated many times, with full measurements of lunar radiation and of other climatic factors, for the problem is one involving the microclimate round a plant—it is far more than the investigation of an astrologically inspired opinion.

Fungus Diseases of the Carrot

THE tenth part of a series of articles by D. E. Green on "Hygiene in the War-time Vegetable Garden" (*J. Roy. Hort. Soc.*, **66**, Pt. 11, Nov., 1941) contains a short reference to several diseases of carrots, information about which is not readily available. Black rot, *Alternaria radicina*, violet root rot, *Helicobasidium purpureum*, storage rot, *Sclerotinia sclerotiorum*, and soft rot, *Bacterium carotovorum*, are briefly described.

Vitamin C and Respiration

IN 1933, Harrison, in exploring the possible connexion between tissue respiration and *l*-ascorbic acid, found that addition of the vitamin to liver tissues of scorbutic animals increases their *in vitro* oxygen uptake. G. A. Snow and S. S. Zilva (*Biochem. J.*, **35**, 783, 787; 1941), in studying this phenomenon in greater detail, now find that the respiration of liver slices from guinea-pigs maintained on a quantitatively restricted diet (containing, however, ample vitamin C) is indeed considerably increased by the addition of ascorbic acid. Furthermore, the stimulating action on the respiration is not confined to ascorbic acid alone, but can be brought about by the presence of chemically related compounds, such as *d*-glucoascorbic acid and reductic acid, which possess a similar reduction potential but no ascorbic activity. The inhibition by phloridzin and pyrophosphate and the failure of cyanide, iodoacetate and malonate to inhibit the above accelerated respiration produced by ascorbate on the liver tissue of underfed animals indicates that this increased respiration may be connected with any of the stages concerned in the anærobic formation of triosophosphate from glycogen or in the aerobic degradation of the intermediate products, but not with the compounds formed by the anaerobic breakdown of triosophosphate.

Seismic Activity since 1904

SEISMIC activity in the twentieth century has recently been discussed by B. Gutenberg and C. F. Richter ("Seismicity of the Earth", by Beno Gutenberg and C. F. Richter, Geological Society of America, Special Paper No. 34, August 30, 1941). The data are chiefly instrumental concerning shallow shocks, though some new data on deep focus shocks are included. 54 great shocks during 1904–39 have been given revised epicentres, all large shocks from 1926 until 1933 are listed, and many other epicentres are given. Much of the data comes from the International Seismological Summary. The authors suggest that the earth's surface consists of relatively inactive blocks separated by active zones of three groups: (1) the circum-Pacific zone, which contains many shallow shocks, many intermediate depth shocks, and all the very deep shocks; (2) the Mediterranean and trans-Asiatic zone; (3) narrow belts of shallow shocks which extend (*a*) through the Arctic and Atlantic Oceans, following the mid-Atlantic ridge, (*b*) through the western Indian Ocean from Arabia into the Antarctic, (*c*) the African rift valleys. Gutenberg and Richter suggest that the annual average includes about one great shock, about a hundred potentially destructive shocks, and about one million shocks potentially strong enough to be felt in a settled area. Seismic energy is released at a mean rate of about 10^7 kilowatts, most of it in

the large shocks. It is possible that the persistence of oceanic troughs and gravity anomalies, together with the occurrence of earthquakes, requires that in the regions affected there is a continuously operating mechanism, such as would be provided by constant subcrustal flow.

Hydrocarbon Flames in Atomic Oxygen

A RE-EXAMINATION by K. H. Geib and W. M. Vaidya (*Proc. Roy. Soc.*, A, 178, 351; 1941) of the flames of hydrocarbons burning in atomic oxygen shows that the ethylene bonds are strong in benzene and acetylene, but are weak and diffuse in ethylene. C_2, CH and HO are also present. Methyl alcohol gives the HO and CH bonds and also 'cool flame' bonds rather faintly, while formaldehyde shows only the HO bond at λ3064. The ethylene flame bonds are absent from the flame of benzene burning in atomic hydrogen, which yields only C_2 and CH bonds. The Balmer lines also appear, however, due to stray light from the main discharge.

Fission Yield by Fast Neutrons

THE 1,100-kv. tube of the Instituto di Sanità Pubblica at Rome was used by a group of workers, M. Ageno, E. Amaldi, D. Bocciarelli, B. N. Cacciapuoti and G. C. Trabacchi, for measurements of the fission cross-section of uranium for neutrons produced in the reactions Rn + Be, D + C, D + D, D + Be, D + B and D + Li (*Phys. Rev.*, 60, 67; 1941). From the fact that the mean cross-section has about the same value for neutrons of the D + D, D + Be, D + B reactions, it was concluded that the fission cross-section has a value σ_f which remains nearly constant between 1 and 10 Mev. For neutrons of the Rn + Be and D + C reactions the fission cross-sections seem to be, respectively, about $\frac{1}{2}\sigma_f$ and $\frac{1}{3}\sigma_f$. Finally, for neutrons of the D + Li reaction the mean cross-section is $1 \cdot 4\,\sigma_f$. This fact was interpreted by N. Bohr as due to successive transformations which are possible for energies of the impinging neutrons larger than 10 Mev. A similar increase of the fission cross-section was observed also for thorium, in very good agreement with the theoretical predictions of Bohr.

The Mills-Nixon Effect

THE bond angles in a molecule containing a saturated 5- or 6-membered ring fused to a benzene ring cannot have the normal values in the aliphatic and aromatic portions. W. H. Mills and I. G. Nixon, in 1930, inferred from substitution experiments that the double bonds in hydrindene and tetralin are frozen to the particular Kekulé structure in which the bond angles are the least strained. This conclusion is somewhat modified in detail by taking account of excited ionic resonance states of the benzene molecule, and in 1935 L. E. Sutton and L. Pauling published an approximate quantum mechanical treatment which showed that theory predicts a relatively small stabilization of one Kekulé structure in hydrindene and in tetralin. An investigation of 1,3,5-tribromobenzene, *o*-dibromoxylene, *o*-dibromohydrindene and *o*-dibromotetralin by the electron diffraction method, made by A. Kossiakoff and H. D. Springall (*J. Amer. Chem. Soc.*, 63, 2223; 1941) has given some interesting results. It is shown that the complete fixation of the double bonds in the hydrindene or the tetralin compound is excluded, that there is a large amount of double-bond character for the C–Br bond in the bromobenzenes, particularly in the hydrindene derivatives, which throws light on the relative importance of the excited ionic states, and that the effect of strain on the benzene molecule (Mills-Nixon effect) is primarily concerned with changes in the contributions of excited states of the molecule rather than with fixation of double bonds into a particular Kekulé structure. In agreement with Sutton and Pauling's calculations, the change in external bond angles of the benzene ring caused by the fusion of a saturated ring is shown to be very small.

Space Motions of Solar Prominences

THE first exhaustive study of the structure of solar prominences in the three space co-ordinates x, y, z is reported from the McMath-Hulbert Observatory (*Pub. Obs. Univ. Michigan*, 8, 123; 1941). From nearly 2,000 $H\alpha$ spectroheliograms of a prominence on September 20, 1940, taken on motion-picture film with two spectroheliographs (one for cross-motions and one for radial velocities), the parameters x, y, dz/dt, and t are measured for four easily identified prominence knots. For each knot a process of graphical integration then gives the true space motion as a function of t. The only difficulty, that of arriving at z from dz/dt, is ingeniously solved by making an approximate estimate of the constant of integration from subsequent observations of the prominence as a dark marking projected on the disk. From the data thus derived, a model of the prominence has been constructed; and photographs of this model taken from various angles show a close resemblance to frequently observed prominence forms. The accelerations derived from the observed displacements and velocities are of the order of one tenth that due to unopposed gravitation at the solar surface, though for short intervals of time accelerations exceeding the gravitational value have been observed. The radial and cross velocities are of the same order, as would be expected if the observed effects are due to mass motion of the prominence atoms, as distinct from a travelling excitation.

Dimensions and Masses of Wolf-Rayet Stars

CECILIA H. PAYNE-GAPOSCHKIN (*Telescope*, May–June) has discussed the star *H.D.* 193576, known to be a spectroscopic binary, and recently found by Dr. S. Gaposchkin at Harvard to be also an eclipsing binary. A considerable amount of speculation had been made about the size and mass of a Wolf-Rayet star; but now, assuming that *H.D.* 193576 is representative of this type, a volume six times and a mass ten times those of the sun can be taken as approximately correct. The bright-line spectra of these stars reveal the presence of highly ionized atoms of the commoner elements, notably helium, carbon, nitrogen and oxygen. The width of these bright lines led to the conjecture of nebular stars of enormous size, because the novæ, which have many points of resemblance to Wolf-Rayet stars, expand to vast dimensions. On the other hand, the displacement from the normal wave-length of these bright lines led to the picture of small, dense stars, the shift arising from the intense gravitational potential. Now that the size and mass are known, both the width and displacement of the lines appear in a new light. It is suggested that the red shift of the bright lines (a phenomenon occurring also in 29 Canis Majoris) is caused by washed-out absorption lines on the violet edges of the bright lines. The gravitational red-shift in a star of size and mass like those just given for a Wolf-Rayet star would be only about one hundredth of what has been observed.

HUMAN BIOLOGY IN EDUCATION*

UNTIL comparatively recently biology might well be said to have been the 'Cinderella' of the sciences so far as primary and secondary education in Great Britain were concerned. Over a period of about ten years, however, the subject has become recognized more and more as of vast cultural and academic importance. Consequently it is finding its place in many schools where it was hitherto completely ignored and in all cases the number of students studying biology has increased. This is well exemplified in the number which take the subject in the School Certificate, though even to this day the percentage is far too low. During 1940 in the School Certificate 22 per cent took biology and 19 per cent General Science; in the Higher School Certificate only 7 per cent took biology.

We are, however, not concerned so much with the importance of biology as an educative subject but rather with the form and content of the biological syllabuses from junior school to university. The syllabuses are unsatisfactory from several points of view but the most important is that of man himself. In most syllabuses he scarcely finds a place. One reason for this might easily be that many academic biologists do not realize that biology is the science of life and not merely a union of zoology with botany. Human biology is the science of life as it affects man himself and it thus finds itself invoking aid not only from zoology and botany but also from the other specialized biological sciences such as medicine, agriculture, anthropology, ethnology and sociology. Human biology consists of a comparative account of the anatomy and physiology of the human body followed by further inquiries into man's place in the web of life, the nature of diseases, especially as they affect mankind, inheritance, and so forth. These are certainly essential components of human biology but the potentialities and applications of this tremendous subject are legion. Surely the study of the biology of mankind must not merely be regarded as a detached and academic survey of structure and function. It must go further and launch bravely into investigations of all these powerful individual social relations which are biological in origin. The question of the results of both good and bad nutrition is involved. The same can be said for population movements and their attendant effects, not excluding war. Soil and its significance is another aspect. So is the influence of psychological study as a powerful weapon in the hands of thinking and feeling man. Human biology is therefore the biology of mankind, not merely the biology of man.

Knowledge of the general principles of positive health is essential in these modern times of urban living, yet it receives scant attention in most biology courses. Aspects of healthy living such as fresh air, housing, exercise, personal cleanliness, human parasites, risk of infection, industrial diseases, etc., need not necessarily be grouped together under a general heading of health, because pegs on which arguments in this connexion can be based are constantly cropping up in a course of biology so that health subjects could be brought in at various points thus giving, apart from empirical knowledge, what is just as important, additional interest.

The science of nutrition was beginning to take shape long before the War. People were beginning to become vitamin conscious but very often along the wrong channels. There are very few people now who have not heard of vitamins, if only through the medium of a dance tune. It is doubtful, however, if one per cent of the population could give any idea of what a vitamin is or what it does. This should therefore form a subject of instruction and the biology course is the place for it. The history of work on vitamins, from the empirical work in the sixteenth century of the navigator Hawkins and later of Dr. J. Lind to the biochemistry and physiology of to-day, simply told, would be of great educative value. The same applies to nutrition. The sociological and economic implications of nutrition have been brought out very clearly by such workers as Sir John Orr, and their work is receiving the consideration it deserves in the planning of the national health and diet. But this is due to the exigencies of war; it must continue in peace-time, and the basis for its continuance lies in the schools and the universities. A detailed knowledge of the chemical composition of carbohydrates, proteins, fats and mineral salts and vitamins is not necessary, but some knowledge of the significance of these foodstuffs in relation to energy, body-building, malnutrition, deficiency diseases, etc., is desirable.

Technical knowledge which might be considered for inclusion in biological courses especially in the schools involves such subjects as farming and gardening. Schools in rural areas often include these subjects in their curricula though in most cases they are treated as separate subjects. They might well be incorporated in a general biology course, but in spite of this only about one in every ten of the British farmers receives any form of technical training.

Another important subject to whom biological knowledge would prove of inestimable value is the mother in the home. The home with its family life is a veritable biological laboratory. Yet few mothers are technically prepared for the responsibility of directing that laboratory, having little or no knowledge of such subjects as normal psychology, health, hygiene, nutrition, sex, child development and child guidance. Other examples could be given, but here are two—one of man outdoors and one of man indoors—which show what a mistake is this ignorance of the general public where elementary problems of the biology of mankind are concerned.

Human reproduction, too, should be given its logical position in biology curricula. It should not be avoided or ignored; nor again should it be over-emphasized. One is on safe ground in stating that by far the majority of elementary biological curricula, though probably dealing with sexual reproduction in general, and in plants and a certain number of the lower animals in particular, stop at the stage where human reproduction should be logically considered. This is undesirable, but, on the other hand, there is a risk of over-emphasizing it. Human reproduction could be brought into that part of the curricula dealing with heredity in plants and animals. Here reproduction might be combined with considerations of evolution, variation and genetics. Heredity in

*Extract from the opening address by the Chairman, Mr. L. J. F. Brimble, to the Conference of Lecturers and Teachers held under the auspices of the Educational Advisory Board of the British Social Hygiene Council at Ashburne Hall, Manchester, during December 13–14.

man is a very wide subject but general points are valuable even to the child mind. The biological conception of ethnic races, for example, should be emphasized, thus, especially at the present time, counteracting the poisonous results of the prostitution of such concepts for political advantage such as is seen in the Nazi Aryan theory of *Herrenvolk*. A general review of these subjects would develop a social consciousness among children and students towards people of weak hereditary endowments.

A general idea of the origin of man could naturally follow instruction on evolution and heredity. So, too, could the origin of many of man's social attributes which would involve an elementary study of the main conceptions of anthropology, ethnology and archæology. This is scarcely touched upon in schools. A review of the origin and history of mankind would logically lead up to the present status of man in the living world and hence to the destiny of mankind. Modern science is changing the environmental setting of man at an ever-increasing rate. This calls for active and continuous readjustments (adaptation) both physically and psychologically. Here human biology through the study of emotions can arouse a better social conscience since it can formulate new social standards. For example, nutritional deficiency could be eliminated in a measurable time from Europe, as shown by Sir John Orr. It would not take much longer to do the same thing in the British Colonies, as shown on several occasions lately by Lord Hailey, though it can and should be tackled. Eventually nutritional deficiency could be attacked and eliminated from the whole world, as envisaged by Mr. J. G. Winant.

So-called abnormalities in man are now much better understood than they were at one time. They have been in many cases set free from mythical and magical taboo, and are known to be psychological or hormonal. Knowledge of the causes of such abnormalities would bring a more practical and less sentimental sympathy from the general public and especially from those in authority. A more rational view of what is right and what is wrong would surely be the outcome of all this. This aspect of human biology could not be included in courses for children, but should certainly be studied by teachers so that they may be adequately equipped to deal with situations as they arise.

Human biology has given a fresh and more balanced approach to personal evaluation and character training. It would equip the teacher himself with a better insight into the character (normal and abnormal) of his pupils. It would liberate the vexed question of sex from the ignorance, taboos and emotional complexes by which man is hemmed in socially.

Thus it may be said without much fear of contradiction that human biology is lifelong and continuous. Some will go so far as to say that it should displace academic biology (as at present formulated) in education. But even the most moderate will agree that man and mankind ought to receive major consideration in any comprehensive general biology syllabus; yet he does not. Places where human biology might well be introduced are chiefly the teacher training colleges and departments and the junior and senior schools where there is no domination of an external examination syllabus. It is a difficult subject to teach, much more difficult, for example, than higher mathematics, and few teachers are at present mentally equipped to deal with it. In spite of this, however, it should be developed because (*a*) it is far more effective in facts and ideas; (*b*) it is far more interesting; (*c*) it relies less on detailed routine laboratory experiments but leads to demonstrations and experiments on the self, and other interesting activities such as visits to farms, water-works, hospital laboratories and to talks by such social biologists as medical officers of health, nurses, etc.

As expressed in the Autumn issue of *Biology* (7, No. 2), there is a strong case for the study of human biology, in which man himself becomes the centre of interest, seen against the background of all the living matter to which he is related, and of the material world. Human biology grows out of nature study and academic biology, which still dominate our text-books and syllabuses; but it is something of more entrancing interest, at once more personal in its application and of far greater educational worth. For the problems of human biology confront us at every turn: problems of individual and public health, of nutritional standards, housing, population movements, of race and nation; problems of family life, of the relations and responsibilities of one person to another, and of the social policy of the State. Human biology brings up questions of personal conduct, of moral values and character formation, and of the most intimate relations between one individual and another. Penetrating further into the realm of the mind, we are faced with problems of the ethical basis of philosophy and of the ultimate ideals of life itself. Here we find vistas opening out inviting action, and leading to further inquiry, especially in the universities, for on many of the burning questions of human biology no clear decision has yet been reached.

Yet in nearly every case existing knowledge is decades ahead of educational practice, and we have before us the immense task of trying to make good the lag between general opinion and what is already known. But the function of human biology does not end at being an academic discipline, for it must be given effect in public administration and national policy, since national policies are the mass movements of mankind. How deeply involved human biology is in national policy comes out clearly in this present war. The whole policy of the Fascist powers rests on conceptions of human biology which were disproved by the leading biologists of the world some decades ago; while the conceptions themselves spring from human attributes and environmental conditions no longer holding full sway in the countries of their origin. By contrast, the Democracies, often almost unconsciously, all too tardily, are in the process of putting into action what is best in biological knowledge, as, for example, in the schemes for free milk, health protection, etc.

Yet in all this, little help is forthcoming from our universities and educational authorities. Only as it were by chance do we come across pointers which show the way, as during the Conference on Science and World Order recently held in London. The widespread apathy with regard to pressing problems of human biology affecting the nation's future is a sad reflection on the ideals for which we are at war. But the outlook for human biology now is more favourable than it has been for a very long time.

Only one or two points have been made here in the attempt to show how important human biology is to educational principles and practice. Like any other

subject it has special applications in special cases and emergencies, and it certainly has its novel and unique problems during war-time. There is scarcely any need to enumerate the special war-time problems which are worthy of consideration from the point of view of human biology. A mere mention of a few of them is sufficient to give basis for later discussion. For example, the whole problem of evacuation. This was one of the most successful sociological experiments of our time, when it first took place; that is so far as the organization of the actual evacuation itself is concerned. But there seems to have been very little consideration of biological and psychological aspects of the case in the reception areas themselves. Authorities, for example, apparently underestimated the strength of parental affection, or overestimated parental self-control. Insufficient regard was directed to the emotional unity of the family, and as little to its economic unity. That is one of the main reasons why the initial success of the scheme has since been generally negatived in a large number of cases. Another problem is that of broken homes and broken family life caused either by evacuation or the calling up of menfolk and of women into the Fighting Services or movement of women and men to other industrial areas. Emotional tension due to the War has received a certain amount of study by the Ministry of Health, chiefly from the medical point of view. Certain psychological studies have also been made, but the problem as a whole has not received the attention which it deserves. The effect of the War on young adolescents is also deserving of attention, especially in the many cases where abnormally high wages are being paid to young boys and girls. These are just a few examples of special problems raised by the War, and there are no doubt many others, all of which come within the purview of human biology.

At no point in the nation's history have young people had such independence and freedom as to-day. Never before have they had such opportunities of following the wrong lines of individual and social development, but complementary to this, never has there been such an opportunity for teachers to offer correct guidance. Never has there been such opportunity for building up the characters of the younger generation on a foundation of true knowledge of personal worth and thus preventing them from being lured away by the cheap type of personality appeal in which an individual is singled out for the special favours of fortune. Emotions come before understanding and personal success bears no relation to the common good. So much nowadays depends upon mutual sympathy and understanding particularly between the opposite sexes. All this was shown only recently by messages sent by the Prime Minister and others to the great International Youth Rally recently held in London telling youth of its responsibilities towards the nation, but we must also realize that youth in a social sense has definite claims upon those of maturer years and this is one of them. That youth deserves our help goes without saying, but how we are going to carry it out is a matter for discussion. That youth can be misguided *en masse* has been shown by Nazi Germany where the Hitler Youth, probably through no fault of their own, may now be considered to be workers of iniquity and of primitive passions. If it is possible to organize and misguide youth, then it should be equally possible to organize and guide youth along the right lines. This could be done through the school, youth organizations, etc.; but the unit of the family itself must never be ignored. It is necessary to impress upon youth the biological principles of family life and to make them realize as few do that (as Cardinal Hinsley pointed out in a recent stirring address in Westminster Cathedral) the dignity of the family is not wrapped up solely in the begetting of children.

ISLAND FAUNA RESEARCH

THE University of Oxford, since 1938, has contributed towards the cost of research into the problems of island faunas, with special reference to the Pacific, and, in particular, the Marquesas Isles.

Mr. E. P. Mumford, of Jesus College, who is conducting the inquiry, has made it one of his chief aims to obtain publication of faunistic lists by experts, so that information may be collated and available. An important recent publication from the Smithsonian Institution (Misc. Coll., 99, No. 8; 1941) by Prof. Jackson is a check-list of the terrestrial and freshwater Isopoda of Oceania. This was made possible by grants-in-aid from the contributions of the Royal Society and the British Association to the central fund at Oxford, and from the publication committee of the University of London. The paper contains a noteworthy discussion of the whole subject in which Prof. Jackson concludes: "The assumption of land connections between the islands is gratuitous and would seem to provide more time than is necessary to account for the comparatively small range of differences observed, while the assumption that man is responsible [for the distribution of the Isopods under review] would seem to provide too little."

Other lists that have been published in connexion with the activities of this research include, among Insecta, the Collembola, Dermaptera, Embioptera, Anoplura, Mallophaga, Homoptera (Cercopidæ), Neuroptera, Coleoptera (some Adephaga, Polyphaga-Diversicornia, Lamellicornia, and Rhynchophora), Hymenoptera (Cynipoidea, Formicoidea, Serphoidea, Bethylidæ and Anteonidæ), Diptera (some Nematocera, Aschiza, and Pupipara), and Siphonaptera. Among Crustacea, the Amphipoda: among Arachnida, the Chelonethida. These lists have appeared in publications of the Bernice P. Bishop and other museums, and in scientific journals.

The recently published fourth volume of the Proceedings of the Sixth Pacific Science Congress at San Francisco in 1939 contains, among other contributions to faunistic questions, two papers by Mr. Mumford on the present status of studies of faunal distribution with reference to oceanic islands, and on the present status of knowledge of Polynesian freshwater faunas. A preliminary account of an investigation of the Euploeine butterflies of Melanesia is contributed by Prof. G. D. Hale Carpenter.

Those interested in furthering this investigation by observations or records, or desirous of obtaining information, are asked to communicate with Mr. E. P. Mumford, Box 802, Stanford University, California, or with Prof. Hale Carpenter, University Museum, Oxford.

TUNG-OIL TREE CULTIVATION IN INDIA

THIS tree (*Aleurites fordii* Hemsl.), an inhabitant of China, produces the Chinese wood oil of commerce, the oil being used in the manufacture of paints and varnishes owing to its rapid drying qualities. It came into prominence during the War of 1914-18 when it was extensively used in the treatment of aeroplane fabrics as a water-resisting varnish. China is the chief source of production of tung oil, and the United States the principal consumer. In 1936 the United States imported more than 600,000 tons, and large quantities are annually imported by Great Britain and India.

In China the tree grows in profusion in the mountainous tropical and sub-tropical regions. The United States commenced to form plantations of the species early in the present century, and there are now about 175,000 acres, chiefly in Mississippi and other southern States. Experiments in its cultivation in the British Empire were first initiated by the Imperial Institute in 1917 in India and a number of Colonies, but they were inconclusive. The matter was taken up in 1927 by the Advisory Committee of the Institute in collaboration with the Director of Kew and the Director of the Research Association of British Paint, Colour and Varnish Manufacturers, seed obtained from China and Florida being distributed to various countries of the Empire.

It is said that there are now grounds for considering that, so far as India and Burma are concerned, the industry can be developed either as a self-supporting one, in view of the growing commercial importance of tung oil, or as a cottage industry in places where the plants can be easily grown and seeds marketed, or in tea-gardens as a subsidiary industry. This opinion is based on the fact that experiments have now been carried out for two decades with varying measures of success in localities in India and Burma and in Ceylon, Malaya and East and South Africa. The question is dealt with in *Indian Forest Records* (New Series) Sylviculture, "Note on the Cultivation of the Tung-oil Tree (Aleurites spp) in India", by M. V. Laurie and J. N. Sen Gupta, both of the Forest Research Institute, Dehra Dun, India, 4, No. 3 (Manager, Govt. of India Press, Delhi, 1941). Artificial regeneration, nursery practice, manures, planting sites, tending, dangers, costs and growth and yield are discussed.

A hint is given that there are market competitors in drying oils such as Perilla oil, Viticica oil and Po-yok oil, although they are inferior, while recently synthetic resins have been developed which may reduce the use of tung oil in process work, one of the latest developments being a castor oil derivative.

REPORTS AND OTHER PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

University of Reading: National Institute for Research in Dairying. Annual Report for the Year ending 30th September 1940. Pp. 52. (Reading: National Institute for Research in Dairying.) [2411

University of Sheffield. Thirty-sixth Annual Report of the Senate to the Court of Governors. Pp. 13. (Sheffield: The University.) [512

Royal College of Surgeons of England. Scientific Report for the Year 1940–1941. Pp. 28. (London: Royal College of Surgeons of England.) [1012

Other Countries

Carnegie Institution of Washington. Publication 532: Magnitudes and Colors of Stars North of +80°. By Frederick H. Seares, Frank E. Ross and Mary C. Joyner. Pp. iii+89. (Washington, D.C.: Carnegie Institution.) 1.50 dollars. [1311

India Meteorological Department. Scientific Notes, Vol. 8, No. 94: Photographic Studies of some Cloud Forms and their Changes with Time. By M. W. Chiplonkar. Pp. 113–116+7 plates. 1.8 rupees; 2*s.* 3*d.* Scientific Notes, Vol. 8, No. 96: Frequency of Thundery Conditions at Bombay compared with those at some other Stations in India. By M. W. Chiplonkar. Pp. 131–138+2 plates. 8 annas; 9*d.* (Delhi: Manager of Publications.) [1711

Annual Report of the Board of Regents of the Smithsonian Institution, showing the Operations, Expenditures and Conditions of the Institution for the Year ended June 30, 1940. (Publication 3606.) Pp. xiii+512+107 plates. (Washington, D.C.: Government Printing Office.) 1.50 dollars. [1911

National Research Council. American Geophysical Union Transactions of 1940. Part 1: Reports and Papers, Joint Regional Meeting, Section of Hydrology and Western Interstate Snow-Survey Conference, South Pacific Coast Area, Stanford University, California, January 12–13, 1940. Pp. 144. 1.25 dollars. Part 2: Twenty-first Annual Meeting, April 24 to 27, 1940, Washington, D.C.; Reports and Papers, General Assembly and Sections of Geodesy, Seismology, Meteorology, Terrestrial Magnetism and Electricity, Oceanography, Volcanology, Hydrology, and Tectonophysics. Pp. 145–780+6. 3.75 dollars. Part 3: Regional Meetings (a) Richmond, Virginia, December 1938, (b and c) Seattle, Washington, June 1940; (a) Symposium with American Association for the Advancement of Science (b and c) Reports and Papers, Western Interstate Snow-Survey Conference and Section of Hydrology (North Pacific Coast and North Continental Divide Areas). Pp. 779–1062. 1.75 dollars. Part 4: Regional Meeting, Colombus, Ohio, December 1939; Symposia under auspices of the American Association for the Advancement of Science (a) Applications of Mathematics in the Earth-Sciences (b) Hydrologic Problems in the Ohio and Michigan Basins. Pp. 1063–1148. 1 dollar. (Washington, D.C.: National Academy of Sciences.) [1911

National Research Council. American Geophysical Union Transactions of 1941. Part 1: Joint Regional Meeting, South Pacific Coast Area, Sacramento, California, January 1941; Reports and Papers (a) Section of Hydrology (b) Western Interstate Snow-Survey Conference. Pp. 216. 1.50 dollars. Part 2: Twenty-second Annual Meeting, April 30 to May 3, 1941, Washington, D.C.; Reports and Papers, General Assemblies and Sections of Geodesy, Seismology, Meteorology, Terrestrial Magnetism and Electricity, Oceanography, Volcanology, and Tectonophysics. Pp. 217–584. 2.50 dollars. Part 3: Twenty-second Annual Meeting, April 30 to May 3, 1941, Washington, D.C.; Reports and Papers, Section of Hydrology. Pp. 585–1036. 3 dollars. FORTHCOMING EVENTS

SATURDAY, JANUARY 3

JOINT MEETING OF TECHNICAL INSTITUTIONS arranged at the request of the Mines Department (in the H. H. Wills Laboratory, Royal Fort, Bristol), at 2.30 p.m.—Discussion on the Best Ways and Means of Improving the Efficient Use of Fuel and Power in Existing Industrial Plants, under Present Conditions, and to Invite Constructive Suggestions. (To be opened by Mr. J. G. Bennett.)

Editorial and Publishing Offices
MACMILLAN & CO., LTD.,
ST. MARTIN'S STREET, LONDON, W.C.2.
Telephone: Whitehall 8831 Telegrams: Phusis Lesquare London
Advertisements should be addressed to
T. G. Scott & Son, Ltd., Three Gables, London Road, Merstham, Surrey
Telephone: Merstham 316
The annual subscription rate is £4 10 0, payable in advance, Inland or Abroad
